The most important causes—because of their incidence or consequence—of severe obstetrical hemorrhage and their contribution to maternal mortality rates are shown in [Figure 41-2](#). Fatal hemorrhage is most likely in circumstances in which blood or components are not immediately available. As discussed on page 815, the ability to provide prompt resuscitation of hypovolemia and blood administration is an absolute requirement for acceptable obstetrical care.

Uterine Atony

The most frequent cause of obstetrical hemorrhage is failure of the uterus to contract sufficiently after delivery and to arrest bleeding from vessels at the placental implantation site (p. 780). That said, some bleeding is inevitable during third-stage labor as the placenta begins to separate. Blood from the implantation site may escape into the vagina immediately—the *Duncan mechanism* of placental separation, or it remains concealed behind the placenta and membranes until the placenta is delivered—the *Schultze mechanism*.

With bleeding during the third stage, the uterus should be massaged if it is not contracted firmly. After the signs of separation, placental descent is indicated by the cord becoming slack. Placental expression should be attempted by manual fundal pressure (Chap. 27, p. 546). If bleeding continues, then manual removal of the placenta may be necessary. *Separation and delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion, which is discussed on page 787.*

Third-Stage Bleeding

If significant bleeding persists after delivery of the infant and while the placenta remains partially or totally attached, then manual placental removal is indicated (Chap. 27, p. 546). For this, adequate analgesia is mandatory, and aseptic surgical technique should be used. As illustrated in [Figure 41-3](#), the placenta is peeled off its uterine attachment by a motion similar to that used in separating the pages of a book. After its removal, trailing membranes are removed by carefully teasing them from the decidua and using ring forceps for this as necessary. Another method is to wipe out the uterine cavity with a gauze-wrapped hand.

Uterine Atony after Placental Delivery

The fundus should always be palpated following placental delivery to confirm that the uterus is well contracted. If it is not

FIGURE 41-3 Manual removal of placenta. **A.** One hand grasps the fundus. The other hand is inserted into the uterine cavity, and the fingers are swept from side to side as they are advanced. **B.** When the placenta has become detached, it is grasped and removed.

firm, then vigorous fundal massage usually prevents postpartum hemorrhage from atony (Hofmeyr, 2008). Simultaneously, 20 units of oxytocin in 1000 mL of crystalloid solution will often be effective given intravenously at 10 mL/min for a dose of 200 mU/min. Higher concentrations are minimally more effective (Tita, 2012). Oxytocin should never be given as an undiluted bolus dose because serious hypotension or cardiac arrhythmias may develop.

Risk Factors

In many women, uterine atony can at least be anticipated well in advance of delivery (see Table 41-2). In one study, however, up to half of women who had atony after cesarean delivery were found to have no risk factors (Rouse, 2006). Thus, the ability to identify which individual woman will experience atony is limited. Risk factors for retained placenta are similar (Endler, 2012).

The magnitude of risk imposed by each of these factors shown in Table 41-2 varies considerably between reports. *Primiparity* has been cited as a risk factor (Driessen, 2011). *High parity* is a long-known risk factor for uterine atony. The incidence of postpartum hemorrhage was reported to increase from 0.3 percent in women of low parity to 1.9 percent with parity of 4 or greater. It was 2.7 percent with parity of 7 or greater (Babinski, 1999). The *overdistended uterus* is prone to hypotonia after delivery, and thus women with a large fetus, multiple fetuses, or hydramnios are at greater risk. *Labor abnormalities* predispose to atony and include hyper- or hypotonic labor. Similarly, *labor induction* or *augmentation* with either prostaglandins or oxytocin is more likely to be followed by atony (Driessen, 2011). Finally, the woman who has had a *prior postpartum hemorrhage* is at risk for recurrence with a subsequent delivery.

Evaluation and Management

With immediate postpartum hemorrhage, careful inspection is done to exclude birth canal laceration. Because bleeding can be caused by retained placental fragments, inspection of the placenta after delivery should be routine. If a defect is seen, the uterus should be manually explored, and the fragment removed. Occasionally, retention of a *succenturiate lobe* may cause postpartum hemorrhage (Chap. 6, p. 117). During examination for lacerations and causes of atony, the uterus is massaged and uterotonic agents are administered.

■ Uterotonic Agents

There are several compounds that prompt the postpartum uterus to contract (Chap. 27, p. 547). One of these is routinely selected and given to *prevent* postpartum bleeding by ensuring uterine contractions. Most of these same agents are also used to *treat* uterine atony with bleeding. Moreover, because many trials combine results from atony prophylaxis and treatment, evaluation of these studies is problematic. For example, *oxytocin* has been used for more than 50 years, and in most cases, it is infused intravenously or given intramuscularly after placental delivery. Neither route has been shown to be superior (Oladapo, 2012). This or other uterotonic agents given prophylactically will prevent most cases of uterine atony.

When atony persists despite preventive measures, ergot derivatives have been used for second-line treatment. These include methylergonovine—*Methergine*—and ergonovine. Only methylergonovine is currently manufactured in the United States. Given parenterally, these drugs rapidly stimulate tetanic uterine contractions and act for approximately 45 minutes (Schimmer, 2011). A common regimen is 0.2 mg of either drug given intramuscularly. A caveat is that ergot agents, especially given intravenously, may cause dangerous hypertension, especially in women with preeclampsia. Severe hypertension is also seen with concomitant use of protease inhibitors given for human immunodeficiency viral (HIV) infection (Chap. 65, p. 1279). These adverse effects notwithstanding, it is speculative whether there are superior therapeutic effects of ergot derivatives compared with oxytocin.

In more recent years, second-line agents for atony have included the E- and F-series prostaglandins. Carboprost tromethamine—*Hemabate*—is the 15-methyl derivative of prostaglandin $F_{2\alpha}$. It was approved more than 25 years ago for uterine atony treatment in a dose of 250 μ g (0.25 mg) given intramuscularly. This dose can be repeated if necessary at 15- to 90-minute intervals up to a maximum of eight doses. Oleen and Mariano (1990) reported its use for postpartum hemorrhage from 12 obstetrical units. Bleeding was controlled in 88 percent of 237 women treated. Another 7 percent required other uterotonics to control hemorrhage, and the remaining 5 percent required surgical intervention. Carboprost causes side effects in approximately 20 percent of women. These include, in descending order of frequency, diarrhea, hypertension, vomiting, fever, flushing, and tachycardia (Oleen, 1990). Another pharmacological effect is pulmonary airway and vascular constriction. Thus, carboprost should not be used for asthmatics and those with suspected amnionic-fluid embolism (p. 812). We have occasionally encountered severe hypertension with carboprost given to women with preeclampsia, and it has also been reported to cause arterial oxygen desaturation that averaged 10 percent (Hankins, 1988).

E-series prostaglandins have been used to prevent or treat atony. Dinoprostone—prostaglandin E_2 —is given as a 20-mg suppository per rectum or per vaginam every 2 hours. It typically causes diarrhea, which is problematic for the rectal route, whereas vigorous vaginal bleeding may preclude its use per vaginam. Intravenous prostaglandin E_2 —sulprostone—is used in Europe, but it is not available in this country (Schmitz, 2011).

Misoprostol—*Cytotec*—is a synthetic prostaglandin E_1 analogue that has also been evaluated for both prevention and treatment of atony and postpartum hemorrhage (Abdel-Aleem, 2001; O'Brien, 1998). Most studies have addressed prevention and have conflicting conclusions. In a Cochrane review, Mousa and Alfirevic (2007) reported no added benefits to misoprostol use compared with oxytocin or ergonovine. Derman and coworkers (2006) compared a 600- μ g oral dose given at delivery against placebo. They found that the drug decreased hemorrhage incidence from 12 to 6 percent and that of severe hemorrhage from 1.2 to 0.2 percent. In another study, however, Gerstenfeld and Wing (2001) concluded that 400- μ g misoprostol administered rectally was not more effective than intravenous oxytocin in preventing postpartum hemorrhage.

From a systematic review, Villar (2002) found that oxytocin and ergot preparations administered after delivery were more effective than misoprostol for prevention of postpartum hemorrhage (Chap. 27, p. 547).

Bleeding Unresponsive to Uterotonic Agents

Hemorrhage that persists despite uterine massage and continued uterotonic administration may be from a yet unrecognized genital tract laceration, for example, uterine rupture. Thus, if bleeding persists after initial measures for atony have been implemented, then the following management steps are performed immediately and simultaneously:

1. Begin bimanual uterine compression, which is easily done and controls most cases of continuing hemorrhage (Fig. 41-4). This technique is not simply fundal massage. The posterior uterine wall is massaged by one hand on the abdomen, while the other hand is made into a fist and placed into the vagina. This fist kneads the anterior uterine wall through the anterior vaginal wall. Concurrently, the uterus is also compressed between the two hands.
2. Immediately mobilize the emergent-care obstetrical team to the delivery room and call for whole blood or packed red cells.
3. Request urgent help from the anesthesia team.
4. Secure at least two large-bore intravenous catheters so that crystalloid with oxytocin is continued simultaneously with blood products. Insert an indwelling Foley catheter for continuous urine output monitoring.
5. Begin volume resuscitation with rapid intravenous infusion of crystalloid (p. 815).
6. With sedation, analgesia, or anesthesia established and now with optimal exposure, once again manually explore the uterine cavity for retained placental fragments and for uterine abnormalities, including lacerations or rupture.

FIGURE 41-4 Bimanual compression for uterine atony. The uterus is positioned with the fist of one hand in the anterior fornix pushing against the anterior wall, which is held in place by the other hand on the abdomen. The abdominal hand is also used for uterine massage.

7. Thoroughly inspect the cervix and vagina again for lacerations that may have escaped attention.
8. If the woman is still unstable or if there is persistent hemorrhage, then blood transfusions are given (p. 815).

At this juncture, after causes other than atony have been excluded and after hypovolemia is reversed, several other measures are considered if bleeding continues. Their use depends on several factors such as parity, desire for sterilization, and experience with each method.

Uterine Packing or Balloon Tamponade. Uterine packing was popular to treat refractory uterine atony during the first half of the 20th century. It subsequently fell from favor because of concerns regarding concealed bleeding and infection (Hsu, 2003). Newer techniques have been described that alleviate some of these concerns (Zelop, 2011). In one technique, the tip of a 24F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage of blood from the uterus. If bleeding subsides, the catheter is typically removed after 12 to 24 hours. Similar devices that have been used for tamponade include Segstaken-Blakemore and Rusch balloons and condom catheters (Georgiou, 2009; Lo, 2013a,b). Alternatively, the uterus or pelvis may be packed directly with gauze (Gilstrap, 2002).

Enthusiasm has developed for specially constructed intrauterine balloons to treat hemorrhage from uterine atony and other causes (Barbieri, 2011). A *Bakri Postpartum Balloon* (Cook Medical) or *BT-Cath* (Utah Medical Products) may be inserted and inflated to tamponade the endometrial cavity and stop bleeding (Fig. 41-5). Insertion requires two or three team members. The first performs abdominal sonography during the procedure. The second places the deflated balloon into the uterus and stabilizes it. The third member instills fluid to inflate the balloon, rapidly infusing at least 150 mL followed by further instillation over a few minutes for a total of 300 to 500 mL to arrest hemorrhage.

There have been few prospective studies with these uterine balloons, and thus data are observational (Aibar, 2013;

FIGURE 41-5 Intrauterine balloon for postpartum hemorrhage.

Grönvall, 2013; Laas, 2012). In all, more than 150 women were managed for postpartum hemorrhage. Perhaps a fourth were caused by uterine atony. For all causes, the success rate was noted to be approximately 85 percent. Combinations of balloon tamponade and uterine compression sutures have also been described (Diemert, 2012; Yoong, 2012). Failures for all of these require various surgical methods including hysterectomy. *Well-designed studies are needed before instituting intrauterine balloon tamponade as a second-line treatment for atony.*

Surgical Procedures. Several invasive procedures can be used to control hemorrhage from atony. These include uterine compression sutures, pelvic vessel ligation, angiographic embolization, and hysterectomy. These are discussed on page 818.

Uterine Inversion

Puerperal inversion of the uterus is considered to be one of the classic hemorrhagic disasters encountered in obstetrics. Unless promptly recognized and managed appropriately, associated bleeding often is massive. Risk factors include alone or in combination:

1. Fundal placental implantation,
2. Delayed-onset or inadequate uterine contractility after delivery of the fetus, that is, uterine atony,
3. Cord traction applied *before* placental separation, and
4. Abnormally adhered placental implantation such as with the accrete syndromes (p. 804).

Depending on which of these factors is contributory, the incidence and severity of uterine inversion varies, with the worst scenario being complete inversion with the uterus protruding from the birth canal as shown in Figure 41-6. There is progressive severity of inversion as shown in Figure 41-7.

The incidence of uterine inversion is variable and is usually different for vaginal and for cesarean delivery. Incidences

FIGURE 41-6 Maternal death from exsanguination caused by uterine inversion associated with a fundal placenta accreta during a home delivery.

FIGURE 41-7 Progressive degrees of uterine inversion depicted. After the fundus begins and continues to invert (Nos. 1 and 2), it would not be visible externally until it was at the level of the introitus (No. 3) or completely inverted (No. 4).

range from approximately 1 in 2000 to 1 in 20,000 deliveries (Baskett, 2002; Ogah, 2011; Rana, 2009; Witteveen, 2013). Our experiences at Parkland Hospital comport with the higher 1:2000 incidence. This is despite our policy to discourage placental delivery by cord traction alone and before certainty of its separation. It is unknown if *active management of third-stage labor* with cord traction applied ostensibly *after* signs of placental separation increases the likelihood of uterine inversion (Deneux-Tharaux, 2013; Gülmezoglu, 2012; Peña-Martí, 2007; Prick, 2013).

Recognition and Management

Immediate recognition of uterine inversion improves the chances of a quick resolution and good outcome. That said, inexperienced attendants may have a delayed appreciation for an inverting uterus, especially if it is only partial and thus not protruding through the introitus. In these cases, continued hemorrhage likely will prompt closer examination of the birth canal. Even so, the partially inverted uterus can be mistaken for a uterine myoma, and this can be resolved by sonography (Pauleta, 2010; Rana, 2009). Many cases are associated with immediate life-threatening hemorrhage, and at least half require blood replacement (Baskett, 2002). It was previously taught that associated shock was disproportionate to blood loss because of parasympathetic stimulation from stretching pelvic tissues. This has been refuted (Watson, 1980).

Once any degree of uterine inversion is recognized, several steps must be implemented urgently and simultaneously:

1. Immediate assistance is summoned, including obstetrical and anesthesia personnel.
2. Blood is brought to the delivery suite in case it may be needed.
3. The woman is evaluated for emergency general anesthesia. Large-bore intravenous infusion systems are secured to begin rapid crystalloid infusion to treat hypovolemia while awaiting arrival of blood for transfusion.
4. If the recently inverted uterus has not contracted and retracted completely and if the placenta has already separated, then the uterus may often be replaced simply by pushing up on the

FIGURE 41-8 The incompletely inverted uterus is repositioned by using the abdominal hand for palpation of the crater-like depression while gently pushing the inverted fundus up out of the lower segment and to its normal anatomical position.

inverted fundus with the palm of the hand and fingers in the direction of the long axis of the vagina (Fig. 41-8). Some use two fingers rigidly extended to push the center of the fundus upward. *Care is taken not to apply so much pressure as to perforate the uterus with the fingertips.*

5. If the placenta is still attached, it is not removed until infusion systems are operational and a uterine relaxant drug administered. Many recommend a trial of an intravenously administered tocolytic drug such as terbutaline, magnesium sulfate, or nitroglycerin for uterine relaxation and repositioning (Hong, 2006; You, 2006). If these fail to provide sufficient relaxation, then a rapidly acting halogenated inhalational agent is administered.
6. After removing the placenta, steady pressure with the fist, palm, or fingers is applied to the inverted fundus in an attempt to push it up into and through the dilated cervix as described in Step 4.
7. Once the uterus is restored to its normal configuration, tocolysis is stopped. Oxytocin is then infused, and other uterotonics may be given as described for atony (p. 785). Meanwhile, the operator maintains the fundus in its normal anatomical position while applying bimanual compression to control further hemorrhage until the uterus is well contracted (see Fig. 41-4). The operator continues to monitor the uterus transvaginally for evidence of subsequent inversion.

Surgical Intervention

In most cases the inverted uterus can be restored to its normal position by the techniques described above. Occasionally, manual replacement fails. One cause is a dense myometrial constriction ring (Kochenour, 2002). At this point, laparotomy is imperative. The anatomical configuration found at surgery can be confusing as shown in Figure 41-9. With agents given for

tocolysis, a combined effort is made to reposition the uterus by simultaneously pushing upward from below and pulling upward from above. Application of atraumatic clamps to each round ligament and upward traction may be helpful—the *Huntington procedure*. In some cases, placing a deep traction suture in the inverted fundus or grasping it with tissue forceps may be of aid. However, these may be technically difficult (Robson, 2005). If the constriction ring still prohibits repositioning, a longitudinal surgical cut—*Haultain incision*—is made posteriorly through the ring to expose the fundus and permit reinversion (Sangwan, 2009). After uterine replacement, tocolytics are stopped, oxytocin and other uterotonics are given, and the uterine incision is repaired. Risks of separation of this posterior hysterotomy incision during subsequent pregnancy, labor, and delivery are unknown.

In some cases, the uterus will again invert almost immediately after repositioning. If this is a problem, then compression sutures shown on page 819 can be used to prevent another inversion (Matsubara, 2009; Mondal, 2012). Occasionally, chronic puerperal uterine inversion may become apparent weeks after delivery.

Injuries to the Birth Canal

Childbirth is invariably associated with trauma to the birth canal, which includes the uterus and cervix, vagina, and perineum. Injuries sustained during labor and delivery range from minor mucosal tears to lacerations that create life-threatening hemorrhage or hematomas.

Vulvovaginal Lacerations

Small tears of the anterior vaginal wall near the urethra are relatively common. They are often superficial with little to no bleeding, and their repair is usually not indicated. Minor superficial perineal and vaginal lacerations occasionally require sutures for hemostasis. Those large enough to require extensive

FIGURE 41-9 Surgical anatomy of a completely inverted uterus viewed from above at laparotomy. The uterine fundus is not visible and the tubes and ovaries have been drawn into the birth canal.

repair are typically associated with voiding difficulty, and an indwelling bladder catheter will obviate this.

Deeper perineal lacerations are usually accompanied by varying degrees of injury to the outer third of the vaginal vault. Some extend to involve the anal sphincter or varying depths of the vaginal walls. In more than 87,000 deliveries in the Consortium on Safe Labor database, the frequency of third- or fourth-degree perineal lacerations was 5.7 percent in nulliparas and 0.6 percent in multiparas (Landy, 2011). Bilateral vaginal lacerations are usually unequal in length, and they are separated by a tongue of vaginal tissue. Lacerations involving the middle or upper third of the vaginal vault usually are associated with injuries of the perineum or cervix. These sometimes are missed unless thorough inspection of the upper vagina and cervix is performed. Bleeding despite a firmly contracted uterus is strong evidence of genital tract laceration. Those that extend upward usually are longitudinal. They may follow spontaneous delivery but frequently result from injuries sustained during operative vaginal delivery with forceps or vacuum extractor. Most involve deeper underlying tissues and thus usually cause significant hemorrhage. Bleeding is typically controlled by appropriate suture repair.

Extensive vaginal or cervical tears should prompt a careful search for evidence of retroperitoneal hemorrhage or peritoneal perforation or hemorrhage. If this is strongly suspected, then laparotomy is considered (Rafi, 2010). Extensive vulvovaginal lacerations should also prompt intrauterine exploration for possible uterine tears or rupture. For deep vulvovaginal lacerations, suture repair is usually required, and effective analgesia or anesthesia, vigorous blood replacement, and capable assistance are mandatory. In the study reported by Melamed and colleagues (2009), 1.5 percent of women with these lacerations required blood transfusions. Repair of vulvovaginal lacerations is detailed in Chapter 27 (p. 548).

Levator Sling Injuries

The levator ani muscles, described in Chapter 2 (p. 22), are usually involved with deep vaginal vault lacerations. They also sustain stretch injuries that result from overdistention of the birth canal. Muscle fibers are torn and separated, and their diminished tone may interfere with pelvic diaphragm function to cause pelvic relaxation. If the injuries involve the pubococcygeus muscle, urinary incontinence also may result.

Cervical Lacerations

Superficial lacerations of the cervix can be seen on close inspection in more than half of all vaginal deliveries. Most of these are less than 0.5 cm and seldom require repair (Fahmy, 1991). Deeper lacerations are less frequent, but even these may be unnoticed. Due to ascertainment bias, variable incidences are described. For example, in the Consortium database, the incidence of cervical lacerations was 1.1 percent in nulliparas and 0.5 percent in multiparas (Landy, 2011). But the overall incidence reported by Melamed and coworkers (2009), in a study of more than 81,000 Israeli women, was only 0.16 percent. Parikh and associates (2007) reported a 0.2-percent incidence of lacerations that needed repair.

Cervical lacerations are not usually problematic unless they cause hemorrhage or extend to the upper third of the vagina.

Rarely, the cervix may be entirely or partially avulsed from the vagina—*colporrhexis*—in the anterior, posterior, or lateral fornices. These injuries sometimes follow difficult forceps rotations or deliveries performed through an incompletely dilated cervix with the forceps blades applied over the cervix. In some women, cervical tears reach into lower uterine segment and involve the uterine artery and its major branches. They occasionally extend into the peritoneal cavity. The more severe lacerations usually manifest as external hemorrhage or as a hematoma, however, they may occasionally be unsuspected. In the large Israeli study reported by Melamed and colleagues (2009), almost 11 percent of women with a cervical laceration required blood transfusions.

Other serious cervical injuries fortunately are uncommon. In one, the edematous anterior cervical lip is caught during labor and compressed between the fetal head and maternal symphysis pubis. If this causes severe ischemia, the anterior lip may undergo necrosis and separate from the rest of the cervix. Another rare injury is when the entire vaginal portion of the cervix is avulsed. Such *annular or circular detachment of the cervix* is seen with difficult deliveries, especially forceps deliveries.

Diagnosis. A deep cervical tear should always be suspected in women with profuse hemorrhage during and after third-stage labor, particularly if the uterus is firmly contracted. It is reasonable to inspect the cervix routinely following major operative vaginal deliveries even if there is no third-stage bleeding. Thorough evaluation is necessary, and often the flabby cervix interferes with digital examination. The extent of the injury can be more fully appreciated with adequate exposure and visual inspection. This is best accomplished when an *assistant* applies firm downward pressure on the uterus while the operator exerts traction on the lips of the cervix with ring forceps. A second assistant can provide even better exposure with right-angle vaginal wall retractors.

Management. In general, cervical lacerations of 1 and even 2 cm are not repaired unless they are bleeding. Such tears heal rapidly and are thought to be of no significance. When healed they result in the irregular, sometime stellate appearance of the external cervical os that indicates previous delivery of a viable-size fetus.

Deep cervical tears usually require surgical repair. When the laceration is limited to the cervix or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view at the vulva as depicted in [Figure 41-10](#). While cervical lacerations are repaired, associated vaginal lacerations may be tamponaded with gauze packs to arrest their bleeding. Because hemorrhage usually comes from the upper angle of the wound, the first suture using absorbable material is placed in tissue above the angle. Subsequently, either interrupted or continuous locking sutures are placed outward toward the operator. If lacerations extend to involve the lateral vaginal sulcus, then attempts to restore the normal cervical appearance may lead to subsequent stenosis.

Most cervical lacerations are successfully repaired using sutures. However, if there is uterine involvement and continued hemorrhage, some of the methods described on page 818 may

FIGURE 41-10 Repair of cervical laceration with appropriate surgical exposure. Continuous absorbable sutures are placed beginning at the upper angle of the laceration.

be necessary to obtain hemostasis. For example, Lichtenberg (2003) described successful angiographic embolization for a high cervical tear after failed surgical repair.

■ Puerperal Hematomas

Pelvic hematomas can have several anatomical manifestations following childbirth. They are most often associated with a laceration, episiotomy, or an operative delivery. However, they may develop following rupture of a blood vessel without associated lacerations (Nelson, 2012; Propst, 1998; Ridgway, 1995). In some cases, they are quickly apparent, but in others, hemorrhage may be delayed. Occasionally, they are associated with an underlying coagulopathy. Faulty clotting may be acquired, such as with consumptive coagulopathy from placental abruption or fatty liver failure, or may stem from a congenital bleeding disorder such as von Willebrand disease.

One classification of puerperal hematomas includes vulvar, vulvovaginal, paravaginal, and retroperitoneal hematomas. Vulvar hematomas may involve the vestibular bulb or branches of the pudendal artery, which are the inferior rectal, perineal, and clitoral arteries (Fig. 41-11). Paravaginal hematomas may involve the descending branch of the uterine artery (Zahn, 1990). In some cases, a torn vessel lies above the pelvic fascia, and a supravaginal hematoma develops. These can extend into the upper portion of the vaginal canal and may almost occlude its lumen. Continued bleeding may dissect retroperitoneally to form a mass palpable above the inguinal ligament. Finally, it may even dissect up behind the ascending colon to the hepatic flexure at the lower margin of the diaphragm (Rafi, 2010).

Vulvovaginal Hematomas

These may develop rapidly and frequently cause excruciating pain, as did the one shown in Figure 41-12. If bleeding ceases, then small- to moderate-sized hematomas may be absorbed. However, we have encountered a few that rebled up to 2 weeks postpartum. In others, the tissues overlying the hematoma may rupture from pressure necrosis. At this time, profuse hemorrhage may follow, but in other cases, the hematoma drains in the form of large clots and old blood. In those that involve the paravaginal space and extend above the levator sling, retroperitoneal bleeding may be massive and occasionally fatal.

Diagnosis. A vulvar hematoma is readily diagnosed by severe perineal pain. A tense, fluctuant, and tender swelling of varying size rapidly develops and is eventually covered by discolored skin. A paravaginal hematoma may escape detection temporarily. However, symptoms of pelvic pressure, pain, or inability to void should prompt evaluation with discovery of a round, fluctuant mass encroaching on the vaginal lumen. When there is a supravaginal extension, the hematoma extends upward in the paravaginal space and between the leaves of the broad ligament. The hematoma may escape detection until it can be felt on abdominal palpation or until hypovolemia develops. Imaging with sonography or computed tomographic (CT) scanning can be useful to assess hematoma location and extent. As discussed, supravaginal hematomas are particularly worrisome because they can lead to hypovolemic shock and death.

Management. Vulvovaginal hematomas are managed according to their size, duration since delivery, and expansion. In general, smaller vulvar hematomas identified after the woman leaves the delivery room may be treated expectantly (Propst, 1998). But, if pain is severe or the hematoma continues to enlarge, then surgical exploration is preferable. An incision is made at the point of maximal distention, blood and clots are evacuated, and bleeding points ligated. The cavity may then be obliterated with absorbable mattress sutures. Often, no sites of bleeding are identified. Nonetheless, the evacuated hematoma cavity is surgically closed, and the vagina is packed for 12 to 24 hours. Supravaginal hematomas are more difficult to treat. Although some can be evacuated by vulvar or vaginal incisions, laparotomy is advisable if there is continued hemorrhage.

Blood loss with large puerperal hematomas is nearly always considerably more than the clinical estimate. Hypovolemia is common, and transfusions are frequently required when surgical repair is necessary.

Angiographic embolization as described on page 820 has become popular for management of some puerperal hematomas. Embolization can be used primarily, or more likely secondarily, if surgical attempts at hemostasis have failed or if the hematoma is difficult to access surgically (Distefano, 2013; Ojala, 2005). The use of a Bakri balloon for a paracervical hematoma has also been described (Grönnvall, 2013).

■ Rupture of the Uterus

Uterine rupture may be *primary*, defined as occurring in a previously intact or unscarred uterus, or may be *secondary* and

FIGURE 41-11 Schematic showing types of puerperal hematoma. **A.** Coronal view showing supralevator and anterior perineal triangle hematomas on the right. **B.** Perineal view shows anterior perineal triangle anatomy and an ischioanal fossa hematoma on the left.

FIGURE 41-12 Left-sided anterior perineal triangle hematoma associated with a vaginal laceration following spontaneous delivery in a woman with consumptive coagulopathy from acute fatty liver of pregnancy.

associated with a preexisting myometrial incision, injury, or anomaly. Some of the etiologies associated with uterine rupture are presented in [Table 41-3](#). Importantly, the contribution of each of these underlying causes has changed remarkably during the past 50 years. Specifically, before 1960, when the cesarean delivery rate was much lower than it is currently and when women of great parity were numerous, primary uterine rupture predominated. As the incidence of cesarean delivery increased and especially as a subsequent trial of labor in these women became prevalent through the 1990s, uterine rupture through the cesarean hysterotomy scar became pre-eminent. As discussed in detail in Chapter 31 (p. 617), along with diminished enthusiasm for trial of labor in women with prior cesarean delivery, the two types of rupture likely now have equivalent incidences. Indeed, in a 2006 study of 41 cases of uterine rupture from the Hospital Corporation of America, half were in women with a prior cesarean delivery (Porreco, 2009).

Predisposing Factors and Causes

In addition to the prior cesarean hysterotomy incision already discussed, risks for uterine rupture include other previous operations or manipulations that traumatize the myometrium. Examples are uterine curettage or perforation, endometrial ablation, myomectomy, or hysteroscopy (Kieser, 2002; Pelosi, 1997). In the study by Porreco and colleagues (2009) cited earlier, seven of 21 women without a prior cesarean delivery had undergone prior uterine surgery.

In developed countries, the incidence of rupture was cited by Getahun and associates (2012) as 1 in 4800 deliveries. The frequency of primary rupture approximates 1 in 10,000 to 15,000 births (Miller, 1997; Porreco, 2009). One reason is a decreased incidence of women of great parity (Maymon, 1991; Miller, 1997). Another is that excessive or inappropriate uterine stimulation with oxytocin—previously a frequent cause—has mostly disappeared. Anecdotally, however, we have encountered primary uterine rupture in a disparate number of women in whom labor was induced with prostaglandin E_1 .

Pathogenesis. Rupture of the previously intact uterus during labor most often involves the thinned-out lower uterine segment. When the rent is in the immediate vicinity of the cervix, it frequently extends transversely or obliquely. When the rent is in the portion of the uterus adjacent to the broad ligament, the tear is usually longitudinal. Although these tears develop primarily in the lower uterine segment, it is not unusual for them to extend upward into the active segment or downward through the cervix and into the vagina ([Fig. 41-13](#)). In some cases, the bladder may

TABLE 41-3. Some Causes of Uterine Rupture

Preexisting Uterine Injury or Anomaly	Uterine Injury or Abnormality Incurred in Current Pregnancy
Surgery involving the myometrium: Cesarean delivery or hysterotomy Previously repaired uterine rupture Myomectomy incision through or to the endometrium Deep cornual resection of interstitial fallopian tube Metroplasty	Before delivery: Persistent, intense, spontaneous contractions Labor stimulation—oxytocin or prostaglandins Intraamniotic instillation—saline or prostaglandins Perforation by internal uterine pressure catheter External trauma—sharp or blunt External version Uterine overdistention—hydramnios, multifetal pregnancy
Coincidental uterine trauma: Abortion with instrumentation—sharp or suction curette, sounds Sharp or blunt trauma—assaults, vehicular accidents, bullets, knives Silent rupture in previous pregnancy	During delivery: Internal version second twin Difficult forceps delivery Rapid tumultuous labor and delivery Breech extraction Fetal anomaly distending lower segment Vigorous uterine pressure during delivery Difficult manual removal of placenta
Congenital: Pregnancy in undeveloped uterine horn Defective connective tissue—Marfan or Ehlers-Danlos syndrome	Acquired: Placental accrete syndromes Gestational trophoblastic neoplasia Adenomyosis Sacculation of entrapped retroverted uterus

also be lacerated (Rachagan, 1991). If the rupture is of sufficient size, the uterine contents will usually escape into the peritoneal cavity. If the presenting fetal part is firmly engaged, however, then only a portion of the fetus may be extruded from the uterus. Fetal prognosis is largely dependent on the degree of placental separation and magnitude of maternal hemorrhage and

hypovolemia. In some cases, the overlying peritoneum remains intact, and this usually is accompanied by hemorrhage that extends into the broad ligament to cause a large retroperitoneal hematoma with extensive blood loss.

Occasionally, there is an inherent weakness in the myometrium in which the rupture takes place. Some examples include anatomical anomalies, adenomyosis, and connective-tissue defects such as Ehlers-Danlos syndrome (Arici, 2013; Nikolaou, 2013).

Management and Outcomes. The varied clinical presentations of uterine rupture and its management are discussed in detail in Chapter 31 (p. 617).

In the most recent maternal mortality statistics from the Centers for Disease Control and Prevention, uterine rupture accounted for 14 percent of deaths caused by hemorrhage (Berg, 2010). Maternal morbidity includes hysterectomy that may be necessary to control hemorrhage. There is also considerably increased perinatal morbidity and mortality associated with uterine rupture. A major concern is that surviving infants develop severe neurological impairment (Porreco, 2009).

Traumatic Uterine Rupture

Although the distended pregnant uterus is surprisingly resistant to blunt trauma, pregnant women sustaining such trauma to the abdomen should be watched carefully for signs of a ruptured uterus (Chap. 47, p. 954). Even so, blunt trauma is more likely to cause placental abruption as described subsequently. In a study by Miller and Paul (1996), trauma accounted for only three cases of uterine rupture in more than 150 women.

FIGURE 41-13 Supracervical hysterectomy specimen showing uterine rupture during spontaneous labor with a vertical tear at the left lateral edge of lower uterine segment.

Other causes of traumatic rupture that are uncommon today are those due to internal podalic version and extraction, difficult forceps delivery, breech extraction, and unusual fetal enlargement such as with hydrocephaly.

Placental Abruption

Separation of the placenta—either partially or totally—from its implantation site before delivery is described by the Latin term *abruptio placentae*. Literally translated, this refers to “rending asunder of the placenta,” which denotes a sudden accident that is a clinical characteristic of most cases. In the purest sense, the cumbersome—and thus seldom used—term *premature separation of the normally implanted placenta* is most descriptive because it excludes separation of a placenta previa implanted over the internal cervical os.

Etiopathogenesis

Placental abruption is initiated by hemorrhage into the decidua basalis. The decidua then splits, leaving a thin layer adhered to the myometrium. Consequently, the process begins as a decidual hematoma and expands to cause separation and compression of the adjacent placenta. Inciting causes of many cases are not known, however, several have been posited. The phenomenon of impaired trophoblastic invasion with subsequent atherosclerosis is related in some cases of preeclampsia and abruption (Brosens, 2011). Inflammation or infection may be contributory. Nath and colleagues (2007) found histological evidence of inflammation to be more common in prematurely separated placentas. *Papio* species of baboons develop *abruptio placentae* similar to humans, and up to half of prematurely separated placentas in these animals demonstrate neutrophilic infiltration (Schenone, 2012; Schlubritz-Loutsevich, 2013a,b).

Abruption likely begins with rupture of a decidual spiral artery to cause a retroplacental hematoma. This can expand to disrupt more vessels and extend placental separation (Fig. 6-3, p. 119). In the early stages of placental abruption, there may be no clinical symptoms. If there is no further separation, the abruption is discovered on examination of the freshly delivered placenta, as a circumscribed depression on the maternal surface. These usually measure a few centimeters in diameter and are covered by dark, clotted blood. Because several minutes are required for these anatomical changes to materialize, a very recently separated placenta may appear totally normal at delivery. Our experiences are like those of Benirschke and associates (2012) in that the “age” of the retroplacental clot cannot be determined exactly. In the example shown in Figure 41-14, a large dark clot is well formed, it has depressed the placental bulk, and it likely is at least several hours old.

Even with continued bleeding and placental separation, placental abruption can

FIGURE 41-14 Partial placental abruption with a dark adhered clot.

still be either *total* or *partial* (Fig. 41-15). With either, bleeding typically insinuates itself between the membranes and uterus, ultimately escaping through the cervix to cause *external hemorrhage*. Less often, the blood is retained between the detached placenta and the uterus, leading to *concealed hemorrhage* and delayed diagnosis (Chang, 2001). The delay translates into much greater maternal and fetal hazards. With concealed hemorrhage, the likelihood of consumptive coagulopathy also is greater. This is because increased pressure within the intervillous space caused by the expanding retroplacental clot forces more placental thromboplastin into the maternal circulation (p. 797).

FIGURE 41-15 Schematic of placental abruption. Shown to left is a total placental abruption with concealed hemorrhage. To the right is a partial abruption with blood and clots dissecting between membranes and decidua to the internal cervical os and then externally into the vagina.

Chronic Abruption. Some cases of chronic placental separation begin early in pregnancy. Dugoff and coworkers (2004) observed an association between some abnormally elevated maternal serum aneuploidy markers and subsequent abruption. Ananth (2006) and Weiss (2004) and their associates have also correlated first- and second-trimester bleeding with third-trimester placental abruption. In some cases of a chronic abruption, subsequent oligohydramnios develops—*chronic abruption-oligohydramnios sequence—CAOS* (Elliott, 1998). Even later in pregnancy, hemorrhage with retroplacental hematoma formation is occasionally arrested completely without delivery. These women may have abnormally elevated serum levels of alpha-fetoprotein (Ngai, 2012). We documented a chronic abruption in a woman with suggestive findings by labeling her red cells with radiochromium. Her symptoms abated, and at delivery 3 weeks later, a 400-mL clot found within the uterus contained no radiochromium, whereas peripheral blood at that time did. Thus, red cells in the clot had accumulated before they were labeled with the radioisotope 3 weeks before delivery.

Traumatic Abruption. External trauma—usually from motor vehicle accidents or aggravated assault—can cause placental separation. The frequency of abruption caused by trauma varies and may be dependent on whether these women are cared for in a major trauma unit. Kettel (1988) and Stafford (1988) and their coworkers have appropriately stressed that abruption can be caused by relatively minor trauma. The clinical presentation and sequelae of these abruptions are somewhat different from spontaneous cases. For example, associated fetomaternal hemorrhage, while seldom clinically significant with most spontaneous abruptions, is more common with trauma because of concomitant placental tears or “fractures” (Fig. 47-11, p. 954). Fetal bleeding that averaged 12 mL was noted in a third of women with a traumatic abruption reported by Pearlman (1990). In eight women cared for at Parkland Hospital, we found fetal-to-maternal hemorrhage of 80 to 100 mL in three of eight cases of traumatic placental abruption (Stettler, 1992). Importantly, in some cases of trauma, a nonreassuring fetal heart rate tracing may not be accompanied by other evidence of placental separation. A sinusoidal tracing is one example (Fig. 24-13, p. 482). Traumatic abruption is considered in more detail in Chapter 47 (p. 953).

Fetal-to-Maternal Hemorrhage. Most blood in the retroplacental hematoma in a nontraumatic placental abruption is maternal. This is because hemorrhage is caused by separation within the maternal decidua, and placental villi are usually initially intact. In 78 women at Parkland Hospital with a nontraumatic placental abruption, fetal-to-maternal hemorrhage was documented in only 20 percent—and all of these had < 10 mL fetal blood loss (Stettler, 1992). As discussed above, significant fetal bleeding is much more likely with a traumatic abruption that results from a concomitant placental tear.

Frequency

The reported incidence of placental abruption varies because of different criteria used. That said, its frequency averages

FIGURE 41-16 Frequency of placental abruption and placenta previa by maternal age in 365,700 deliveries at Parkland Hospital from 1988 through 2012. (Data courtesy of Dr. Don McIntire.)

0.5 percent or 1 in 200 deliveries. In the National Center for Health Statistics database of 15 million deliveries, Salihu and colleagues (2005) reported an incidence of 0.6 percent or 1 in 165 births. From the National Hospital Discharge Summary database from 1999 through 2001, the incidence of placental abruption was found to be 1 percent (Ananth, 2005). From a Maternal-Fetal Medicine Units Network study of approximately 10,000 nulliparous women, the incidence was 0.6 percent (Roberts, 2010). In nearly 366,000 deliveries at Parkland Hospital from 1988 through 2012, the incidence of placental abruption averaged 0.35 percent or 1 in 290 (Fig. 41-16).

According to Ananth (2001b, 2005), the frequency of placental abruption has *increased* in this country from 0.8 percent in 1981 to 1.0 percent in 2001. Most of this increase was in black women. At Parkland Hospital, however, both the incidence and severity have *decreased*. With placental abruption *so extensive as to kill the fetus*, the incidence was 0.24 percent or 1 in 420 births from 1956 through 1967 (Pritchard, 1967). As the number of high-parity women giving birth decreased along with improved availability of prenatal care and emergency transportation, the frequency of abruption causing fetal death decreased to 0.12 percent or 1 in 830 births through 1989. Thereafter and through 2003, it decreased further to 0.06 percent or 1 in 1600, and most recently through 2012, it declined to 0.048 percent or 1 in 2060.

Perinatal Morbidity and Mortality

Major fetal congenital anomalies have an increased association with placental abruption (Riihimäki, 2013). Overall, perinatal outcomes are influenced by gestational age, and the frequency of placental abruption increases across the third trimester up to term. As seen in Figure 41-17, more than half of the placental abruptions at Parkland Hospital developed at ≥ 37 weeks. Perinatal mortality and morbidity, however, are more common with earlier abruptions. Perinatal deaths caused by abruptions can be assessed by their contribution to mortality or as an actual mortality ratio. Looked at the first way, although the

FIGURE 41-17 Frequency of placental abruption by gestational age.

rates of fetal death have declined, the contribution of abruption as a cause of stillbirths remains prominent because other causes have also decreased. For example, since the early 1990s, 10 to 12 percent of all third-trimester stillbirths at Parkland Hospital have been the consequence of placental abruption. This is similar to the rate reported by Fretts and Usher (1997) for the Royal Victoria Hospital in Montreal during the 18-year period ending in 1995 (Chap. 35, p. 662).

Looked at the other way, several investigators have documented high perinatal mortality rates caused by placental abruption. Salihi and colleagues (2005) analyzed more than 15 million singleton births in the United States between 1995 and 1998. The perinatal mortality rate associated with placental abruption was 119 per 1000 births compared with 8 per 1000 for the general obstetrical population. They emphasized that the high rate was due not just to placental abruption, but also to the associated increases in preterm delivery and fetal-growth restriction. Of the two, preterm birth has been reported to be the most important (Nath, 2008).

Perinatal morbidity—often severe—is common in survivors. An early study by Abdella and associates (1984) documented significant neurological deficits within the first year of life in 15 percent of survivors. Two subsequent studies by Matsuda and coworkers (2003, 2013) reported that 20 percent of survivors developed cerebral palsy. These observations are similar to ours from Parkland Hospital. Notably, 20 percent of live-born neonates of women with an abruption had severe acidemia, defined by a pH < 7.0 or base deficit of ≥ 12 mmol/L. Importantly, 15 percent of liveborn neonates subsequently died.

Predisposing Factors

Demographic Factors. Several predisposing factors may increase the risk for placental abruption, and some are listed in Table 41-4. First, the incidence of abruption increases with *maternal age* (see Fig. 41-16). In the First- and Second-Trimester Evaluation of Risk (FASTER) trial, women older than 40 years were 2.3 times more likely to experience abruption compared with those 35 years or younger (Cleary-Goldman, 2005). There are conflicting data regarding women of *great parity* (Pritchard, 1991; Toohey, 1995). *Race* or ethnicity also appears to be important. In almost 366,000 deliveries at

TABLE 41-4. Risk Factors for Placental Abruption

Risk Factor	Relative Risk
Prior abruption	10–50
Increased age and parity	1.3–2.3
Preeclampsia	2.1–4.0
Chronic hypertension	1.8–3.0
Chorioamnionitis	3.0
Preterm ruptured membranes	2.4–4.9
Multifetal gestation	2.1
Low birthweight	14.0
Hydramnios	2.0
Cigarette smoking	1.4–1.9
Thrombophilias	3–7
Cocaine use	NA
Uterine leiomyoma	NA

NA = not available.

Data from Ananth, 1999a,b, 2001b, 2004, 2007; Cleary-Goldman, 2005; Eskes, 2001; Nath, 2007, 2008.

Parkland Hospital, abruption severe enough to kill the fetus was most common in African-American and white women—1 in 200—less so in Asian women—1 in 300—and least in Latin-American women—1 in 350 (Pritchard, 1991). A *familial association* was found in an analysis of a Norwegian population-based registry that included almost 378,000 sisters with more than 767,000 pregnancies (Rasmussen, 2009). If a woman had a severe abruption, then the risk for her sister was doubled, and the heritability risk was estimated to be 16 percent. The control group of their sisters-in-law had a risk similar to that for the general obstetrical population.

Hypertension and Preeclampsia. Some form of hypertension is the most frequent condition associated with placental abruption. This includes gestational hypertension, preeclampsia, chronic hypertension, or a combination thereof. In the report by Pritchard and colleagues (1991) that described 408 women with placental abruption and fetal demise cared for at Parkland Hospital, hypertension was apparent in half once hypovolemia was corrected. Half of these women—a fourth of all 408—had chronic hypertension. Looked at another way, a Network study reported that 1.5 percent of pregnant women with chronic hypertension suffered placental abruption (Sibai, 1998). Risk estimates by Zetterstrom and associates (2005) included a two-fold increased incidence of abruption in women with chronic hypertension compared with normotensive women—an incidence of 1.1 versus 0.5 percent.

Chronic hypertension with superimposed preeclampsia or fetal-growth restriction confers an ever greater increased risk (Ananth, 2007). Even so, the severity of hypertension does not necessarily correlate with abruption incidence (Zetterstrom, 2005). The long-term effects of these associations are apparent from the significantly increased cardiovascular mortality risk in affected women (Pariente, 2013). Observations from the Magpie Trial Collaborative Group (2002) suggest that women with preeclampsia given magnesium sulfate may have a reduced risk for abruption.

Preterm Prematurely Ruptured Membranes. There is no doubt that there is a substantially increased risk for abruption when the membranes rupture before term. Major and colleagues (1995) reported that 5 percent of 756 women with ruptured membranes between 20 and 36 weeks developed an abruption. Kramer and coworkers (1997) found an incidence of 3.1 percent if membranes were ruptured for longer than 24 hours. Ananth and associates (2004) reported that the threefold risk of abruption with preterm rupture was further increased with infection. This same group has suggested that inflammation and infection as well as preterm delivery may be the primary causes leading to abruption (Nath, 2007, 2008).

Cigarette Smoking. Given other vascular diseases caused by smoking, it is not surprising that studies from the Collaborative Perinatal Project linked this to an increased risk for abruption (Misra, 1999; Naeye, 1980). Results of meta-analyses of 1.6 million pregnancies included a twofold risk for abruption in smokers (Ananth, 1999b). This risk increased to five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings have been reported by Mortensen (2001), Hogberg (2007), Kaminsky (2007), and all their coworkers.

Cocaine Abuse. Women who use cocaine can have an alarming frequency of placental abruption. Bingol and colleagues (1987) described 50 women who abused cocaine during pregnancy—eight had a stillbirth caused by placental abruption. In a systematic review, Addis and associates (2001) reported that placental abruption was more common in women who used cocaine than in those who did not.

Lupus Anticoagulant and Thrombophilias. Women affected by some of these have higher associated rates of thromboembolic disorders during pregnancy. However, the link with placental abruption is less clear (American College of Obstetricians and Gynecologists, 2012a, 2013a). Lupus anticoagulant is associated with maternal floor infarction of the placenta, but is less so with typical abruptions. There is no convincing evidence that thrombophilias—for example, factor V Leiden or prothrombin gene mutation—are associated with placental abruption. These have been reviewed by Kenny and coworkers (2014) and are discussed further in Chapters 52 (p. 1029) and 59 (p. 1174).

Uterine Leiomyomas. Especially if located near the mucosal surface behind the placental implantation site, uterine myomas can predispose to abortion or later to placental abruption (Chaps. 18, p. 360 and 63, p. 1225).

Recurrent Abruption. Because many of the predisposing factors are chronic and therefore repetitive, it would be reasonable to conclude that placental abruption would have a high recurrence rate. In fact, the woman who has suffered an abruption—especially one that caused fetal death—has an extraordinarily high risk for recurrence. In these women, Pritchard and associates (1970) identified a recurrence rate of 12 percent—and half of these caused another fetal death. Furuhashi and colleagues (2002) reported a 22-percent recurrence rate—half recurred at a gestational age 1 to 3 weeks earlier than the first

abruption. Looked at a second way, Tikkanen and coworkers (2006) found that of 114 parous women who experienced an abruption, 9 percent had a prior abruption. A third perspective is provided by a population-based study of 767,000 pregnancies completed by Rasmussen and Irgens (2009). They reported a 6.5-fold increased risk for recurrence of a “mild” abruption and 11.5-fold risk for a “severe” abruption. For women who had two severe abruptions, the risk for a third was increased 50-fold.

Management of a pregnancy subsequent to an abruption is difficult because another separation may suddenly occur, even remote from term. In many of these recurrences, fetal well-being is almost always reassuring beforehand. Thus, antepartum fetal testing is usually not predictive (Toivonen, 2002).

Clinical Findings and Diagnosis

Most women with a placental abruption have sudden-onset abdominal pain, vaginal bleeding, and uterine tenderness. In a prospective study, Hurd and colleagues (1983) reported that 78 percent with placental abruption had vaginal bleeding, 66 percent had uterine tenderness or back pain, and 60 percent had a nonreassuring fetal status. Other findings included frequent contractions and persistent hypertonus. In a fifth of these women, preterm labor was diagnosed, and abruption was not suspected until fetal distress or death ensued.

Importantly, the signs and symptoms of placental abruption can vary considerably. In some women, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus. In others, there may be no external bleeding, but the placenta is sufficiently sheared off that the fetus is dead—a concealed abruption. In one unusual case, a multiparous woman cared for at Parkland Hospital presented with a nosebleed. She had no abdominal or uterine pain, tenderness, or vaginal bleeding. Her fetus was dead, however, and her blood did not clot. The plasma fibrinogen level was 25 mg/dL. Labor was induced, and a total abruption was confirmed at delivery.

Differential Diagnosis. With severe placental abruption, the diagnosis generally is obvious. From the previous discussion, it follows that less severe, more common forms of abruption cannot always be recognized with certainty. Thus, the diagnosis is one of exclusion. Unfortunately, there are no laboratory tests or other diagnostic methods to accurately confirm lesser degrees of placental separation. Sonography has limited use because the placenta and fresh clots may have similar imaging characteristics. In an early study, Sholl (1987) confirmed the clinical diagnosis with sonography in only 25 percent of women. In a later study, Glantz and Purnell (2002) reported only 24-percent sensitivity in 149 consecutive women with a suspected placental abruption. *Importantly, negative findings with sonographic examination do not exclude placental abruption.* Conversely, magnetic resonance (MR) imaging is highly sensitive for placental abruption, and if knowledge of this would change management, then it should be considered (Masselli, 2011).

With abruption, intravascular coagulation is almost universal. Thus, elevated serum levels of D-dimers may be suggestive, but this has not been adequately tested. Ngai and associates

(2012) have provided preliminary data that serum levels of alpha-fetoprotein > 280 µg/L have a positive-predictive value of 97 percent.

Thus, in the woman with vaginal bleeding and a live fetus, it is often necessary to exclude placenta previa and other causes of bleeding by clinical and sonographic evaluation. It has long been taught—perhaps with some justification—that *painful* uterine bleeding signifies placental abruption, whereas *painless* uterine bleeding is indicative of placenta previa. The differential diagnosis is usually not this straightforward, and labor accompanying previa may cause pain suggestive of placental abruption. On the other hand, pain from abruption may mimic normal labor, or it may be painless, especially with a posterior placenta. At times, the cause of the vaginal bleeding remains obscure even after delivery.

Hypovolemic Shock. *Placental abruption is one of several notable obstetrical entities that may be complicated by massive and sometimes torrential hemorrhage.* Hypovolemic shock is caused by maternal blood loss. In an earlier report from Parkland Hospital, Pritchard and Brekken (1967) described 141 women with abruption so severe as to kill the fetus. Blood loss in these women often amounted to at least half of their pregnant blood volume. Importantly, massive blood loss and shock can develop with a concealed abruption. Prompt treatment of hypotension with crystalloid and blood infusion will restore vital signs to normal and reverse oliguria from inadequate renal perfusion. In the past, placental abruption was an all-too-common cause of acute kidney injury requiring dialysis (Chap. 53, p. 1063).

Consumptive Coagulopathy. Obstetrical events—mainly placental abruption and amniotic-fluid embolism—led to the initial recognition of *defibrination syndrome*, which is currently referred to as *consumptive coagulopathy* or *disseminated intravascular coagulation*. The major mechanism causing procoagulant consumption is intravascular activation of clotting. Abruption is the most common cause of clinically significant consumptive coagulopathy in obstetrics—and indeed, probably in all of medicine. There are significant amounts of procoagulants in the retroplacental clots, but these cannot account for all missing fibrinogen (Pritchard, 1967). We and others have observed that the levels of fibrin degradation products are higher in serum from peripheral blood compared with that found in serum from blood contained in the uterine cavity (Bonnar, 1969). The reverse would be anticipated in the absence of significant intravascular coagulation.

An important consequence of intravascular coagulation is the activation of plasminogen to plasmin, which lyses fibrin microemboli to maintain microcirculatory patency. With placental abruption severe enough to kill the fetus, there are always pathological levels of fibrinogen–fibrin degradation products and D-dimers in maternal serum.

Most women with placental abruption will have some degree of intravascular coagulation. However, in a third of those with an abruption severe enough to kill the fetus, the plasma fibrinogen level will be < 150 mg/dL. These clinically significant levels may cause troublesome surgical bleeding. Elevated serum levels

of fibrinogen–fibrin degradation products, including D-dimers, are also found, but their quantification is not clinically useful. Serum levels of several other coagulation factors are also variably decreased. Thrombocytopenia, sometimes profound, may accompany severe hypofibrinogenemia initially and becomes common after repeated blood transfusions.

Consumptive coagulopathy is more likely with a concealed abruption because intrauterine pressure is higher, thus forcing more thromboplastin into the large veins draining the implantation site. With a partial abruption and a live fetus, severe coagulation defects are seen less commonly. Our experience has been that if serious coagulopathy develops, it is usually evident by the time abruption symptoms appear. Disseminated intravascular coagulation is discussed in more detail on page 808.

Couvellaire Uterus. At the time of cesarean delivery, it is not uncommon to find widespread extravasation of blood into the uterine musculature and beneath the serosa (Fig. 41-18). It is named after Couvellaire, who in the early 1900s termed it *uteroplacental apoplexy*. Effusions of blood are also seen beneath the tubal serosa, between the leaves of the broad ligaments, in the substance of the ovaries, and free in the peritoneal cavity. These myometrial hemorrhages seldom cause uterine atony, and alone they are not an indication for hysterectomy.

Acute Kidney Injury. Previously known as acute renal failure, acute kidney injury is a general term describing renal dysfunction from many causes (Chap. 53, p. 1063). In obstetrics, it is most commonly seen in cases of severe placental abruption in which treatment of hypovolemia is delayed or incomplete. Even when abruption is complicated by severe intravascular

FIGURE 41-18 Couvellaire uterus from total placental abruption after cesarean delivery. Blood markedly infiltrates the myometrium to reach the serosa, especially at the cornua. It gives the myometrium a bluish-purple tone as shown. After the hysterotomy incision was closed, the uterus remained well contracted despite extensive extravasation of blood into the uterine wall. The small serosal leiomyoma seen on the lower anterior uterine surface is an incidental finding. (Courtesy of Dr. Angela Fields Walker).

coagulation, however, prompt and vigorous treatment of hemorrhage with blood and crystalloid solution usually prevents clinically significant renal dysfunction. It is unclear what contributory role abruption occupies in the increasing incidence of obstetric-related acute kidney injury in this country (Bateman, 2010; Kuklina, 2009). Undoubtedly, the risk for renal injury with abruption is magnified when preeclampsia coexists (Drakeley, 2002; Hauth, 1999). Currently, most cases of acute kidney injury are reversible and not so severe as to require dialysis. That said, irreversible *acute cortical necrosis* encountered in pregnancy is most often associated with abruption. In past years, a third of all patients admitted to renal units for chronic dialysis were women who had suffered an abruption (Grünfeld, 1987; Lindheimer, 2007).

Sheehan Syndrome. Rarely, severe intrapartum or early postpartum hemorrhage is followed by pituitary failure—*Sheehan syndrome*. The exact pathogenesis is not well understood, especially since endocrine abnormalities are infrequent even in women who suffer catastrophic hemorrhage. Findings include failure of lactation, amenorrhea, breast atrophy, loss of pubic and axillary hair, hypothyroidism, and adrenal cortical insufficiency. In some women, there may be varying degrees of anterior pituitary necrosis and impaired secretion of one or more trophic hormones (Matsuwaki, 2014; Robalo, 2012). The syndrome is discussed further in Chapter 58 (p. 1163).

Management

Treatment of the woman with a placental abruption varies depending primarily on her clinical condition, the gestational age, and the amount of associated hemorrhage. With a living viable-size fetus and with vaginal delivery not imminent, emergency cesarean delivery is chosen by most. In some women, fetal compromise will be evident (Figs. 41-19 and 41-20). When evaluating fetal status, sonographic confirmation of fetal heart activity may be necessary because sometimes an electrode applied directly to a dead fetus will provide misleading information by recording the maternal heart rate. If the fetus has died or if it is not considered mature enough to live outside the uterus, then vaginal delivery is preferable. In either case,

FIGURE 41-19 Placental abruption with fetal compromise. Lower panel: Uterine hypertonus with a baseline pressure of 20 to 25 mm Hg and frequent contractions peaking at approximately 75 mm Hg. Upper panel: The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.

FIGURE 41-20 Intrapartum placental abruption with acute onset of fetal compromise prompted emergent cesarean delivery. An infant with 1- and 5-minute Apgar scores of 4 and 7, respectively, was delivered.

prompt and intensive resuscitation with blood plus crystalloid is begun to replace blood lost from retroplacental and external hemorrhage. These measures are lifesaving for the mother and hopefully for her fetus. If the diagnosis of abruption is uncertain and the fetus is alive and without evidence of compromise, then close observation may be warranted provided that immediate intervention is available.

A major hazard to cesarean delivery is imposed by clinically significant consumptive coagulopathy. As discussed on page 797, this likelihood is lessened if the fetus is still alive—and thus the abruption “less severe.” Preparations include assessment of coagulability—especially fibrinogen content—and plans for blood and component replacement.

Cesarean Delivery. The compromised fetus is usually best served by cesarean delivery, and the speed of response is an important factor in perinatal outcomes (see Fig. 41-20). Kayani and coworkers (2003) studied this relationship in 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact survivors, 15 were delivered within a 20-minute decision-to-delivery interval. However, eight of 11 infants who died or developed cerebral palsy were delivered with an interval > 20 minutes.

Vaginal Delivery. If the fetus has died, then vaginal delivery is usually preferred. As reviewed on page 780, hemostasis at the placental implantation site depends primarily on myometrial contraction and not blood coagulability. Thus, after vaginal delivery, uterotonic agents and uterine massage are used to stimulate myometrial contractions. Fibers compress placental site vessels and prompt hemostasis even if coagulation is defective.

There are exceptions for which vaginal delivery may not be preferable even if the fetus is dead. For example, in some cases, hemorrhage is so brisk that it cannot be successfully managed even by vigorous blood replacement. Obstetrical complications that prohibit vaginal delivery such as a term fetus with a transverse lie are another example. Women with a prior high-risk hysterotomy incision, that is, a prior vertical or classical cesarean delivery, pose a complex situation.

Labor with extensive placental abruption tends to be rapid because the uterus is usually persistently hypertonic. This can

magnify fetal compromise (see Fig. 41-19). In some cases, *baseline* intraamniotic pressures reach 50 mm Hg or higher, and rhythmic increases reach more than 100 mm Hg with contractions.

Early amniotomy has long been championed in the management of placental abruption. This ostensibly achieves better spiral artery compression that might decrease implantation site bleeding and reduce thromboplastin infusion into the maternal vascular system. Although evidence supporting this theory is lacking, membrane rupture may hasten delivery. However, if the fetus is small, the intact sac may be more efficient in promoting cervical dilatation. If rhythmic uterine contractions are not superimposed on baseline hypertonus, then oxytocin is given in standard doses. There are no data indicating that oxytocin enhances thromboplastin escape into the maternal circulation to worsen coagulopathy (Clark, 1995; Pritchard, 1967).

In the past, some had set arbitrary time limits to permit vaginal delivery. Instead, experiences indicate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy are pursued rather than on the interval to delivery. Observations from Parkland Hospital described by Pritchard and Brekken (1967) are similar to those from the University of Virginia reported by Brame and associates (1968). Specifically, women with severe abruption who were transfused during 18 hours or more before delivery had similar outcomes to those in whom delivery was accomplished sooner.

Expectant Management with Preterm Fetus. Delaying delivery may prove beneficial when the fetus is immature. Bond and colleagues (1989) expectantly managed 43 women with placental abruption before 35 weeks' gestation, and 31 of them were given tocolytic therapy. The mean interval-to-delivery for all 43 was approximately 12 days. Cesarean delivery was performed in 75 percent, and there were no stillbirths. As discussed on page 794, women with a very early abruption frequently develop chronic abruption-oligohydramnios sequence—CAOS. In one report, Elliott and coworkers (1998) described four women with an abruption at a mean gestation of 20 weeks who developed oligohydramnios and delivered at an average gestational age of 28 weeks. In a description of 256 women with an abruption \leq 28 weeks, Sabourin and colleagues (2012) reported that a mean of 1.6 weeks was gained. Of the group, 65 percent were delivered $<$ 29 weeks, and half of all women underwent emergent cesarean delivery.

Unfortunately, even continuous fetal heart rate monitoring does not guarantee universally good outcomes. For example, a normal tracing may precede sudden further separation with instant fetal compromise as shown in Figure 41-20. In some of these, if the separation is sufficient, the fetus will die before it can be delivered. Tocolysis is advocated by some for suspected abruption if the fetus does not display compromise. One drawback reported in the early study by Hurd (1983) was that abruption went unrecognized for dangerously long periods if tocolysis was initiated. Subsequent studies were more optimistic and observed that tocolysis improved outcomes in a highly

selected cohort of women with preterm pregnancies (Bond, 1989; Combs, 1992; Sholl, 1987). In another study, Towers and coworkers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with abruption diagnosed before 36 weeks. The perinatal mortality rate was 5 percent in both groups with or without tocolysis. We are of the view that until a randomized trial is done, a clinically evident abruption contraindicates tocolytic therapy. This does not preclude magnesium sulfate given for severe gestational hypertension.

Placenta Previa

The Latin *previa* means *going before*—and in this sense, the placenta goes before the fetus into the birth canal. In obstetrics, placenta previa describes a placenta that is implanted somewhere in the lower uterine segment, either over or very near the internal cervical os. Because these anatomical relationships cannot always be precisely defined, and because they frequently change across pregnancy, terminology can sometimes be confusing.

Placental Migration

With the frequent use of sonography in obstetrics, the term *placental migration* was used to describe the apparent movement of the placenta away from the internal os (King, 1973). Obviously, the placenta does not move per se, and the mechanism of *apparent* movement is not completely understood. To begin with, *migration* is clearly a misnomer, because decidual invasion by chorionic villi on either side of the cervical os persists. Several explanations are likely additive. First, apparent movement of the low-lying placenta relative to the internal os is related to the imprecision of two-dimensional sonography in defining this relationship. Second, there is differential growth of the lower and upper uterine segments as pregnancy progresses. With greater upper uterine blood flow, placental growth more likely will be toward the fundus—*trophotropism*. Many of those placentas that “migrate” most likely never were circumferentially implanted with true villous invasion that reached the internal cervical os. *Finally, a low-lying placenta is less likely to “migrate” within a uterus with a prior cesarean hysterotomy scar.* Of interest, at the time of delivery there are an equal number of anterior and posterior placentas (Young, 2013).

Placental migration has been quantified in several studies. Sanderson and Milton (1991) studied 4300 women at midpregnancy and found that 12 percent had a low-lying placenta. Of those not covering the internal os, previa did not persist, and none subsequently had placental hemorrhage. Conversely, approximately 40 percent of placentas that covered the os at midpregnancy continued to do so until delivery. Thus, placentas that lie close to but not over the internal os up to the early third trimester are unlikely to persist as a previa by term (Dashe, 2002; Laughon, 2005; Robinson, 2012). Still, Bohrer and associates (2012) reported that a second-trimester low-lying placenta was associated with antepartum admission for hemorrhage and increased blood loss at delivery.

The likelihood that placenta previa persists after being identified sonographically at given epochs before 28 weeks' gestation is shown in Figure 41-21. Similar findings for twin

FIGURE 41-21 Likelihood of persistence of placenta previa or low-lying placenta at delivery. These are shown as a function of sonographic diagnosis at three pregnancy epochs of a previa or placental edges 1 to 5 mm from the cervical internal os. CD = cesarean delivery. (Data from Oyelese, 2006.)

pregnancies are reported until 23 weeks, after which the previa persistence rate is much higher (Kohari, 2012). A prior uterine incision also has an obvious effect. Stafford and coworkers (2010), but not Trudell and colleagues (2013), found that a previa and a third-trimester cervical length < 30 mm increased the risk for hemorrhage, uterine activity, and preterm birth. Friszer and associates (2013) showed that women admitted for bleeding had a greater chance of delivery by 7 days with the cervix < 25 mm, although Trudell and colleagues (2013) did not confirm this.

As indicated and discussed subsequently, persistent previa is more common in women who have had a prior cesarean delivery. In the absence of any other indication, sonography need not be frequently repeated simply to document placental position. Moreover, restriction of activity is not necessary unless a previa persists beyond 28 weeks or if clinical findings such as bleeding or contractions develop before this time.

Classification

Terminology for placenta previa has been confusing. In a recent Fetal Imaging Workshop sponsored by the National Institutes of Health (Dashe, 2013), the following classification was recommended:

- *Placenta previa*—the internal os is covered partially or completely by placenta. In the past, these were further classified as either total or partial previa (Figs. 41-22 and 41-23).
- *Low-lying placenta*—implantation in the lower uterine segment is such that the placental edge does not reach the internal os and remains outside a 2-cm wide perimeter around the os. A previously used term, *marginal previa*, described a placenta that was at the edge of the internal os but did not overlie it.

Clearly, the classification of some cases of previa will depend on cervical dilatation at the time of assessment (Dashe, 2013). For example, a low-lying placenta previa at 2-cm dilatation may

FIGURE 41-22 Total placenta previa showing that copious hemorrhage could be anticipated with any cervical dilatation.

become a partial placenta previa at 4-cm dilatation because the cervix has dilated to expose the placental edge (see Fig. 41-23). Conversely, a placenta previa that appears to be total before cervical dilatation may become partial at 4-cm dilatation because the cervical opening now extends beyond the edge of the placenta. *Digital palpation in an attempt to ascertain these changing*

FIGURE 41-23 Second-trimester partial placenta previa. On speculum examination, the cervix is 3- to 4-cm dilated. The arrow points to mucus dripping from the cervix. (Photograph contributed by Dr. Rigoberto Santos.)

relations between the placental edge and internal os as the cervix dilates usually causes severe hemorrhage!

With both total and partial placenta previa, a certain degree of spontaneous placental separation is an inevitable consequence of lower uterine segment remodeling and cervical dilatation. Although this frequently causes bleeding, and thus technically constitutes a placental abruption, this term is usually not applied in these instances.

Somewhat but not always related is *vasa previa*, in which fetal vessels course through membranes and present at the cervical os (Bronsteen, 2013). This is discussed in Chapter 6 (p. 123).

Incidence and Associated Factors

Reported incidences for placenta previa average 0.3 percent or 1 case per 300 to 400 deliveries. It was reported to be almost 1 in 300 deliveries in the United States in 2003 (Martin, 2005). The frequency at Parkland Hospital from 1988 through 2012 was approximately 1 in 360 for nearly 366,000 births. Similar frequencies have been reported from Canada, England, and Israel, but it was only 1 in 700 deliveries from a Japanese study (Crane, 1999; Gurol-Urganci, 2011; Matsuda, 2011; Rosenberg, 2011). Except for the last study, these reported frequencies are remarkably similar considering the lack of precision in definition and classification discussed above.

Several factors increase the risk for placenta previa. One of these—multifetal gestation—seems intuitive because of the larger placental area. And indeed, the incidence of associated previa with twin pregnancy is increased by 30 to 40 percent compared with that of singletons (Ananth, 2003a; Weis, 2012). Many of the other associated factors are less intuitive.

Maternal Age. The frequency of placenta previa increases with maternal age (Biro, 2012). At Parkland Hospital, this incidence increased from a low rate of approximately 1 in 1660 for women 19 years or younger to almost 1 in 100 for women older than 35 (see Fig. 41-16). Coincidental with increasing maternal age in the United States and Australia, the overall incidence of previa has increased substantively (Frederiksen, 1999; Roberts, 2012). The FASTER Trial, which included more than 36,000 women, cited the frequency of previa to be 0.5 percent for women younger than 35 years compared with 1.1 percent in those older than 35 years (Cleary-Goldman, 2005).

Multiparity. The risk for previa increases with parity. The obvious effects of advancing maternal age and parity are confounding. Still, Babinszki and colleagues (1999) reported that the 2.2-percent incidence in women with parity of 5 or greater was increased significantly compared with that of women with lower parity.

Prior Cesarean Delivery. The cumulative risks for placenta previa that accrue with the increasing number of cesarean deliveries are extraordinary. In a Network study of 30,132 women undergoing cesarean delivery, Silver and associates (2006) reported an incidence of 1.3 percent for those with only one prior cesarean delivery, but it was 3.4 percent if there were six or more prior cesarean deliveries. In a retrospective cohort of nearly 400,000 women who were delivered of two consecutive singletons, those with a cesarean delivery for the first pregnancy

had a significant 1.6-fold increased risk for previa in the second pregnancy (Gurol-Urganci, 2011). These same investigators reported a 1.5-fold increased risk from six similar population-based cohort studies. Gesteland (2004) and Gilliam (2002) and their coworkers calculated that the likelihood of previa was increased more than eightfold in women with parity greater than 4 and who had more than four prior cesarean deliveries.

Importantly, women with a prior uterine incision and placenta previa have an increased likelihood that cesarean hysterectomy will be necessary for hemostasis because of an associated accrete syndrome (p. 804). In the study by Frederiksen and colleagues (1999), 6 percent of women who had a primary cesarean delivery for previa required a hysterectomy. This rate was 25 percent for women with a previa undergoing repeat cesarean delivery.

Cigarette Smoking. The relative risk of placenta previa is increased at least twofold in women who smoke (Ananth, 2003a; Usta, 2005). It has been postulated that carbon monoxide hypoxemia causes compensatory placental hypertrophy and more surface area. Smoking may also be related to decidual vasculopathy that has been implicated in the genesis of previa.

Elevated Prenatal Screening MSAFP Levels. Women who have otherwise unexplained abnormally elevated prenatal screening levels of maternal serum alpha-fetoprotein (MSAFP) are at increased risk for previa and a host of other abnormalities as discussed on page 806. Moreover, women with a previa who also had a MSAFP level ≥ 2.0 MoM at 16 weeks' gestation were at increased risk for late-pregnancy bleeding and preterm birth. Screening with MSAFP is considered in detail in Chapter 14 (p. 284).

Clinical Features

Painless bleeding is the most characteristic event with placenta previa. Bleeding usually does not appear until near the end of the second trimester or later, but it can begin even before mid-pregnancy. And undoubtedly, some late abortions are caused by an abnormally located placenta. Bleeding from a previa usually begins without warning and without pain or contractions in a woman who has had an uneventful prenatal course. This so-called *sentinel bleed* is rarely so profuse as to prove fatal. Usually it ceases, only to recur. In perhaps 10 percent of women, particularly those with a placenta implanted near but not over the cervical os, there is no bleeding until labor onset. Bleeding at this time varies from slight to profuse, and it may clinically mimic placental abruption.

A specific sequence of events leads to bleeding in cases in which the placenta is located over the internal os. First, the uterine body remodels to form the lower uterine segment. With this, the internal os dilates, and some of the implanted placenta inevitably separates. Bleeding that ensues is augmented by the inherent inability of myometrial fibers in the lower uterine segment to contract and thereby constrict avulsed vessels. Similarly, bleeding from the lower segment implantation site also frequently continues after placental delivery. Last, there may be lacerations in the friable cervix and lower segment. This may be especially problematic following manual removal of a somewhat adhered placenta.

Abnormally Implanted Placenta. A frequent and serious complication associated with placenta previa arises from its abnormally firm placental attachment. This is anticipated because of poorly developed decidua that lines the lower uterine segment. Biswas and coworkers (1999) performed placental bed biopsies in 50 women with a previa and in 50 control women. Trophoblastic giant-cell infiltration of spiral arterioles—rather than endovascular trophoblast—was found in half of previa specimens. However, only 20 percent from normally implanted placentas had these changes.

Placenta accrete syndromes arise from abnormal placental implantation and adherence and are classified according to the depth of placental ingrowth into the uterine wall. These include *placenta accreta*, *increta*, and *percreta* (p. 804). In a study of 514 cases of previa reported by Frederiksen and associates (1999), abnormal placental attachment was identified in 7 percent. As discussed above, previa overlying a prior cesarean incision conveys a particularly high risk for accreta.

Coagulation Defects. Placenta previa is rarely complicated by coagulopathy even when there is extensive implantation site separation (Wing, 1996b). Placental thromboplastin, which incites the intravascular coagulation seen with placental abruption, is presumed to readily escape through the cervical canal rather than be forced into the maternal circulation. The paucity of large myometrial veins in this area may also be protective.

Diagnosis

Whenever there is uterine bleeding after midpregnancy, placenta previa or abruption should always be considered. In the Canadian Perinatal Network study discussed on page 783, placenta previa accounted for 21 percent of women admitted from 22 to 28 weeks' gestation with vaginal bleeding (Sabourin, 2012). Previa should not be excluded until sonographic evaluation has clearly proved its absence. Diagnosis by clinical examination is done using the *double set-up* technique because it requires that a finger be passed through the cervix and the placenta palpated. A digital examination should not be performed

unless delivery is planned. *A cervical digital examination is done with the woman in an operating room and with preparations for immediate cesarean delivery. Even the gentlest examination can cause torrential hemorrhage.* Fortunately, double set-up examination is rarely necessary because placental location can almost always be ascertained sonographically.

Sonographic Placental Localization. Quick and accurate localization can be accomplished using standard sonographic techniques (Dashe, 2013). In many cases, *transabdominal sonography* is confirmatory, as shown in [Figure 41-24A](#), and an average accuracy of 96 percent has been reported (Laing, 1996). Imprecise results may be caused by bladder distention, so doubtful cases should be confirmed after bladder emptying. Moreover, sometimes a large fundal placenta is not appreciated to extend down to the internal cervical os. *Transvaginal sonography* is safe, and the results are superior as shown in [Figures 41-24B](#) and [41-25](#). In a comparative study by Farine and associates (1988), the internal os was visualized in all cases using transvaginal sonography but was seen in only 70 percent using transabdominal sonography. Transperineal sonography is also accurate to localize placenta previa (Hertzberg, 1992). In a study by Rani and colleagues (2007), placenta previa was correctly identified in 69 of 70 women and was confirmed at delivery. They reported the positive-predictive value to be 98 percent, whereas the negative-predictive value was 100 percent.

Magnetic Resonance Imaging. Although several investigators have reported excellent results using MR imaging to visualize placental abnormalities, it is unlikely that this technique will replace sonography for routine evaluation anytime soon. That said, MR imaging has proved useful for evaluation of placenta accreta (p. 807).

Management of Placenta Previa

Women with a previa are managed depending on their individual clinical circumstances. The three factors that usually

FIGURE 41-24 Total placenta previa. **A.** Transabdominal sonogram shows placenta (white arrowheads) covering the cervix (black arrows). **B.** Transvaginal sonogram shows placenta (arrows), lying between the cervix and fetal head.

FIGURE 41-25 Transvaginal sonogram of an anterior placenta previa at 36 weeks' gestation. The placental margin (red arrow) extends downward toward the cervix. The internal os (yellow arrow) and cervical canal (short white arrows) are marked to show their relationship to the leading edge of the placenta.

are considered include fetal age and thus maturity; labor; and bleeding and its severity.

If the fetus is preterm and there is no persistent active bleeding, management favors close observation in an obstetrical unit. Data are sparse regarding tocolytic administration for uterine contractions. Although good randomized trials are lacking, Bose and colleagues (2011) recommend that if tocolytics are given, they be limited to 48 hours of administration. We categorically recommend against their use in this setting. After bleeding has ceased for about 2 days and the fetus is judged to be healthy, the woman can usually be discharged home. Importantly, the woman and her family must fully appreciate the possibility of recurrent bleeding and be prepared for immediate transport back to the hospital. In other cases, prolonged hospitalization may be ideal.

In properly selected patients, there appear to be no benefits to inpatient compared with outpatient management (Mouer, 1994; Neilson, 2003). In a randomized study by Wing and colleagues (1996a), no differences in maternal or fetal morbidity were noted with either management method. This trial of inpatient versus home management included 53 women who had a bleeding previa at 24 to 36 weeks' gestation. Of these 53 women, 60 percent had recurrent bleeding. Also, of all 53 women, half eventually required expeditious cesarean delivery. Home management is more economical. In one study, hospital stay length and costs for mother-infant care were reduced by half with outpatient management (Drost, 1994).

For women who are near term and who are not bleeding, plans are made for scheduled cesarean delivery. Timing is important to maximize fetal growth but to minimize the possibility of antepartum hemorrhage. A National Institutes of Health workshop concluded that women with a previa are best served by elective delivery at 36 to 37 completed weeks (Spong, 2011). With suspected placenta accrete syndromes,

delivery was recommended at 34 to 35 completed weeks. At Parkland Hospital, we prefer to wait until 37 to 38 weeks before delivery (p. 807).

Delivery

Practically all women with placenta previa undergo cesarean delivery. Many surgeons recommend a vertical skin incision. Cesarean delivery is emergently performed in more than half because of hemorrhage, for which about a fourth require blood transfusion (Boyle, 2009; Sabourin, 2012). Although a low transverse hysterotomy is usually possible, this may cause fetal bleeding if there is an anterior placenta and the placenta is cut through. In such cases, fetal delivery should be expeditious. Thus, a vertical uterine incision may be preferable in some instances. That said, even when the incision extends through the placenta, maternal or fetal outcomes are rarely compromised.

Following placental removal, there may be uncontrollable hemorrhage because of poorly contracted smooth muscle of the lower uterine segment. When hemostasis at the placental implantation site cannot be obtained by pressure, the implantation site can be oversewn with 0-chromic sutures. Cho and associates (1991) described interrupted 0-chromic sutures at 1-cm intervals to form a circle around the bleeding portion of the lower segment to control hemorrhage in all eight women in whom it was employed. Huissoud and coworkers (2012) also described use of circular sutures. Kayem (2011) and Penotti (2012) and their colleagues reported that only 2 of 33 women with a previa and no accreta who had anterior-posterior uterine compression sutures required hysterectomy. Kumru and associates (2013) reported success with the Bakri balloon in 22 of 25 cases. Diemert and coworkers (2012) described good results with combined use of a Bakri balloon and compression sutures. Albayrak and colleagues (2011) described Foley balloon tamponade. Druzin (1989) proposed tightly packing the lower uterine segment with gauze, and the pack was removed transvaginally 12 hours later. Law and coworkers (2010) reported successful use of hemostatic gel. Other methods include bilateral uterine or internal iliac artery ligation as described on page 819. Finally, pelvic artery embolization as described on page 820 has also gained acceptance.

If these more conservative methods fail and bleeding is brisk, then hysterectomy is necessary. Placenta previa—especially with abnormally adhered placental variations—currently is the most frequent indication for peripartum hysterectomy at Parkland Hospital and from other reports (Wong, 2011). It is not possible to accurately estimate the impact on hysterectomy from previa alone without considering the associated accrete syndromes. *Again, for women whose placenta previa is implanted anteriorly at the site of a prior uterine incision, there is an increased likelihood of associated placenta accrete syndrome and need for hysterectomy.* In a study of 318 peripartum hysterectomies from in the United Kingdom, 40 percent were done for abnormally implanted placentation (Knight, 2007). At Parkland Hospital, 44 percent of cesarean hysterectomies were done for bleeding placenta previa or placenta accrete syndrome. In an Australian study of emergency peripartum hysterectomy, 19 percent were done for placenta previa, and another 55 percent for a morbidly

adhered placenta (Awan, 2011). The technique for peripartum hysterectomy is described in Chapter 30 (p. 599).

Maternal and Perinatal Outcomes

A marked reduction in maternal mortality rates from placenta previa was achieved during the last half of the 20th century. Still, as shown in Figure 41-2, placenta previa and coexistent accrete syndromes both contribute substantively to maternal morbidity and mortality. In one review, there was a threefold increased maternal mortality ratio of 30 per 100,000 for women with previa (Oyelese, 2006). In another report of 4693 maternal deaths in the United States, placenta previa and accrete syndromes accounted for 17 percent of deaths from hemorrhage (Berg, 2010).

The report from the Consortium on Safe Labor emphasizes the ongoing perinatal morbidity with placenta previa (Lai, 2012). Preterm delivery continues to be a major cause of perinatal death (Nørgaard, 2012). For the United States in 1997, Salihu and associates (2003) reported a threefold increased neonatal mortality rate with placenta previa that was caused primarily from preterm delivery. Ananth and colleagues (2003b) reported a comparably increased risk of neonatal death even for fetuses delivered at term. This is at least partially related to fetal anomalies, which are increased two- to threefold in pregnancies with placenta previa (Crane, 1999).

The association of fetal-growth restriction with placenta previa is likely minimal after controlling for gestational age (Crane, 1999). In a population-based cohort of more than 500,000 singleton births, Ananth and associates (2001a) found that most low-birthweight infants associated with placenta previa resulted from preterm birth. Harper and coworkers (2010) reported similar findings from a cohort of nearly 58,000 women who underwent routine second-trimester sonographic evaluation at their institution.

■ Placenta Accrete Syndromes

These syndromes describe the abnormally implanted, invasive, or adhered placenta. Derivation of *accrete* comes from the Latin *ac-* + *crescere*—to grow from adhesion or coalescence, to adhere, or to become attached to (Benirschke, 2012). Accrete syndromes thus include any placental implantation with abnormally firm adherence to myometrium because of partial or total absence of the decidua basalis and imperfect development of the fibrinoid or *Nitabuch layer*. If the decidua spongy layer is lacking either partially or totally, then the physiological line of cleavage is absent, and some or all cotyledons are densely anchored. The surface area of the implantation site involved and the depth of trophoblastic tissue ingrowth are variable between women, but all affected placentas can potentially cause significant hemorrhage.

Accrete syndromes have evolved into one of the most serious problems in obstetrics. As subsequently discussed, the likelihood of placenta accrete syndrome is closely linked to prior uterine surgery. Thus, related to the increasing and current all-time high rate of cesarean delivery in the United States, the frequency of placenta accrete syndromes has reached seemingly epidemic proportions. And, at least until recently, there seems to be no consensus for management (Wright, 2013).

To better codify some of the serious consequences associated with accrete syndromes, the American College of Obstetricians and Gynecologists (2012b) and the Society for Maternal-Fetal Medicine (2010) have taken the lead to address management problems. Accrete syndromes have also been the subject of recent reviews (Rao, 2012; Wortman, 2013a).

Etiopathogenesis

Microscopically, placental villi are anchored to muscle fibers rather than to decidual cells. Decidual deficiency then prevents normal placental separation after delivery. Intuitive thinking and now substantiated data suggest that accrete syndromes are not solely caused by an anatomical layer deficiency (Tantbirojn, 2008). Evidence indicates that the cytotrophoblasts may control decidual invasion through factors such as angiogenesis and growth expression (Cohen, 2010; Duzyj, 2013; Wehrum, 2011). Indeed, accrete syndrome tissue specimens have shown evidence for “hyperinvasiveness” compared with otherwise uncomplicated previa specimens (Pri-Paz, 2012). The distribution of large vessels is different than that seen with nonaccrete placentas (Chantraine, 2012). As described by Benirschke and colleagues (2012), there is an antecedent “constitutional endometrial defect” in most cases. The increased risk conveyed by previous uterine trauma—for example, cesarean delivery—may be partially explained by an increased vulnerability of the decidua to trophoblast invasion following incision into the decidua (Garmi, 2012).

Classification

Variants of placenta accrete syndrome are classified by the depth of trophoblastic growth (Fig. 41-26). *Placenta accreta* indicates that villi are attached to the myometrium. With *placenta increta*, villi actually invade the myometrium, and *placenta percreta* defines villi that penetrate through the myometrium and to or through the serosa. In clinical practice, these three variants are encountered in an approximate ratio of 80:15:5, respectively (Wong, 2008). In all three varieties, abnormal adherence may involve all lobules—*total placenta accreta* (Fig. 41-27). If all or part of a single lobule is abnormally attached, it is described as a *focal placenta accreta*. Histological diagnosis cannot be made from the placenta alone, and the uterus or curettings with myometrium are necessary for histopathological confirmation (Benirschke, 2012).

Incidence and Associated Conditions

The increased frequency of accrete syndromes during the past 50 years stems from the liberalized use of cesarean delivery. In 1924, Polak and Phelan presented their data from Long Island College Hospital, which had one case of placenta accreta complicating 6000 deliveries. In a 1951 review, a maternal mortality rate of up to 65 percent was cited (McKeogh, 1951). In 1971, in the 14th edition of *Williams Obstetrics*, Hellman and Pritchard described placenta accreta as the subject of case reports. In a review several years later, Breen and coworkers (1977) cited a reported average incidence of 1 in 7000 deliveries.

Since these reports, however, the incidence of accrete syndromes has increased remarkably, in direct relationship to the increasing cesarean delivery rate (Chap. 31, p. 618). The incidence of placenta accrete syndrome was cited as 1 in

FIGURE 41-26 Placenta accrete syndromes. **A.** Placenta accreta. **B.** Placenta increta. **C.** Placenta percreta.

Dowd). **B.** Hysterectomy specimen containing a partial placenta previa with placenta percreta that invaded the lateral fundal region to cause hemoperitoneum.

2500 in the 1980s, and currently, the American College of Obstetricians and Gynecologists (2012b) cites it to be as high as 1 in 533 deliveries. Because of this increasing frequency, accrete syndromes are now one of the most serious problems in obstetrics. In addition to their significant contribution to maternal morbidity and mortality, accrete syndromes are a leading cause of intractable postpartum hemorrhage and emergency peripartum hysterectomy (Awan, 2011; Eller, 2011; Rossi, 2010). Their contribution as a cause of maternal deaths from hemorrhage is shown in Figure 41-2. *In their review of nearly 10,000 pregnancy-related maternal deaths in the United States, Berg and associates (2010) reported that 8 percent of deaths due to hemorrhage were caused by accrete syndromes.*

Risk Factors

These are similar in many aspects to those for placenta previa (p. 801). That said, the two most important risk factors are an associated previa, a prior cesarean delivery, and more likely a combination of the two. In one study, an accrete placenta more likely followed emergency compared with elective cesarean delivery (Kamara, 2013). A classical hysterotomy incision has a higher risk for a subsequent accrete placenta (Gyamfi-Bannerman, 2012). Decidual formation may be defective over a previous hysterotomy scar, and it also may follow any type of myometrial trauma such as curettage (Benirschke, 2012). Myomectomy apparently confers a low risk (Gyamfi-Bannerman, 2012). In one study, 10 percent of women with a previa had an associated accrete placenta. In another study, almost half of women with a prior cesarean delivery had myometrial fibers seen microscopically adhered to the placenta (Hardardottir, 1996; Zaki, 1998). Findings from a Maternal-Fetal Medicine Units Network study by Silver and colleagues (2006) of women with one or more prior cesarean deliveries who also had a placenta previa are shown in Figure 41-28. The astonishing increase in frequency of associated accrete syndromes is apparent.

FIGURE 41-28 Frequency of accrete syndromes in women with 1 to 5 prior cesarean deliveries (CDs) now with a previa. (Data from Silver, 2006.)

Another risk factor became apparent with widespread use of MSAFP and human chorionic gonadotropin (hCG) screening for neural-tube defects and aneuploidies (Chap. 14, p. 285). In a study reported by Hung (1999) of more than 9300 women screened at 14 to 22 weeks, the risk for accrete syndromes was increased eightfold with MSAFP levels > 2.5 MoM, and it was increased fourfold when maternal free β -hCG levels were > 2.5 MoM.

Cesarean-Scar Pregnancy. In some women with an accrete placenta, there may be adverse outcomes before fetal viability. One presentation generally referred to as a *cesarean scar pregnancy* clinically is similar to that of an ectopic pregnancy. Its frequency has been reported to be approximately 1 in 2000 pregnancies (Ash, 2007; Rotas, 2006). Timor-Tritsch (2012) provided a scholarly review of 751 such cases, and the subject is discussed in detail in Chapter 19 (p. 391).

Clinical Presentation and Diagnosis

In cases of first- and second-trimester accrete syndromes, there is usually hemorrhage that is the consequence of coexisting placenta previa. Such bleeding will usually prompt evaluation and management. In some women who do not have an associated previa, accreta may not be identified until third-stage labor when an adhered placenta is encountered.

Ideally, abnormal placental ingrowth is identified antepartum, usually by sonography (Chantraine, 2013; Tam Tam, 2012). For gray-scale transvaginal sonography, the American College of Obstetricians and Gynecologists (2012b) cites a sensitivity of 77 to 87 percent, specificity of 96 to 98 percent, and a positive- and negative-predictive value of 65 to 93 and 98 percent, respectively. Individual studies have reported similar findings (Chalubinski, 2013; Elhawary, 2013; Maher, 2013). Although controversial, at Parkland Hospital, we have found that the addition of Doppler color flow mapping is highly predictive of myometrial invasion (Fig. 41-29). This is suspected

FIGURE 41-29 Transvaginal sonogram of placental invasion with accrete syndrome. Retroplacental vessels (white arrows) invade the myometrium and obscure the bladder-serosal interface. Abnormal intraplacental venous lakes (black arrowheads) are commonly seen in this setting.

if the distance between the uterine serosa-bladder wall interface and the retroplacental vessels is < 1 mm and if there are large intraplacental lacunae (Twickler, 2000). Similarly, Cali and associates (2013) reported that hypervascularity of the uterine serosa-bladder wall interface had the highest positive- and negative-predictive values for placenta percreta.

MR imaging can be used as an adjunct to sonography to define anatomy, degree of invasion, and possible ureteral or bladder involvement (Chalubinski, 2013; Palacios Jaraquemada, 2005). Lax and coworkers (2007) identified three MR imaging findings that suggested accreta. These include uterine bulging, heterogeneous signal intensity within the placenta, and dark intraplacental bands on T2-weighted imaging. Some suggest MR imaging when sonography results are inconclusive or there is a posterior previa (American College of Obstetricians and Gynecologists, 2012b; Elhawary, 2013).

Management

Preoperative assessment should begin at the time of recognition during prenatal care (Fitzpatrick, 2014; Sentilhes, 2013). A major decision concerns the ideal institution for delivery. Exigencies to be considered are appropriate surgical, anesthesia, and blood banking capabilities. An obstetrical surgeon or gynecological oncologist as well as surgical, urological, and interventional radiological consultants should all be available (Eller, 2011; Stafford, 2008). The American College of Obstetricians and Gynecologists (2012b) and the Society for Maternal-Fetal Medicine (2010) recommend planned delivery in a tertiary-care facility. In some of these, especially designed teams have been assembled and are on call (Walker, 2013). Women who refuse blood or its derivatives pose especially difficult management decisions (Barth, 2011). If possible, delivery is best scheduled for peak availability of all resources and team members. However, emergency contingent plans should also be in place.

Timing of Delivery. To accomplish scheduled surgical intervention, preterm delivery is necessary and justified given the serious adverse maternal consequences of emergency cesarean delivery. The American College of Obstetricians and Gynecologists (2012b) recommends individualization of delivery timing. It cites a decision-analysis study that justifies elective delivery without fetal lung maturity testing after 34 completed weeks (Robinson, 2010). The results of two recent surveys indicate that most practitioners do not deliver these women until 36 weeks or later (Esakoff, 2012; Wright, 2013). At Parkland Hospital, we generally schedule these procedures after 36 completed weeks but are prepared also to manage them in nonelective situations.

Preoperative Arterial Catheterization. There has been enthusiasm for placement of intraarterial catheters to mitigate blood loss and to enhance surgical visibility. Balloon-tipped catheters advanced into the internal iliac arteries are inflated after delivery to occlude pelvic blood flow to aid placental removal and hysterectomy (Ballas, 2012; Desai, 2012). Alternatively, the catheters can be used to embolize bleeding arterial sites. Others have concluded that these procedures offer borderline efficacy and have serious risks (Sentilhes, 2009; Yu, 2009). Complications have included thromboses of the common and

left iliac arteries (Bishop, 2011; Greenberg, 2007). At this time, we agree with the American College of Obstetricians and Gynecologists (2012b) that a firm recommendation cannot be made for or against their use.

Cesarean Delivery and Hysterectomy. Before commencing with delivery, the risk of hysterectomy to prevent exsanguination should be estimated. Confirmation of a percreta or increta almost always mandates hysterectomy. However, some of these abnormal placentations, especially if partial, may be amenable to placental delivery with hemostatic suture placement. Because the scope of invasion may not be apparent before delivery of the fetus, we usually attempt to create a wide bladder flap *before* making the hysterotomy incision. The round ligaments are divided, and the lateral edges of the peritoneal reflection are dissected downward. If possible, these incisions are extended to encircle the entire placental implantation site that visibly occupies the prevesical space and posterior bladder wall. Following this, a classical hysterotomy incision is made to avoid the placenta and profuse hemorrhage before fetal delivery. Some advocate a transverse fundal incision if the placenta occupies the entire anterior wall (Kotsuji, 2013).

After fetal delivery, the extent of placental invasion is assessed without attempts at manual placental removal. In a report from the United Kingdom, attempts for partial or total placental removal prior to hysterectomy were associated with twice as much blood loss (Fitzpatrick, 2014). Generally speaking, with obvious percreta or increta, hysterectomy is usually the best course, and the placenta is left in situ. As discussed in Chapter 36 (p. 670), a focal partial accreta may avulse easily and later emerge as a placental polyp (Benirschke, 2012). With more extensive placental ingrowth—even with total accreta—there may be little or no bleeding until manual placental removal is attempted. Unless there is spontaneous separation with bleeding that mandates emergency hysterectomy, the operation begins after full assessment is made. With bleeding, successful treatment depends on immediate blood replacement therapy and other measures that include uterine or internal iliac artery ligation, balloon occlusion, or embolization. Various case reports have described argon beam coagulation and hemostatic combat gauze (Karam, 2003; Schmid, 2012).

Leaving the Placenta in Situ. In a few cases, after the fetus has been delivered, it may be possible to trim the umbilical cord and repair the hysterotomy incision but leave the placenta in situ. This may be wise for women in whom abnormal placentation was not suspected before cesarean delivery and in whom uterine closure stops bleeding. After this, she can be transferred to a higher-level facility for definitive management. Another consideration is the woman with a strong desire for fertility and who has received extensive counseling. In some cases, the placenta spontaneously resorbs. In others, a subsequent hysterectomy—either planned or prompted by bleeding or infection—is performed weeks postpartum when blood loss might be lessened (Hays, 2008; Kayem, 2002; Lee, 2008; Timmermans, 2007). Of 26 women treated this way, 21 percent ultimately required hysterectomy. Of the remainder, most required additional medical and surgical interventions for bleeding and infection (Bretelle, 2007). Evidence that

treatment with methotrexate aids resorption is lacking. We agree with the American College of Obstetricians and Gynecologists (2012b) that this method of management is seldom indicated. For women in whom the placenta is left in situ, serial serum β -hCG measurements are not informative, and serial sonographic or MR imaging is recommended (Timmermans, 2007; Worley, 2008).

Pregnancy Outcomes

Reports describing outcomes with accrete syndromes have limited numbers of patients. That said, two large series provide data from which some basic observations can be made. First, these syndromes can have disastrous outcomes for both mother and fetus. Although the depth of placental invasion does not correspond with perinatal outcome, it is of paramount maternal significance (Seet, 2012). Shown in Table 41-5 are outcomes from three reports of women from tertiary-care hospitals and in whom the diagnosis of accrete placenta was made preoperatively. Despite these advantages, a litany of complications included hemorrhage, urinary tract injury, ICU admission, and secondary surgical procedures. These reports chronicled outcomes in a second cohort of women in whom care was not given at a tertiary-care facility or in whom the diagnosis of accrete placenta was not made until delivery, or both. In these cohorts, morbidity was higher, and there was one maternal death.

Second, in the Utah experiences, attempts at placental removal increased morbidity significantly—67 versus 36 percent—compared with no attempts at removal before hysterectomy. They also found that preoperative bilateral ureteral stenting reduced morbidity. However, no benefits accrued from internal iliac artery ligation (Eller, 2011; Po, 2012). Our management at

Parkland Hospital is similar, however, the final decision for hysterectomy is not made until assessment at delivery. Also, we do not routinely perform preoperative ureteral stent placement. We have at times inserted stents transvesically if indicated intraoperatively. As discussed on page 820, preoperative arterial catheterization may be beneficial (Desai, 2012).

Subsequent Pregnancy

There is some evidence that women with accrete syndromes have an increased risks for recurrence, uterine rupture, hysterectomy, and previa (Eshkoli, 2013).

CONSUMPTIVE COAGULOPATHY

Obstetrical syndromes commonly termed *consumptive coagulopathy* or *disseminated intravascular coagulation (DIC)* were described in the 1901 report by DeLee in which “temporary hemophilia” developed with placental abruption or with a long-dead macerated fetus. In ensuing decades, similar—but frequently less intense—coagulopathic syndromes have been described for almost all areas of medicine (Levi, 2010b; Montagnana, 2010).

Disseminated Intravascular Coagulation in Pregnancy

Because of many definitions used and its variable severity, citing an accurate incidence for consumptive coagulopathy is not possible in pregnant women. For example, as will be discussed, some degree of significant coagulopathy is found with most cases of placental abruption and amnionic-fluid embolism. Other instances in which frequently occurring but insignificant degrees of coagulation activation can be found include sepsis,

TABLE 41-5. Selected Maternal Outcomes in Women with Accrete Syndromes Identified Prenatally and Delivered in Tertiary-Care Units

Outcome ^a	San Diego ^b n = 62	Utah ^c n = 60	Toronto ^d n = 33

thrombotic microangiopathies, acute kidney injury, and pre-eclampsia and HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndromes (Rattray, 2012; Su, 2012). Although profound consumptive coagulopathy can be associated with fatty liver disease of pregnancy, diminished hepatic synthesis of procoagulants makes a significant contribution (Nelson, 2013).

When consumptive coagulopathy is severe, the likelihood of maternal and perinatal morbidity and mortality is increased. Rattray and colleagues (2012) described 49 cases from Nova Scotia during a 30-year period. Antecedent causes included placental abruption, obstetrical hemorrhage, preeclampsia and HELLP syndromes, acute fatty liver, sepsis, and amniotic fluid embolism. Of these, 59 percent received blood transfusions, 18 percent underwent hysterectomy, 6 percent were dialyzed, and there were three maternal deaths. The perinatal mortality rate was 30 percent.

Pregnancy-Induced Coagulation Changes

Several changes in coagulation and fibrinolysis can be documented during normal pregnancy. Some of these include appreciable increases in the plasma concentrations of factors I (fibrinogen), VII, VIII, IX, and X. A partial list of these normal values can be found in the Appendix (p. 1288) and in Chapter 4 (p. 57). At the same time, plasminogen levels are increased considerably, but levels of plasminogen activator inhibitor-1 and -2 (PAI-1 and PAI-2) also increase. Thus, *plasmin activity* usually decreases until after delivery (Hale, 2012; Hui, 2012).

The mean platelet count decreases by 10 percent during pregnancy, and there is increased platelet activation (Kenny, 2014).

The net results of these changes include increased levels of fibrinopeptide A, β -thromboglobulin, platelet factor 4, and fibrinogen-fibrin degradation products, which includes D-dimers. Along with decreased concentrations of anticoagulant protein S, hypercoagulability, and decreased fibrinolysis, there is augmented—yet compensated—intravascular coagulation that may function to maintain the uteroplacental interface.

Pathological Activation of Coagulation

Normal coagulation and fibrinolysis can be pathologically activated via two pathways. The *extrinsic pathway* is active by thromboplastin from tissue destruction, whereas the *intrinsic pathway* is initiated by collagen and other tissue components that become exposed with loss of endothelial integrity (Fig. 41-30). Tissue factor III is an integral membrane protein. It is released by endothelial cells to complex with factor VII, which in turn activates tenase (factor IX) and prothrombinase (factor X) complexes. Uncontrolled thrombin generation converts fibrinogen to fibrin, which polymerizes to deposit in small vessels of virtually every organ system. This seldom causes organ failure, because these vessels are protected by enhanced fibrinolysis stimulated by fibrin monomers released by coagulation. These monomers combine with tissue plasminogen activator and plasminogen to release plasmin, which lyses fibrinogen and fibrin monomers and polymers.

FIGURE 41-30 Mechanisms of coagulation and fibrinolysis.

The products form a series of fibrinogen-fibrin derivatives that are measured by immunoassay. These are the *fibrin degradation products* or *fibrin-split products*, which include *D-dimers* (see Fig. 41-30). There may also be evidence for *microangiopathic hemolysis* from mechanical trauma to the red cell membrane by fibrin strands in small vessels. This is likely a contributing cause of hemolysis in women with preeclampsia and HELLP syndromes (Pritchard, 1976a).

The pathologically activated cycle of coagulation and fibrinolysis becomes clinically important when coagulation factors and platelets are sufficiently depleted to cause bleeding—hence, *consumptive coagulopathy*. Several obstetrical conditions are accompanied by release of potent inciting factors for clinically significant consumptive coagulation. The best known and most common, and therefore most serious, results from thromboplastin release with placental abruption. Also, unique to obstetrics is the immediate and profound coagulation factor depletion that can follow entry of amniotic fluid into the maternal circulation. This causes activation of factor X by abundant mucin in fetal squames. Other causes include activation by release of endotoxins from gram-negative bacteria and exotoxins from gram-positive bacteria.

■ **Diagnosis**

The International Society on Thrombosis and Haemostasis has promulgated a *DIC score* to aid identification and prognosis prediction (Taylor, 2001). This algorithm, shown in Table 41-6, has not been applied in obstetrical conditions but can serve as a rough guideline to identify a pregnant woman with consumptive coagulopathy. Again, although not including obstetrical patients, the Prowess Trial evaluated 840 subjects with severe sepsis. The mortality rate increased from approximately 25 percent with a DIC score of 3 to 70 percent with a score of 7 (Dhainaut, 2004).

TABLE 41-6. Algorithm for Diagnosis of Overt Disseminated Intravascular Coagulation—"DIC Score" ^a	
Factor	Score
Presence of known underlying disorder associated with DIC: no = 0; yes = 2	—
Coagulation tests:	
Platelets: > 100K = 0; < 100K = 1; < 50K = 2	—
D-dimer levels increased: no = 0; moderate = 2; strong = 3	—
PT prolongation (sec): < 3 = 0; > 3 but < 6 = 1; > 6 = 2	—
Fibrinogen (mg/dL): > 100 mg/dL = 0; < 100 mg/dL = 1	—
Total score:	
≥ 5: compatible with overt DIC	
< 5: suggestive of nonovert DIC	—

Evaluation and Management

Obstetrical causes of consumptive coagulopathy are almost always due to an identifiable, underlying pathological process that must be eliminated to halt ongoing defibrination. Thus, prompt identification and removal of the source of the coagulopathy is given priority. With surgical incisions or extensive lacerations accompanied by severe hemorrhage, rapid replacement of procoagulants is usually indicated. Vigorous restoration and maintenance of the circulation to treat hypovolemia cannot be overemphasized. With adequate perfusion, activated coagulation factors, fibrin, and fibrin degradation products are promptly removed by the reticuloendothelial system, along with restoration of hepatic and endothelial synthesis of procoagulants.

Some treatments for intravascular coagulation have been conceived by armchair theorists and are mentioned here only to be condemned. For example, in years past, some recommended heparin administration to block consumption of procoagulants. Others recommended epsilon-aminocaproic acid to inhibit fibrinolysis by blocking plasminogen conversion to plasmin. The dangers of giving heparin to an actively bleeding woman are obvious. Fibrinolysis inhibition is probably not quite as dangerous, but any putative benefits remain unproven.

Identification of Defective Hemostasis. *Bioassay* is an excellent method to detect or suspect clinically significant coagulopathy. *Excessive bleeding at sites of modest trauma characterizes defective hemostasis.* Examples include persistent bleeding from venipuncture sites, nicks from shaving the perineum or abdomen, trauma from bladder catheterization, and spontaneous bleeding from the gums, nose, or gastrointestinal tract. Purpuric areas at pressure sites such as sphygmomanometer cuffs or tourniquets suggest significant thrombocytopenia. As discussed, any surgical procedure provides the ultimate bioassay and elicits generalized oozing from the skin, subcutaneous and fascial tissues, the retroperitoneal space, the episiotomy, or incisions and dissections for cesarean delivery or hysterectomy.

Fibrinogen and Degradation Products. In late pregnancy, plasma fibrinogen levels typically have increased to 300 to 600 mg/dL. Even with severe consumptive coagulopathy, levels may sometimes be high enough to protect against clinically significant hypofibrinogenemia. For example, defibrination caused by a placental abruption might lower an initial fibrinogen level of 600 mg/dL to 250 mg/dL. Although this would indicate massive fibrinogen consumption, there are still adequate levels to promote clinical coagulation—usually about 150 mg/dL. If serious *hypofibrinogenemia*—less than 50 mg/dL—is present, the clot formed from whole blood in a glass tube may initially be soft but not necessarily remarkably reduced in volume. Then, over the next half hour or so, as platelet-induced clot retraction develops, the clot becomes quite small. When many of the erythrocytes are extruded, the volume of liquid in the tube clearly exceeds that of clot.

Fibrinolysis cleaves fibrin and fibrinogen into various fibrin degradation products that are detected by several sensitive test systems. There are many fragment types, and monoclonal antibodies in assay kits usually measure D-dimers specific for that assay. These values are always abnormally high with clinically

significant consumptive coagulopathy. At least in obstetrical disorders, quantification has not been correlated with outcomes, although “moderate” to “strong” increases constitute part of the diagnostic algorithm shown in Table 41-6.

Thrombocytopenia

Seriously low platelet concentrations are likely if petechiae are abundant or if clotted blood fails to retract within an hour or so. Confirmation is provided by a platelet count. If there is associated severe preeclampsia syndrome, there may also be *qualitative platelet dysfunction* (Chap. 40, p. 738).

Prothrombin and Partial Thromboplastin Times

Prolongation of these standard coagulation tests may result from appreciable reductions in procoagulants essential for generating thrombin, from very low fibrinogen concentrations, or from appreciable amounts of circulating fibrinogen-fibrin degradation products. Prolongation of the prothrombin time and partial thromboplastin time need not be the consequence of consumptive coagulopathy.

Placental Abruptio

This is the most common cause of severe consumptive coagulopathy in obstetrics and is discussed on page 793.

Preeclampsia Syndrome

Endothelial activation or injury is a hallmark of preeclampsia, eclampsia, and HELLP syndrome. In general, the clinical severity of preeclampsia is directly correlated with thrombocytopenia and fibrinogen-fibrin degradation products (Levi, 2010b; Kenny, 2014). That said, intravascular coagulation is seldom clinically worrisome. Delivery reverses these changes, and treatment until then is supportive. These syndromes are discussed in detail in Chapter 40.

Fetal Death and Delayed Delivery

Consumptive coagulopathy associated with prolonged retention of a dead fetus is unusual today because fetal death can be easily confirmed and there are highly effective methods for labor induction. Currently, the syndrome is only occasionally encountered when there is one dead twin fetus and an ongoing pregnancy. With singleton pregnancies, if the dead fetus is undelivered, most women enter spontaneous labor within 2 weeks. Gross disruption of maternal coagulation rarely develops before 4 weeks (Pritchard, 1959, 1973). After 1 month, however, almost a fourth will develop consumptive coagulopathy.

The pathogenesis of coagulopathy appears to be mediated by thromboplastin released by the dead fetus and the placenta (Jimenez, 1968; Lerner, 1967). Typically, the fibrinogen concentration falls during 6 weeks or more to levels that are normal for nonpregnant adults, but in some cases, this declines to < 100 mg/dL. Simultaneously, fibrin degradation product and D-dimer levels become elevated in serum, and moderate thrombocytopenia develops (Pritchard, 1973). If enough time elapses to seal the placental-decidual interface, these coagulation defects may correct spontaneously before evacuation (Pritchard, 1959).

Discordant Fetal Death in Multifetal Gestation

Obvious coagulation derangement occasionally develops in a multifetal pregnancy in which there is at least one fetal death and survival of another (Chescheir, 1988; Landy, 1989). This situation is uncommon, and in one study of 22 such pregnancies, none developed a coagulopathy (Petersen, 1999). Most cases are seen in monochorionic twins with shared circulations, which are described in Chapter 45 (p. 904). The course in such a woman cared for at Parkland Hospital is shown in Figure 41-31. In this case, the coagulopathy ceased spontaneously, and the surviving healthy twin was delivered near term. The placenta of the long-dead fetus was filled with fibrin.

A

B

FIGURE 41-31 A. Following the confirmed death of one twin at 28 weeks' gestation, serial studies demonstrated decreasing plasma fibrinogen concentrations and elevated serum fibrin-degradation products that reached a nadir 4 weeks later. After this, fibrinogen concentrations increased and fibrin degradation product levels decreased in mirror-like fashion. B. When delivered at 36 weeks, the fibrin-filled placenta (clear arrow) of the long-dead fetus (asterisk) is apparent. The liveborn cotwin was healthy and had normal coagulation studies and a normal-appearing placenta (blue arrow).

Amnionic-Fluid Embolism

This uniquely obstetrical syndrome was described in 1941 by Steiner and Lushbaugh and became classically characterized by the abrupt onset of hypotension, hypoxia, and severe consumptive coagulopathy. Even so, amnionic-fluid embolism has great individual variation in its clinical manifestation. For example, only one of these three clinical hallmarks predominates in some affected women.

Despite variations in the reported incidence of this uncommon but extremely important complication, many reports describe a similar frequency. A study that included 3 million births in the United States cited an estimated frequency of 7.7 cases per 100,000 births (Abenhaim, 2008). The United Kingdom Obstetric Surveillance System reported an incidence of 2.0 per 100,000 births (Knight, 2010). And review of more than 4 million births in Canada yielded an incidence of 2.5 per 100,000 births (Kramer, 2012). Another review of data from five high-resource countries cites frequencies from 1.9 to 6.1 per 100,000 deliveries. The case-fatality rates in all of these studies ranged from 11 to 43 percent. From another perspective, amnionic-fluid embolism was the cause of 10 to 15 percent of all pregnancy-related deaths in the United States and Canada (Berg, 2003; 2010; Clark, 2008; Kramer, 2012).

Predisposing conditions are rapid labor, meconium-stained amnionic fluid, and tears into uterine and other large pelvic veins. Other risk factors commonly cited include older maternal age; postterm pregnancy; labor induction or augmentation; eclampsia; cesarean, forceps, or vacuum delivery; placental abruption or previa; and hydramnios (Knight, 2010, 2012; Kramer, 2012). The association of uterine hypertonus appears to be the *effect* rather than the *cause* of amnionic-fluid embolism. This is likely because uterine blood flow ceases when intrauterine pressures exceed 35 to 40 mm Hg. Thus, a hypertonic contraction would be the *least* likely circumstance for amnionic fluid and other debris to enter uterine veins (Clark, 1995). Because of this, there is also no association between this disorder and hypertonus from oxytocin.

In obvious cases of amnionic-fluid embolism, the clinical picture is unquestionably dramatic. The classic example is that of a woman in the late stages of labor or immediately postpartum

who begins gasping for air and then rapidly suffers seizures or cardiorespiratory arrest complicated by massive hemorrhage from consumptive coagulopathy. It has become apparent that there is a variation in the clinical manifestations of this condition. For example, we and others have managed several women in whom otherwise uncomplicated vaginal or cesarean delivery was followed by severe acute consumptive coagulopathy without overt cardiorespiratory difficulties. In those women, consumptive coagulopathy appears to be the *forme fruste* of amnionic-fluid embolism (Kramer, 2012; Porter, 1996).

Etiopathogenesis

Some amnionic fluid commonly enters the maternal circulation at the time of normal delivery through a minor breach in the physiological barrier between maternal and fetal compartments. Thus, it is fortunate that infused amnionic fluid is generally innocuous, even in large amounts (Adamsons, 1971; Stolte, 1967). At delivery, squames, other cellular elements of fetal origin, and trophoblasts can be identified in maternal peripheral blood (Clark, 1986; Lee, 1986). These are presumed to enter venous channels from the placental implantation site or from small lacerations that inevitably develop in the lower uterine segment or cervix with delivery. Although these events are usually innocuous, amnionic fluid constituents in some women initiate a complex series of pathophysiological sequelae shown in Table 41-7. The wide range of clinical manifestations underscores the subjective nature of diagnosis of many of these women.

Considering the wide spectrum of cardiovascular pathophysiological aberrations and sometimes profound coagulopathy, one can reasonably conclude that amnionic fluid and its constituents have a multitude of actions. For example, tissue factor in amnionic fluid presumably activates factor X to incite coagulation (Ecker, 2012; Levi, 2013). Others that have been described include endothelin-1 expressed by fetal squames, phosphatidylserine expressed by amnion, and complement activators (Khong, 1998; Zhou, 2009). An anaphylactoid reaction with complement activation has been postulated because serum levels of tryptase and histamine are also elevated (Benson, 2001; Clark, 1995).

TABLE 41-7. Clinical Findings in 204 Women with Amnionic-Fluid Embolism

Clinical Findings	Clark (1995) n = 46	Weiwen (2000) n = 38	Kramer (2012) n = 120	Aggregate (%)
Hypotension	43	38	39	~60
Fetal distress	30/30	NS	NS	> 90
Pulmonary edema or ARDS	28/30	11	~44	~45
Cardiopulmonary arrest	40	38	56	~65
Cyanosis	38	38	NS	~90
Coagulopathy	38	12/16	36	~50
Dyspnea	22/45	38	~17	~75
Seizure	22	6	2	~15

Author data presents number of affected women. Denominators reflect circumstances in which the whole cohort was not evaluated for a particular finding.
ARDS = acute respiratory distress syndrome; NS = not stated.

Pathophysiology

Animal studies in primates and goats have provided important insights into central hemodynamic aberrations caused by amniotic fluid infused intravenously (Adamsons, 1971; Hankins, 1993). In general, evidence for fetal debris embolization and toxicity increases with the volume infused and the amount of meconium contamination (Hankins, 2002). If a response is evoked, its initial phase consists of pulmonary and systemic hypertension. A similar response was reported in a woman in whom transesophageal echocardiography was performed within minutes of collapse. Findings included a massively dilated akinetic right ventricle and a small, vigorously contracting, cavity-obiterated left ventricle (Stanten, 2003). Profound oxygen desaturation is often seen in the initial phase, and this is the cause of neurological injury in most survivors (Harvey, 1996). All of these observations are consistent with failure to transfer blood from the right to the left heart because of severe and unrelenting pulmonary vasoconstriction. This initial phase is probably followed by decreased systemic vascular resistance and diminished cardiac output (Clark, 1988). Women who survive beyond these first two phases invariably have a consumptive coagulopathy and usually lung and brain injury.

Postmortem Findings. Histopathological findings may be dramatic in fatal cases of amniotic-fluid embolism such as the one shown in Figure 41-32. The detection of such debris, however, may require special staining, and even then, it may not be seen. In one study, fetal elements were detected in 75 percent of autopsies and in 50 percent of specimens prepared from concentrated buffy coat aspirates taken antemortem from a pulmonary artery catheter (Clark, 1995). Several other studies, however, have demonstrated that fetal squamous cells, trophoblasts, and other debris of fetal origin may commonly be found in the central circulation of women with conditions other than amniotic-fluid embolism. Thus, the diagnosis is generally made by identifying clinically characteristic signs and symptoms and excluding other causes.

Management and Clinical Outcomes

Immediate resuscitative actions are necessary to interdict the high mortality rate. As discussed, the initial period of systemic and pulmonary hypertension that frequently heralds amniotic-fluid embolism is transient. Tracheal intubation, cardiopulmonary resuscitation, and other supportive measures must be instituted without delay. Treatment is directed at oxygenation and support of the failing myocardium, along with circulatory support that includes rapid blood and component replacement. That said, there are no data indicating that any type of intervention improves maternal or fetal prognosis. In undelivered women undergoing cardiopulmonary resuscitation, consideration should be given to emergency cesarean delivery to perhaps optimize these efforts and improve newborn outcome. Decision making for perimortem cesarean delivery is more complex in a woman who is hemodynamically unstable but who has not suffered cardiac arrest (Chap. 47, p. 956).

A

B

FIGURE 41-32 Fatal amniotic-fluid embolism. **A.** Lung findings at autopsy: fetal squames (arrows) packed into a small pulmonary artery. Most of the empty spaces within the vessel were demonstrated by special lipid stains to be filled with vernix caseosa. **B.** Laboratory findings from the same woman demonstrated acute defibrination with decreased levels of fibrinogen and platelets along with increased levels of fibrinogen-fibrin degradation products.

Most reports describe dismal outcomes with amniotic-fluid embolism. However, this is likely influenced by underdiagnosis and reporting biases that favor the most severe cases, which are recognized but also have the greatest mortality rates. Several reports are illustrative. From a California database of 1.1 million deliveries, there was a 60-percent mortality rate with amniotic-fluid embolism (Gilbert, 1999). In a report from the Suzhou region of China, 90 percent of mothers died (Weiwen, 2000). This latter report emphasizes that death can be amazingly rapid because 12 of the 34 women who died did so within 30 minutes. The mortality rate was less dismal in the largest study from a Canadian database. Of 120 women with an amniotic-fluid embolism, only a fourth died. In many reports, survivors commonly have profound neurological impairment. Clark (1995) observed that only 8 percent of women who lived despite cardiac arrest survived neurologically intact.

As perhaps expected, perinatal outcomes are also poor and are inversely related to the maternal cardiac arrest-to-delivery

interval. Even so, neonatal survival rate is 70 percent, but unfortunately, up to half of survivors suffer residual neurological impairment. In the Canadian study, 28 percent of infants were considered to be asphyxiated at birth (Kramer, 2012).

■ Sepsis Syndrome

Various infections that are accompanied by endo- or exotoxin release can result in sepsis syndrome in pregnant women. Although a feature of this syndrome includes activation of coagulation, seldom does sepsis alone cause massive procoagulant consumption. *Escherichia coli* bacteremia is frequently seen with antepartum pyelonephritis and puerperal infections, however, accompanying consumptive coagulopathy is usually not severe. Some notable exceptions are septicemia associated with puerperal infection or septic abortion caused by exotoxins released from infecting organisms such as group A *Streptococcus pyogenes*, *Staphylococcus aureus*, or *Clostridium perfringens* or *sordellii*. Treatment of sepsis syndrome and septic shock is discussed in Chapter 47 (p. 946).

Purpura Fulminans

This severe—often lethal—form of consumptive coagulopathy is caused by microthrombi in small blood vessels leading to skin necrosis and sometimes vasculitis. Debridement of large areas of skin over the extremities and buttocks frequently requires treatment in a burn unit. Purpura fulminans usually complicates sepsis in women with heterozygous protein C deficiency and low protein C serum levels (Levi, 2010b). Recall that homozygous protein C deficiency results in fatal *neonatal purpura fulminans* (Chap. 52, p. 1031).

■ Abortion

Septic abortion—especially associated with the organisms discussed above—can incite coagulation and worsen hemorrhage, especially with midtrimester abortions. Indeed, sepsis syndrome accompanied by intravascular coagulation accounts for 25 percent of abortion-related deaths (Saraiya, 1999). In the past, especially with illegal abortions, infections with *Clostridium perfringens* were a frequent cause of intense intravascular hemolysis at Parkland Hospital (Pritchard, 1971). More recently, however, septic abortions from infection with *Clostridium sordellii* have emerged as important causes (Chap 18, p. 357).

Second-trimester induced abortions can stimulate intravascular coagulation even in the absence of sepsis. Ben-Ami and associates (2012) described a 1.6-percent incidence in 1249 late second-trimester pregnancies terminated by dilatation and evacuation. Two thirds were done for fetal demise, which may have been contributory to coagulopathy. Another source of intense coagulation is from instillation of hypertonic solutions to effect midtrimester abortions. These are not commonly performed currently for pregnancy terminations (Chap. 18, p. 369). The mechanism is thought to initiate coagulation by thromboplastin release into maternal circulation from placenta, fetus, and the decidua by the necrobiotic effect of the hypertonic solutions (Burkman, 1977).

MANAGEMENT OF HEMORRHAGE

One of the most crucial elements of obstetrical hemorrhage management is recognition of its severity. As discussed on page 781, visual estimation of blood loss, especially when excessive, is notoriously inaccurate, and true blood loss is often two to three times the clinical estimates. Consider also that in obstetrics, part and sometimes even all of the lost blood may be concealed. Estimation is further complicated in that peripartum hemorrhage—when most severe cases are encountered—also includes the pregnancy-induced increased blood volume. If pregnancy hypervolemia is not a factor, then following blood loss of 1000 mL, the hematocrit typically falls only 3 to 5 volume percent within an hour. The hematocrit nadir depends on the speed of resuscitation using infused intravenous crystalloids. *Recall that with abnormally increased acute blood loss, the real-time hematocrit is at its maximum whenever measured in the delivery, operating, or recovery room.*

A prudent rule is that any time blood loss is considered more than average by an experienced team member, then the hematocrit is determined and plans are made for close observation for physiological deterioration. Urine output is one of the most important “vital signs” with which to monitor the woman with obstetrical hemorrhage. Renal blood flow is especially sensitive to changes in blood volume. *Unless diuretic agents are given—and these are seldom indicated with active bleeding—accurately measured urine flow reflects renal perfusion, which in turn reflects perfusion of other vital organs.* Urine flow of at least 30 mL, and preferably 60 mL, per hour or more should be maintained. With potentially serious hemorrhage, an indwelling bladder catheter is inserted to measure hourly urine flow.

■ Hypovolemic Shock

Shock from hemorrhage evolves through several stages. Early in the course of massive bleeding, there are decreases in mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure. Increases in arteriovenous oxygen content difference reflect a relative increase in tissue oxygen extraction, although overall oxygen consumption falls.

Blood flow to capillary beds in various organs is controlled by arterioles. These are resistance vessels that are partially controlled by the central nervous system. However, approximately 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Catecholamine release during hemorrhage causes a generalized increase in venular tone that provides an autotransfusion from this capacitance reservoir (Barber, 1999). This is accompanied by compensatory increases in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. In addition, there is redistribution of cardiac output and blood volume by selective, centrally mediated arteriolar constriction or relaxation—*autoregulation*. Thus, although perfusion to the kidneys, splanchnic beds, muscles, skin, and uterus is diminished, relatively more blood flow is maintained to the heart, brain, and adrenal glands.

When the blood volume deficit exceeds approximately 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. Importantly, additional small losses of blood will now cause rapid clinical deterioration. Following an initial increased *total oxygen extraction* by maternal tissue, maldistribution of blood flow results in *local* tissue hypoxia and metabolic acidosis. This creates a vicious cycle of vasoconstriction, organ ischemia, and cellular death. Another important clinical effect of hemorrhage is activation of lymphocytes and monocytes, which in turn cause endothelial cell activation and platelet aggregation. These cause release of vasoactive mediators with small vessel occlusion and further impairment of microcirculatory perfusion. Other common obstetrical syndromes—preeclampsia and sepsis—also lead to loss of capillary endothelial integrity, additional loss of intravascular volume into the extracellular space, and platelet aggregation (Chaps. 40, p. 734 and 47, p. 947).

The pathophysiological events just described lead to the important but often overlooked extracellular fluid and electrolyte shifts involved in both the genesis and successful treatment of hypovolemic shock. These include changes in the cellular transport of various ions such as sodium and water into skeletal muscle and potassium loss. Replacement of extracellular fluid and intravascular volume are both necessary. *Survival is enhanced in acute hemorrhagic shock if blood plus crystalloid solution is given compared with blood transfusions alone.*

■ Immediate Management and Resuscitation

Whenever there is suggestion of excessive blood loss in a pregnant woman, steps are simultaneously taken to identify the source of bleeding and to begin resuscitation. If she is undelivered, restoration of blood volume is beneficial to mother and fetus, and it also prepares for emergent delivery. If she is postpartum, it is essential to immediately identify uterine atony, retained placental fragments, or genital tract lacerations. At least one and preferably more large-bore intravenous infusion systems are established promptly with rapid administration of crystalloid solutions, while blood is made available. An operating room, surgical team, and anesthesia providers are assembled immediately. Specific management of hemorrhage is further dependent on its etiology. For example, antepartum bleeding from placenta previa is approached somewhat differently than that from postpartum atony.

Fluid Resuscitation

It cannot be overemphasized that treatment of serious hemorrhage demands prompt and adequate refilling of the intravascular compartment with crystalloid solutions. These rapidly equilibrate into the extravascular space, and only 20 percent of crystalloid remains intravascularly in critically ill patients after 1 hour (Zuckerbraun, 2010). Because of this, initial fluid is infused in a volume three times the estimated blood loss.

Resuscitation of hypovolemic shock with colloid versus crystalloid solutions is debated. In a Cochrane review of resuscitation of nonpregnant critically ill patients, Perel and

Roberts (2007) found equivalent benefits but concluded that colloid solutions were more expensive. Similar results were found in the Saline versus Albumin Fluid Evaluation (SAFE) randomized trial of almost 7000 nonpregnant patients (Finfer, 2004). We concur with Zuckerbraun and colleagues (2010) that acute volume resuscitation is preferably done with crystalloid and blood.

Blood Replacement

There is considerable debate regarding the hematocrit level or hemoglobin concentration that mandates blood transfusion. Cardiac output does not substantively decrease until the hemoglobin concentration falls to approximately 7 g/dL or hematocrit of 20 volume percent. At this level the Society of Thoracic Surgeons (2011) recommends consideration for red-cell transfusions. Also, Military Combat Trauma Units in Iraq used a target hematocrit of 21 volume percent (Barbieri, 2007). In general, with *ongoing* obstetrical hemorrhage, we recommend rapid blood infusion when the hematocrit is < 25 volume percent. This decision is dependent on whether the fetus has been delivered, surgery is imminent or ongoing operative blood loss is expected, or acute hypoxia, vascular collapse, or other factors are present.

Scant clinical data elucidate these issues. In a study from the Canadian Critical Care Trials Group, nonpregnant patients were randomly assigned to restrictive red cell transfusions to maintain hemoglobin concentration > 7 g/dL or to liberal transfusions to maintain the hemoglobin level at 10 to 12 g/dL. The 30-day mortality rate was similar—19 versus 23 percent in the restrictive versus liberal groups, respectively (Hebert, 1999). In a subanalysis of patients who were less ill, the 30-day mortality rate was significantly lower in the restrictive group—9 versus 26 percent. In a study of women who had suffered postpartum hemorrhage and who were now isovolemic and not actively bleeding, there were no benefits of red cell transfusions when the hematocrit was between 18 and 25 volume percent (Morrison, 1991). *The number of units transfused in a given woman to reach a target hematocrit depends on her body mass and on expectations of additional blood loss.*

Blood Component Products. Contents and effects of transfusion of various blood components are shown in [Table 41-8](#). *Compatible whole blood is ideal for treatment of hypovolemia from catastrophic hemorrhage.* It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Whole blood replaces many coagulation factors—which is important in obstetrics—especially fibrinogen—and its plasma treats hypovolemia. A collateral derivative is that women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components (Shaz, 2009).

There are reports that support the preferable use of whole blood for massive hemorrhage, including our experiences at Parkland Hospital (Alexander, 2009; Hernandez, 2012). Of more than 66,000 deliveries, women with obstetrical hemorrhage treated with whole blood had significantly decreased incidences of renal failure, acute respiratory distress syndrome,

TABLE 41-8. Blood Products Commonly Transfused in Obstetrical Hemorrhage

Product	Volume per Unit	Contents per Unit	Effect on Hemorrhage
Whole blood	About 500 mL; Hct ~ 40 percent	RBCs, plasma, 600–700 mg fibrinogen, no platelets	Restores blood volume and fibrinogen, increases Hct 3–4 volume percent per unit
Packed RBCs	About 250–300 mL; Hct ~ 55–80 percent	RBCs, minimal fibrinogen, no platelets	Increases Hct 3–4 volume percent per unit
Fresh-frozen plasma (FFP)	About 250 mL; 30-minute thaw	Colloid, 600–700 mg fibrinogen, no platelets	Restores circulating volume and fibrinogen
Cryoprecipitate	About 15 mL, frozen	One unit ~ 200 mg fibrinogen, other clotting factors, no platelets	15–20 units or about 3–4 g will increase baseline fibrinogen ~150 mg/dL
Platelets	About 50 mL, stored at room temperature	One unit raises platelet count about 5000/ μ L; single-donor apheresis bag preferable	6–10 units transfused: single-donor bag preferable to raise platelets ~30,000/ μ L

Hct = hematocrit; RBCs = red blood cells.

pulmonary edema, hypofibrinogenemia, ICU admissions, and maternal death compared with those given packed red cells and component therapy. Freshly donated whole blood has also been used successfully for life-threatening massive hemorrhage at combat support hospitals in Iraq (Spinella, 2008).

It is problematic that in most institutions today, whole blood is rarely available. Thus, most women with obstetrical hemorrhage and ongoing massive blood loss are given packed red cells and crystalloid in 2:1 or 3:1 proportions. In these instances, there are no data to support a 1:1 red cell:plasma transfusion ratio. Many institutions use *massive transfusion protocols* designed to anticipate all facets of obstetrical hemorrhage defined as massive. These “recipes” commonly contain a combination of red cells, plasma, cryoprecipitate, and platelets (Pacheco, 2011; Shields, 2011). If time permits, we usually prefer to await results of emergently performed hematological laboratory assessments to treat deficiencies of fibrinogen or platelets. If time does not permit this, however, the massive transfusion protocol is activated.

Dilutional Coagulopathy. A major drawback of treatment for massive hemorrhage with crystalloid solutions and packed red blood cells is depletion of platelets and clotting factors. As discussed on page 808, this can lead to a dilutional coagulopathy clinically indistinguishable from disseminated intravascular coagulation (Hossain, 2013). In some cases, impaired hemostasis further contributes to blood loss.

Thrombocytopenia is the most frequent coagulation defect found with blood loss and multiple transfusions (Counts, 1979). In addition, packed red cells have very small amounts of soluble clotting factors, and stored whole blood is deficient in platelets and in factors V, VIII, and XI. Massive replacement with red cells only and without factor replacement can also cause *hypofibrinogenemia* and prolongation of the prothrombin and partial thromboplastin times. Because many causes of obstetrical hemorrhage also cause consumptive coagulopathy, the distinction between dilutional and consumptive coagulopathy can be confusing. Fortunately, treatment for both is similar.

A few studies have assessed the relationship between massive transfusion and resultant coagulopathy in civilian trauma units and military combat hospitals (Bochicchio, 2008; Borgman, 2007; Gonzalez, 2007; Johansson, 2007). Patients undergoing massive transfusion—defined as 10 or more units of blood—had much higher survival rates as the ratio of plasma to red cell units was near 1.4, that is, one unit of plasma given for each 1.4 units of packed red cells. By way of contrast, the highest mortality group had a 1:8 ratio. *Most of these studies found that component replacement is rarely necessary with acute replacement of 5 to 10 units of packed red cells.*

From the foregoing, when red cell replacement exceeds five units or so, a reasonable practice is to evaluate the platelet count, clotting studies, and plasma fibrinogen concentration. In the woman with obstetrical hemorrhage, the platelet count should be maintained above 50,000/ μ L by the infusion of platelet concentrates. A fibrinogen level < 100 mg/dL or a sufficiently prolonged prothrombin or partial thromboplastin time in a woman with surgical bleeding is an indication for replacement. Fresh-frozen plasma is administered in doses of 10 to 15 mL/kg, or alternatively, cryoprecipitate is infused (see Table 41-8).

Type and Screen versus Crossmatch. A blood type and antibody screen should be performed for any woman at significant risk for hemorrhage. Screening involves mixing maternal serum with standard reagent red cells that carry antigens to which most of the common clinically significant antibodies react. Crossmatching involves the use of actual donor erythrocytes rather than the standardized red cells. Clinical results show that the type-and-screen procedure is amazingly efficient. Indeed, only 0.03 to 0.07 percent of patients identified to have no antibodies are subsequently found to have antibodies by crossmatch (Boral, 1979). *Importantly, administration of screened blood rarely results in adverse clinical sequelae.*

Packed Red Blood Cells. One unit of packed erythrocytes is derived from one unit of whole blood to have a hematocrit of 55 to 80 volume percent, depending on the length of gentle centrifugation. Thus one unit contains the same volume

of erythrocytes as one whole blood unit. It will increase the hematocrit by 3 to 4 volume percent depending on patient size. *Packed red blood cell and crystalloid infusion are the mainstays of transfusion therapy for most cases of obstetrical hemorrhage.*

Platelets. With operative delivery or with lacerations, platelet transfusions are considered with ongoing obstetrical hemorrhage when the platelet count falls below 50,000/ μ L (Kenny, 2014). In the *nonsurgical patient*, bleeding is rarely encountered if the platelet count is 10,000/ μ L or higher (Murphy, 2010). The preferable source of platelets is a bag obtained by single-donor apheresis. This is the equivalent of six units from six individual donors. Depending on maternal size, each single-donor apheresis bag raises the platelet count by approximately 20,000/ μ L (Schlichter, 2010). If these bags are not available, then individual-donor platelet units are used. One unit contains about 5.5×10^{10} platelets, and six to eight such units are generally transfused.

Importantly, the donor plasma in platelet units must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only units from D-negative donors should be given to D-negative recipients. If necessary, however, adverse sequelae are unlikely. For example, transfusion of ABO-nonidentical platelets in nonpregnant patients undergoing cardiovascular surgery had no clinical effects (Lin, 2002).

Fresh-Frozen Plasma. This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for frozen plasma to thaw. It is a source of all stable and labile clotting factors, including fibrinogen. Thus, it is often used for treatment of women with consumptive or dilutional coagulopathy. *Plasma is not appropriate for use as a volume expander in the absence of specific clotting factor deficiencies.* It should be considered in a bleeding woman with a fibrinogen level < 100 mg/dL or with an abnormal prothrombin or partial thromboplastin time.

An alternative to frozen plasma is *liquid plasma (LQP)*. This never-frozen plasma is stored at 1 to 6°C for up to 26 days, and in vitro, it appears to be superior to thawed plasma (Matijevic, 2013).

Cryoprecipitate and Fibrinogen Concentrate. Each unit of cryoprecipitate is prepared from one unit of fresh-frozen plasma. Each 10- to 15-mL unit contains at least 200 mg of fibrinogen, factor VIII:C, factor VIII: von Willebrand factor, factor XIII, and fibronectin (American Association of Blood Banks, 2002). It is usually given as a “pool” or “bag” using an aliquot of fibrinogen concentrate taken from 8 to 120 donors. Cryoprecipitate is an ideal source of fibrinogen when levels are dangerously low and there is oozing from surgical incisions. Another alternative is virus-inactivated fibrinogen concentrate. Each gram of this raises the plasma fibrinogen level approximately 40 mg/dL (Ahmed, 2012; Kikuchi, 2013). Either is used to replace fibrinogen. However, there are no advantages to these compared with fresh-frozen plasma for general clotting factor replacement. Exceptions are general factor deficiency replacement for women in whom volume overload may be a problem—an unusual situation in obstetrics—and for those with a specific factor deficiency.

Recombinant Activated Factor VII (rFVIIa). This synthetic vitamin K-dependent protein is available as *NovoSeven*. It binds to exposed tissue factor at the site of injury to generate thrombin that activates platelets and the coagulation cascade. Since its introduction, rFVIIa has been used to help control hemorrhage from surgery, trauma, and many other causes (Mannucci, 2007). More than three fourths of Level I trauma centers include it in their massive transfusion protocols (Pacheco, 2011). It is included in the massive transfusion protocol at Parkland Hospital.

One major concern with rFVIIa use is arterial—and to a lesser degree venous—thrombosis. In a review of 35 randomized trials with nearly 4500 subjects, arterial thromboembolism developed in 55 percent (Levi, 2010a). A second concern is that it was found to be only marginally effective in most of these studies (Pacheco, 2011). In obstetrics, recombinant FVIIa has also been used to control severe hemorrhage in women with and without hemophilia (Alfirevic, 2007; Franchini, 2007). It has been used with uterine atony, lacerations, and placental abruption or previa. In approximately a third of cases, hysterectomy was required. Importantly, rFVIIa will not be effective if the plasma fibrinogen level is < 50 mg/dL or the platelet count is < 30,000/ μ L.

Topical Hemostatic Agents. Several agents can be used to control persistent oozing. These were recently reviewed by dos Santos and Menzin (2012). In general, these are rarely used in obstetrical hemorrhage.

Autologous Transfusion. Patient phlebotomy and autologous blood storage for transfusion has been disappointing. Exceptions are women with a rare blood type or with unusual antibodies. In one report, three fourths of women who began such a program in the third trimester donated only one unit (McVay, 1989). This is further complicated in that the need for transfusion cannot be predicted (Reyal, 2004). For these and other reasons, most have concluded that autologous transfusions are not cost effective (Etchason, 1995; Pacheco, 2011, 2013).

Cell Salvage. To accomplish autotransfusion, blood lost intraoperatively into the surgical field is aspirated and filtered. The red cells are then collected into containers with concentrations similar to packed red cells and are infused as such. Intraoperative blood salvage with reinfusion is considered to be safe in obstetrical patients (Pacheco, 2011; Rainaldi, 1998). That said, Allam and associates (2008) reported the lack of prospective trials but also found no reports of serious complications.

Complications with Transfusions. During the past several decades, substantial advances have been achieved in blood transfusion safety. Although many risks are avoided or mitigated, the most serious known risks that remain include errors leading to ABO-incompatible blood transfusion, transfusion-related acute lung injury (TRALI), and bacterial and viral transmission (Lerner, 2010).

The transfusion of an incompatible blood component may result in acute hemolysis. If severe, this can cause disseminated intravascular coagulation, acute kidney injury, and death. Preventable errors responsible for most of such reactions

frequently include mislabeling of a specimen or transfusing an incorrect patient. Although the rate of such errors in the United States has been estimated to be 1 in 14,000 units, these are likely underreported (Lerner, 2010; Linden, 2001). A transfusion reaction is characterized by fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, provoking diuresis, and alkalinizing the urine. Assays for urine and plasma hemoglobin concentration and an antibody screen help confirm the diagnosis.

The syndrome of *transfusion-related acute lung injury* (TRALI) can be a life-threatening complication. It is characterized by severe dyspnea, hypoxia, and noncardiogenic pulmonary edema that develop within 6 hours of transfusion (Triulzi, 2009). TRALI is estimated to complicate at least 1 in 5000 transfusions. Although the pathogenesis is incompletely understood, injury to the pulmonary capillaries may arise from anti-human leukocyte antigen (HLA) antibodies in donor plasma (Lerner, 2010; Schubert, 2013). These antibodies bind to leukocytes that aggregate in pulmonary capillaries and release inflammatory mediators. A delayed form of TRALI syndrome has been reported to have an onset 6 to 72 hours following transfusion (Marik, 2008). Management is with supportive therapy that may include mechanical ventilation (Chap. 47, p. 944).

Bacterial infection from transfusion of a contaminated blood component is unusual because bacterial growth is discouraged by refrigeration. The most often implicated contaminant of red cells include *Yersinia*, *Pseudomonas*, *Serratia*, *Acinetobacter*, and *Escherichia* species. The more important risk is from bacterial contamination of platelets, which are stored at room temperature. Current estimates are that 1 in 1000 to 2000 platelet units are contaminated. Death from transfusion-related sepsis is 1 per 17,000 for single-donor platelets and 1 per 61,000 for apheresis-donor packs (Lerner, 2010).

Risks from many transfusion-related viral infections have been curtailed. Fortunately, the most feared infection—HIV—is the least common. With current screening methods using nucleic acid amplification, the risk of HIV or hepatitis C virus infection in screened blood is estimated to be 1 case per 1 to 2 million units transfused (Stramer, 2004). The risk for HIV-2 infection is less.

Other viral infections include *hepatitis B* transmission, which is estimated to be < 1 per 100,000 transfused units (Jackson, 2003). Choosing donors who have been vaccinated will lower this incidence. Because of its high prevalence, cytomegalovirus-infected leukocytes are necessarily often transfused. Thus, precautions are taken for immunosuppressed recipients, keeping in mind that this includes the fetus (Chap. 15, p. 310). Finally, there are slight risks for transmitting West Nile virus, human T-lymphotropic virus Type I, and parvovirus B19 (American Association of Blood Banks, 2013).

Red Cell Substitutes. Use of these artificial carriers of oxygen has been abandoned (Ness, 2007; Spiess, 2009). Three that have been studied include perfluorocarbons, liposome-encapsulated hemoglobin, and hemoglobin-based oxygen carriers.

Adjunctive Surgical Procedures to Treat Hemorrhage

Uterine Artery Ligation

Several surgical procedures may be helpful to arrest of obstetrical hemorrhage. Of these, the technique for unilateral or bilateral uterine artery ligation is used primarily for lacerations at the lateral part of a hysterotomy incision (Fig. 41-33). In our experiences, this procedure is less helpful for hemorrhage from uterine atony.

Uterine Compression Sutures. Almost 20 years ago a surgical technique to arrest hemorrhage for severe postpartum atony was introduced by B-Lynch and coworkers (1997). The procedure involves placement of a No. 2-chromic suture to compress the anterior and posterior uterine walls together. Because they give the appearance of suspenders, they are also called *braces* (Fig. 41-34). Several modifications of the B-Lynch technique have been described (Cho, 2000; Hayman, 2002; Matsubara, 2013b; Nelson, 2007). Indications vary for its application, and this will affect the success rate. For example, B-Lynch (2005) cited 948 cases with only seven failures. Conversely, Kayem and associates (2011) described 211 women in whom compression sutures were employed. The overall failure rate of 25 percent did not differ between B-Lynch sutures and their modifications. Our experiences at Parkland Hospital are not nearly so successful. The technique has been effective in perhaps half of cases in which it is used.

FIGURE 41-33 Uterine artery ligation. The suture goes through the lateral uterine wall anteriorly, curves around posteriorly, then re-enters anteriorly. When tied, it encompasses the uterine artery.

FIGURE 41-34 Uterine compression suture or “brace.” The B-Lynch suture technique is illustrated from an anterior view of the uterus in Figures **A**, **B**, and **D** and a posterior view in Figure **C**. The numbers denote the sequential path of the suture and are shown in more than one figure. **Step 1.** Beginning below the incision, the needle pierces the lower uterine segment to enter the uterine cavity. **Step 2.** The needle exits the cavity above the incision. The suture then loops up and around the fundus to the posterior uterine surface. **Step 3.** The needle pierces the posterior uterine wall to reenter the uterine cavity. The suture then traverses from left to right within the cavity. **Step 4.** The needle exits the uterine cavity through the posterior uterine wall. From the back of the uterus, the suture loops up and around the fundus to the front of the uterus. **Step 5.** The needle pierces the myometrium above the incision to reenter the uterine cavity. **Step 6.** The needle exits below the incision and the sutures at points 1 and 6 are tied below the incision. The hysterotomy incision is then closed in the usual fashion.

There are complications with compression sutures, and some are unique (Matsubara, 2013b). Their precise frequency is unknown, but it is likely low. The most common involve variations of uterine ischemic necrosis with peritonitis (Gottlieb, 2008; Joshi, 2004; Ochoa, 2002; Treloar, 2006). Total uterine necrosis was described by Friederich and associates (2007) in a woman in whom B-Lynch sutures were placed along with bilateral ligation of uterine, uteroovarian, and round ligament arteries. In most cases, subsequent pregnancies are uneventful if compression sutures are placed. A few women, however, with B-Lynch or Cho sutures have been reported to have defects in

the uterine wall (Akoury, 2008; An, 2013). Another long-term complication is uterine cavity synechiae, which may develop in 20 to 50 percent of these women by 3 months (Alouini, 2011; Ibrahim, 2013; Poujade, 2011).

Internal Iliac Artery Ligation

Ligation of one or both internal iliac arteries has been used for many years to reduce hemorrhage from pelvic vessels (Allahbadia, 1993; Joshi, 2007). Drawbacks are that the procedure may be technically difficult and is only successful half of the time (American College of Obstetricians and Gynecologists,

FIGURE 41-35 Ligation of the right internal iliac artery. **A.** The peritoneum covering the right iliac vessels is opened and reflected. **B.** Unembalmed cadaveric dissection shows the right-angle clamp passing underneath the anterior division of the internal iliac artery just distal to its posterior division. (Photograph contributed by Dr. Marlene Corton.)

2012b). It is not particularly helpful to abate hemorrhage with postpartum atony (Clark, 1985; Joshi, 2007).

Adequate exposure is obtained by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries (Fig. 41-35). Branches distal to the external iliac arteries are palpated to verify pulsations at or below the inguinal area. Ligation of the internal iliac artery 5 cm distal to the common iliac bifurcation will usually avoid the posterior division branches (Bleich, 2007). The areolar sheath of the artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery from lateral to medial. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture—usually nonabsorbable—is passed under the artery with a clamp, and the vessel is then securely ligated.

Following ligation, pulsations in and distal to the external iliac artery are again confirmed. If not, pulsations must be identified after arterial hypotension has been successfully treated to ensure that the artery has not been compromised. The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts an arterial pressure system into one with pressures approaching those in the venous circulation. This creates vessels more amenable to hemostasis via pressure and clot formation.

Even bilateral internal iliac artery ligation does not appear to interfere with subsequent reproduction. Nizard and colleagues (2003) reported follow-up in 17 women who had bilateral artery ligation. From a total of 21 pregnancies, 13 were normal, three ended with miscarriage, three were terminated, and there were two ectopic pregnancies.

Angiographic Embolization

This tool is now used for many causes of intractable hemorrhage when surgical access is difficult. In more than 500 women reported, embolization was 90-percent effective (Bodner, 2006; Lee, 2012; Poujade, 2012; Sentilhes, 2009). Rouse (2013) recently reviewed the subject and concluded that embolization can be used to arrest refractory postpartum hemorrhage. However, the author cautioned that the procedure is less effective with placenta percreta or with concurrent coagulopathy. Other reports have been less enthusiastic, and the American College of Obstetricians and Gynecologists (2012b) describes its efficacy as “unclear.” Fertility is not impaired, and many subsequent successful pregnancies have been reported (Chauleur, 2008; Fiori, 2009; Kolomeyevskaya, 2009). There are limited data describing its antepartum use. Embolization in a 20-week pregnant woman was reported for a large lower uterine segment arteriovenous malformation (Rebarber, 2009). It has also been used for renal hemorrhage (Wortman, 2013b).

Complications of embolization are relatively uncommon, but they can be severe. Uterine ischemic necrosis has been described (Coulange, 2009; Katakam, 2009; Sentilhes, 2009). Uterine infection has been reported (Nakash, 2012). Finally, Al-Thunyan and coworkers (2012) described a woman with massive buttock necrosis and paraplegia following bilateral internal iliac artery embolization.

Preoperative Pelvic Arterial Catheter Placement

There are a few instances in which massive blood loss and difficult surgical dissection is anticipated. For these, investigators have described use of balloon-tipped catheters inserted into the iliac or uterine arteries preoperatively. Catheters can then

be inflated or embolization performed to mitigate heavy blood loss if it develops (Desai, 2012; Matsubara, 2013a). These techniques are used more commonly in cases of accrete syndromes (p. 804), and they have also been described for abdominal pregnancy (Chap. 19, p. 388). The reported success rates have been variable, and these techniques are not universally recommended (Angstmann, 2012; Pacheco, 2011, 2013; Zacharias, 2003). Again the American College of Obstetricians and Gynecologists (2012b) considers the use and efficacy of these techniques to be “unclear.” Adverse effects are uncommon, but postoperative iliac and popliteal artery thrombosis and stenosis have been reported (Greenberg, 2007; Hoffman, 2010; Sewell, 2006).

Pelvic Umbrella Pack

The *umbrella* or *parachute pack* was described by Logothetopoulos (1926) to arrest intractable pelvic hemorrhage following hysterectomy. Although seldom used today, it can be lifesaving if all other measures have failed. The pack is constructed of a sterile x-ray cassette bag that is filled with gauze rolls knotted together to provide enough volume to fill the pelvis (Fig. 41-36). The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a 1-liter

fluid bag, which is hung over the foot of the bed. An indwelling urinary catheter is placed to prevent urinary obstruction and to monitor urinary output. Percutaneous pelvic drains can be placed to monitor ongoing bleeding within the peritoneal cavity. Broad-spectrum antimicrobials are given, and the umbrella pack is removed vaginally after 24 hours.

Dildy and colleagues (2006) described use of the pelvic pack to arrest hemorrhage following hysterectomy in 11 women. These women were given seven to 77 units of red cells, and the pack successfully stopped bleeding in all but two women. Over the years, we have had mixed results with this technique, but we can recommend it as a “last-ditch” attempt when exsanguination is inevitable, especially in “low-resource” areas.

FIGURE 41-36 Assembly of a pelvic pressure pack to control hemorrhage. A sterile x-ray cassette cover drape (plastic bag) is filled with gauze rolls tied end-to-end. The length of gauze is then folded into a ball (A) and placed within the cassette bag in such a way that the gauze can be unwound eventually with traction on the tail (D). Intravenous tubing (E) is tied to the exiting part of the neck (C) and connected to a 1-liter bag or other suitable weight (F). Once in place, the gauze pack (A) fills the pelvis to tamponade vessels, and the narrow upper neck (B) passes to exit the vagina (C). The IV bag is suspended off the foot of the bed to sustain pressure of the gauze pack on bleeding sites.

Low birthweight defines neonates who are born too small. *Preterm* or *premature births* are terms used to describe neonates who are born too early. With respect to gestational age, a newborn may be preterm, term, or postterm. With respect to size, a newborn may be normally grown and *appropriate for gestational age*; undersized, thus, small for gestational age; or overgrown and consequently, large for gestational age. In recent years, the term *small for gestational age* has been widely used to categorize newborns whose birthweight is usually < 10th percentile for gestational age. Other frequently used terms have included *fetal-growth restriction* or *intrauterine growth restriction*. The term *large for gestational age* has

been widely used to categorize newborns whose birthweight is > 90th percentile for gestational age. The term *appropriate for gestational age* designates newborns whose weight is between the 10th and 90th percentiles.

Thus, infants born before term can be small or large for gestational age but still fit the definition of preterm. *Low birthweight* refers to neonates weighing 1500 to 2500 g; *very low birthweight* refers to those between 500 and 1500 g; and *extremely low birthweight* refers to those between 500 and 1000 g. In 1960, a neonate weighing 1000 g had a 95-percent risk of death. Today, a neonate with the same birthweight has a 95-percent chance of surviving (Ingelfinger, 2007). This remarkable improvement in survival is due to the widespread application of neonatal intensive care in the early 1970s.

DEFINITION OF PRETERM

Up until the 15th edition of this textbook (1976), a *preterm* or *premature infant* was defined by birthweight < 2500 g. Beginning with the 15th edition, preterm infants were those delivered before 37 completed weeks, that is, $\leq 36^{6/7}$ weeks. This definition, which has now been in use for almost 40 years, was first promulgated in 1976 by the World Health Organization (WHO) and the International Federation of Gynecology and Obstetrics (FIGO). This definition was based on a statistical analysis of gestational age distribution at birth (Steer, 2005). It lacks a specific functional basis and should be clearly distinguished from the concept of prematurity. Prematurity represents incomplete development of various organ systems at birth. The lungs are particularly affected, leading to the respiratory distress syndrome.

Beginning in 2005, in recognition that infants born between $34^{0/7}$ weeks and $36^{6/7}$ weeks experience morbidities and mortality characteristic of premature infants, preterm births were subdivided. Those before $33^{6/7}$ weeks are

labeled—*early preterm*, and those occurring between 34 and 36 completed weeks—*late preterm*. Most recently, Spong (2013) observed, “it has become apparent that infants born between 37 weeks 0 days and 38 weeks 6 days gestation experience morbidities that are associated with prematurity compared to births at 39 weeks 0 days through 40 weeks 6 days when infant mortality is lower than at any other time in human gestation.” Those births 37^{0/7} weeks through 38^{6/7} weeks are now defined as *early term* and those 39 weeks 0 days through 40 weeks 6 days are defined as *term*.

In the United States in 2011, 23,910 infants died in their first year of life (Hamilton, 2012). *Preterm birth*, defined as delivery before 37 completed weeks, has been implicated in approximately two thirds of these deaths (Mathews, 2013). As shown in Table 42-1, *late preterm births*, defined as those 34 to 36 weeks’ gestation, comprised approximately 70 percent of all births before 37 completed weeks. The data in Table 42-1 suggest the possibility of redefining births attributed to short gestation to be those before 39 weeks. Surprisingly, 40 percent of live births in the United States in 2009 were associated with a shortened period of gestation when births 39 to 41 weeks are taken as the reference standard. Moreover, these 40 percent of live births with shortened gestation contributed 80 percent of the infant deaths. Another implication of these data is that only 55 percent of births in the United States occurred during the optimal 39 to 41 weeks’ gestation. Put yet another way, only 55 percent of births were “normal” based on infant outcomes. Does this mean that almost half of pregnancies resulting in live births are “abnormal”? Alternatively, perhaps the adjectives “normal” and “abnormal” should be abandoned and replaced with the realization that fetal maturation in humans is a continuum that is completed later in human pregnancy than previously appreciated.

Steer (2005) observed that signs of immaturity at birth and shorter than average gestational length have an unusually high incidence in *Homo sapiens* compared with other mammals. This has been attributed to the development of a narrow pelvis for bipedal gait, coupled with evolution toward a large brain and head that is associated with language and social skill acquisition. It is hypothesized that this combination results in

a relatively high incidence of obstructed labor, which favors an evolutionary trend toward shorter gestation and thus an earlier birth.

As previously noted, if infant mortality rates are used as the outcome of interest, the data in Table 42-1 suggest that optimal pregnancy outcomes vis-à-vis prematurity are achieved at 39 weeks’ gestation. Is the 39-week threshold correct for defining pathologically shortened human gestation? For example, if neonatal death is used as the outcome of interest, delivery at 38^{0/7} through 38^{6/7} weeks is equivalent to delivery at 39 weeks (McIntire, 2008). Similarly, if respiratory morbidity is used as the outcome of interest, 38^{0/7} through 38^{6/7} weeks is equivalent to 39 weeks (Consortium on Safe Labor, 2010). These examples suggest that shortened human gestation with regard to prematurity is birth before 38^{0/7} weeks rather than before 39^{0/7} weeks.

A consequence of defining optimal pregnancy outcomes to occur at 39 weeks has been the concern that some births before 39 weeks may be unnecessary, that is, intentional deliveries not based on medical indications. Indeed, Bailit (2012) observed, “The dangers of delivering a newborn before 39 weeks for non-medical reasons have become increasingly clear.” The evidence that unnecessary deliveries are occurring before 39 weeks in the United States is not robust. Martin (2009b) used birth certificate data to analyze late preterm births between 1990 and 2006. The rate of infants born late preterm increased 20 percent during this time period. Moreover, the percentage of late preterm births for which labor was induced more than doubled between 1990 and 2006, climbing from 7.5 to 17.3 percent. The percentage of late preterm births delivered by cesarean also rose substantially, from 23.5 to 34.3 percent. Such increases in obstetrical interventions inevitably raise the specter of medically unnecessary interventions.

Reddy (2009) used 2001 United States birth certificate data to examine delivery indications for late preterm birth. A total of 23 percent of late preterm births had no recorded indication for delivery. Some of the factors significantly increasing the chance of no recorded indication were older maternal age, non-Hispanic white mother, and ≥ 13 years of education. Factors such as these raised the possibility that patient factors—as opposed to medical factors—were playing a role in late preterm births without a specified medical indication in the birth certificate. But Bailit (2012) has described the complexities of ascertaining the indications for delivery.

In contrast, an analysis of the indications for delivery of 21,771 late preterm births at Parkland Hospital using a research data set showed that 99.8 percent of such births were indicated and that 80 percent were due to idiopathic preterm labor or preterm spontaneously ruptured membranes. Indeed, and as shown in Figure 42-1, medically *indicated* preterm births are largely responsible for the increase in preterm births in the United States.

Undoubtedly, unnecessary obstetrical interventions are occurring before 38 or 39 weeks’ gestation, but the magnitude of this problem is unclear at this time. Caution is urged before assuming that obstetrical interventions before 38 or 39 weeks are unnecessary. For example, Koopmans and colleagues (2009) randomized women with mild preeclampsia or

TABLE 42-1. Infant Mortality Rates in the United States in 2009		
	Live Births No. (%)	Infant Deaths (per 1000 births)
Total infants	4,130,665 (100)	26,408 (6)
Gestational age at birth:		
< 34 weeks	144,961 (4)	15,000 (104)
34–36 weeks	357,345 (9)	2549 (7)
< 37 weeks	502,306 (12)	17,550 (35)
37–38 weeks	1,138,029 (28)	3521 (3)
39–41 weeks	2,256,457 (55)	4474 (2)
≥ 42 weeks	228,588 (6)	654 (3)

gestational hypertension at 36 weeks' gestation to induction of labor versus expectant management. This trial showed that delivery at 37 weeks was better for women and their newborns compared with later delivery. The American College of Obstetricians and Gynecologists (2013b) also recommends caution before withholding indicated intervention.

TRENDS IN PRETERM BIRTH RATES

The percentage of preterm births increased 36 percent from 9.4 percent in 1984 to a high of 12.8 percent in 2006 (Mathews, 2013). Since 2006, however, the trend has reversed, and the percentage of preterm births declined to 11.7 percent in 2011 (Figure 42-2). This decline in the percentage of preterm births occurred for both the early—less than 34 weeks—and later preterm periods (Hamilton, 2012). Although the lowest level in more than a decade, the 2011 preterm birth rate is still higher than rates reported during the 1980s and most of the 1990s.

Is the decrease in preterm births shown in Figure 42-2 real? It could be argued that the decrease since 2006 is a result of changes in the birth certificate that is used to compute United States preterm birth rates. In 2003, a revised birth certificate intended to expand the collection of clinical information was introduced in the United States. Implementation depends on the rapidity with which the various states transitioned to the new version. For example, by 2008, the revised birth certificate had been implemented in 27 states representing 65 percent of

FIGURE 42-2 Preterm and low-birthweight rate: United States, final 1990 to 2010 and preliminary 2011. (Redrawn from Hamilton, 2012.)

all 2008 births (Osterman, 2011). This “trickle in” implementation coincides with the decline in preterm births shown in Figure 42-2.

Importantly, the 2003 version of the birth certificate introduced use of a clinical estimate of gestational age rather than primarily the last menstrual period, which was used in the previous 1989 version of the birth certificate. Joseph and associates (2007) noticed that preterm birth rates were much higher in the United States compared with Canada. This difference, however, was reduced when the United States rate was based on the clinical estimate of gestational age rather than menstrual dating. For example, the preterm birth rate in the United States in 2002 was 12.3 percent if computed using menstrual dating compared with 10.1 percent when a clinical estimate was used. The decrease in preterm births shown in Figure 42-2 from 12.8 percent in 2006 to 11.7 percent in 2011 is well within the range of change to be expected if the change was attributable to the method used for determining gestational age for the 2003 birth certificate.

A disturbing aspect of the trend in preterm birth rates in the United States is the persistence of racial and ethnic disparity (Fig. 42-3). Indeed, 77 percent of the race/ethnicity-related disparity in infant mortality rates in the United States in 2009 was associated with preterm birth (Mathews, 2013). Some investigators attribute this disparity to socioeconomic circumstances (Collins, 2007). Rates of preterm birth in the United States are also higher compared with those in other industrialized countries (Ananth, 2009; Joseph, 2007). For example, the preterm birth rate was 12.3 percent in the United States in 2003 compared with 7.7 percent in Canada. Indeed, similar differences have been noted in the preterm delivery rates between the United States and virtually all the other industrialized countries.

FIGURE 42-3 Preterm births in the United States in 2011 according to maternal race and ethnicity. (Redrawn from Hamilton, 2012.)

MORBIDITY IN PRETERM INFANTS

Various morbidities, largely due to organ system immaturity, are significantly increased in infants born before 37 weeks’ gestation compared with those delivered at term (Table 42-2). For approximately 40 years, complications in infants born before 34 weeks have been the primary focus. Only recently (2005) have *late preterm* infants—34 to 36 weeks—gained attention because of their increased morbidity. Attention has also been given to increasingly small preterm infants—*very low birth-weight* and *extremely low birthweight*. These very small infants suffer disproportionately not only the immediate complications of prematurity but also long-term sequelae such as neurodevelopmental disability. Indeed, live births once considered

“abortuses” because they weighed < 500 g are now classified as live births. Indeed, there were 6331 live births between 400 and 500 g recorded in the United States in 2009 (Martin, 2011). Remarkable strides have been made in neonatal survival for infants born preterm. This is especially true for those born after 28 weeks. Shown in Figure 42-4 are survival rates for more than 18,000 infants born between 400 and 1500 g or between 22 and 32 weeks’ gestation. Importantly, the results are shown as a function of both birthweight *and* gestational age. After achieving a birthweight of ≥ 1000 g or a gestational age of 28 weeks for females or 30 weeks for males, survival rates reach 95 percent.

Resources used to care for low-birthweight infants are a measure of the societal burden of preterm birth. The annual cost of preterm birth in the United States in 2006 was estimated to be \$26.2 billion, or \$51,000 per premature infant (Institute of Medicine, 2007). The economic consequences of preterm birth that reach beyond the newborn period into infancy, adolescence, and adulthood are difficult to estimate. However, they must be enormous when the effects of adult diseases associated with prematurity, such as hypertension and diabetes, are considered.

Mortality and Morbidity at the Extremes of Prematurity

The tremendous advances in the perinatal and neonatal care of the preterm infant have been found predominantly in those infants delivered at ≤ 33 weeks. With survival of increasingly very immature infants in the 1990s, there has been uncertainty and controversy as to the lower limit of fetal maturation compatible with extrauterine survival. This has resulted in continual reassessment of the *threshold of viability*.

TABLE 42-2. Major Short- and Long-Term Problems in Very-Low-Birthweight Infants

Organ or System	Short-Term Problems	Long-Term Problems
Pulmonary	Respiratory distress syndrome, air leak, bronchopulmonary dysplasia, apnea of prematurity	Bronchopulmonary dysplasia, reactive airway disease, asthma
Gastrointestinal or nutritional	Hyperbilirubinemia, feeding intolerance, necrotizing enterocolitis, growth failure	Failure to thrive, short-bowel syndrome, cholestasis
Immunological	Hospital-acquired infection, immune deficiency, perinatal infection	Respiratory syncytial virus infection, bronchiolitis
Central nervous system	Intraventricular hemorrhage, periventricular leukomalacia, hydrocephalus	Cerebral palsy, hydrocephalus, cerebral atrophy, neurodevelopmental delay, hearing loss
Ophthalmological	Retinopathy of prematurity	Blindness, retinal detachment, myopia, strabismus
Cardiovascular	Hypotension, patent ductus arteriosus, pulmonary hypertension	Pulmonary hypertension, hypertension in adulthood
Renal	Water and electrolyte imbalance, acid-base disturbances	Hypertension in adulthood
Hematological	Iatrogenic anemia, need for frequent transfusions, anemia of prematurity	
Endocrinological	Hypoglycemia, transiently low thyroxine levels, cortisol deficiency	Impaired glucose regulation, increased insulin resistance

Data from Eichenwald, 2008.

FIGURE 42-4 Mortality rates by birthweight, gestational age, and gender. The limits of the colored area indicate the upper 95th and lower 5th percentiles of birthweight for each gestational age. The curved lines indicate combinations of birthweight and gestational age with the same estimated probability of mortality from 10 to 90 percent. The gradation of color denotes the change in estimated probability of death. Green indicates infants of lower gestational age and birthweight who are more likely to die, whereas yellow indicates infants of higher gestational age and birthweight who are less likely to die. The methods used underestimate mortality rates in those at 22 and 23 weeks with a birthweight up to 600 g. (Redrawn from Fanaroff, 2007, with permission.)

Threshold of Viability

Births *before* 26 weeks are generally considered at the current threshold of viability, and these preterm infants pose various complex medical, social, and ethical considerations. For example, Sidney Miller is a child who was born at 23 weeks, weighed 615 g, and survived but developed severe physical and mental impairment (Annas, 2004). At age 7 years, she was described as a child who “could not walk, talk, feed herself, or sit up on her own...was legally blind, suffered from severe mental retardation, cerebral palsy, seizures, and spastic quadriparesis in her limbs.” An important issue for her family was the need for a lifetime of medical care estimated to cost tens of millions of dollars.

Infants now considered to be at the threshold of viability are those born at 22, 23, 24, or 25 weeks (American College of Obstetricians and Gynecologists, 2012a,b). These infants have been described as fragile and vulnerable because of their immature organ systems. Moreover, they are at high risk for brain injury from hypoxic-ischemic injury and sepsis. In this setting, hypoxia and sepsis start a cascade of events that lead to brain hemorrhage, white-matter injury that causes periventricular leukomalacia, and poor subsequent brain growth eventuating in neurodevelopmental impairment (Chap. 34, p. 656). Because active brain development normally occurs throughout

the second and third trimesters, those infants born at 22 to 25 weeks are believed especially vulnerable to brain injury.

Until recently, discussion of clinical management and ethical and economic considerations of extremely premature infants were hampered by data compromised by ascertainment bias (American College of Obstetricians and Gynecologists, 2012a,b). For example, the mean survival rate was 45 percent if the denominator was all live births compared with 72 percent if the denominator used was only infants admitted to neonatal intensive care (Guillen, 2011). Another source of ascertainment bias was use of multicenter datasets. There were considerable center differences in obstetrical and early neonatal interventions, particularly at 22 and 23 weeks (Stoll, 2010).

A remarkable report on infants born before 27 weeks was recently published (Serenius, 2013). This report is unique in that it details a national population-based prospective study of all infants born alive or stillborn before 27 weeks in Sweden. This country is a uniform society without extreme poverty, and antenatal care is easily accessible and used by almost 100 percent of mothers. All citizens are covered by health insurance including 480 days of parental leave after childbirth and additional benefits for severely sick children. Active perinatal care in Sweden includes early and free access to specialist perinatal care, centralization of extremely preterm births to

TABLE 42-3. Outcomes at 2½ Years Corrected Age by Gestational Age at Birth in Sweden, 2004–2007

Outcome	Gestational Age (wk)					
	22	23	24	25	26	Total
Liveborn infants (No.)	51	101	144	205	206	707
Survived to 1 year (%)	10	53	67	82	85	70
Percentage with disability ^a at 2½ years corrected age:						
No disability	0	30	34	44	49	42
Mild	40	19	33	29	34	31
Moderate	20	30	21	17	10	16
Severe	40	21	13	10	7	11

^aThe overall rate of disabilities includes performance on the Bayley III assessments, mental development delay, cerebral palsy, and visual and hearing disabilities. Adapted from Serenius, 2013.

level III hospitals, a low threshold to provide life support at birth, and near universal admission of infants born at 23 to 26 weeks for neonatal intensive care. Thus, this report likely describes infant outcomes at the threshold of viability under optimal circumstances.

Shown in Table 42-3 are the survival and disability rates for 707 infants born alive from 22 to 26 weeks between 2004 and 2007 in Sweden. The proportion of children with mild or no disabilities increased from 40 percent at 22 weeks to 83 percent at 26 weeks. Conversely, the number of infants with moderate or severe disabilities decreased with advancing gestational age at birth. Moderate or severe disabilities were found in 31 percent of preterm boys compared with 23 percent of preterm girls. No differences in overall outcomes were noted if singletons and multiple births were compared.

The most recent report from the United States concerning survival and morbidity rates for births at 22 to 26 weeks is from the National Institute of Child Health and Human Development (NICHD) Neonatal Network. This dataset includes 5736 live births delivered between 2003 and 2007 at 20 medical centers across the United States. Rates of survival and survival without morbidity in the neonatal period are shown in Table 42-4.

Cesarean delivery at the threshold of viability is controversial. For example, if the fetus-infant is perceived to be too immature for aggressive support, then cesarean delivery for common indications such as breech presentation or nonreassuring fetal heart rate patterns might be preempted. This aside, national data clearly show a high frequency of cesarean delivery for these small infants (Fig. 42-5). Determining the optimal delivery mode for newborns at the threshold of viability is virtually impossible given that randomizing the delivery route has extreme ethical considerations. That said, retrospective, nonrandomized studies have consistently failed to document a

TABLE 42-4. Survival and Disability Rates for 5736 Live Births Born between 22 and 26 Weeks' Gestation at 20 Medical Centers in the United States During 2003–2007

Outcome	Gestational Age (wk)					
	22	23	24	25	26	
Liveborn infants (No.)	421	871	1370	1498	1576

benefit of cesarean delivery for the extremely preterm fetus (American College of Obstetricians and Gynecologists, 2012a). Reddy (2012) analyzed 2906 singleton live births between 24^{0/7} and 31^{6/7} weeks selected because they were eligible for attempted vaginal birth after excluding those cases with fetal distress, placenta previa, placental abruption, and anomalies. Attempted vaginal delivery for cephalic presenting fetuses had a high success rate (84 percent), and there was no difference in the neonatal mortality rate compared with that with planned cesarean delivery. For breech presentations, however, there was a threefold increased relative risk in mortality when vaginal delivery was attempted. Werner (2013) analyzed 20,231 preterm infants at 24 to 34 weeks born in New York City between 1995 and 2003. Cesarean delivery was not protective against poor outcomes such as neonatal death, intraventricular hemorrhage, seizures, respiratory distress, and subdural hemorrhage.

FIGURE 42-5 United States cesarean delivery rates by birthweight from 1999 to 2000. (Redrawn from Lee, 2006, with permission.)

Threshold of Viability at Parkland Hospital

Policies were developed in conjunction with the Neonatology Service. We must emphasize that the decision not to perform cesarean delivery does not necessarily imply that the fetus is “nonviable” or “written off.” Neonatologists are consulted before delivery, and there is discussion of survival and morbidity with the woman and her family. A neonatologist attends each delivery and determines subsequent management.

From an obstetrical standpoint, all fetal indications for cesarean delivery in more advanced pregnancies are practiced in women at 25 weeks. Cesarean delivery is not offered for fetal indications at 23 weeks. At 24 weeks, cesarean delivery is not offered unless fetal weight is estimated at 750 g or greater. Aggressive obstetrical management is practiced in cases of growth restriction.

Late Preterm Birth

As shown in Figure 42-6, infants between 34 and 36 weeks account for more than 70 percent of all preterm births. These are the fastest increasing and largest proportion of singleton preterm births in the United States (Raju, 2006). Thus, increased attention is being given to determining optimal obstetrical and neonatal management of late preterm birth.

To estimate the risks associated with late preterm births, we analyzed neonatal mortality and morbidity rates at 34, 35, and 36 weeks compared with those of births at term between 1988 and 2005 at Parkland Hospital (McIntire, 2008). We were particularly interested in obstetrical complications during this time, because if modified, rates of late preterm birth can possibly be decreased. Approximately 3 percent of all births during the study period occurred between 24 and 32 weeks, and 9 percent were during the late preterm weeks. Thus, late preterm births accounted for three fourths of all preterm births. Approximately 80 percent of these were due to idiopathic spontaneous preterm labor or prematurely ruptured membranes (Fig. 42-7). Complications such as hypertension or placental accidents were implicated in the other 20 percent of cases.

Neonatal mortality rates were significantly increased in each late preterm week compared with those at 39 weeks as the referent and as shown in Figure 42-8. Similarly, Tomashek (2007)

FIGURE 42-7 Obstetrical complications associated with 21,771 late preterm births at Parkland Hospital. (Adapted from McIntire, 2008.)

analyzed all United States births between 1995 and 2002 and also found higher neonatal mortality rates for late preterm infants. Importantly, indices of neonatal morbidity shown in Table 42-5 are increased in these late preterm infants born at Parkland. Fuchs (2008) reported similar results regarding respiratory morbidity in 722 infants. Specifically, the frequency of respiratory morbidity decreased by approximately 50 percent per week from 34 to 37 completed weeks. Increased rates of adverse neurodevelopment have also been found in late preterm infants compared with term newborns (Petrini, 2009).

These findings suggest that the health-care focus on prematurity should be expanded to include late preterm births. Even so, because approximately 80 percent of these women begin labor spontaneously—similar to births before 34 weeks—attempts to interrupt preterm labor have not been satisfactory. Specifically, the Institute of Medicine (2007) report, *Preterm Birth: Causes, Consequences, and Prevention*, acknowledges that treatment of preterm labor has not prevented preterm

FIGURE 42-6 Distribution in percent of preterm births in the United States for 2004. (Redrawn from Martin, 2006.)

birth. Thus, we are of the view that a national strategy aimed at prevention of late preterm births is unlikely to provide discernible benefit without new developments in the prevention and management of preterm labor. In the meantime, the Maternal-Fetal Medicine Units (MFMU) Network is studying the efficacy of corticosteroids in late preterm births. The American College of Obstetricians and Gynecologists (2013b) has emphasized that intentional late preterm deliveries should occur only when an accepted maternal or fetal indication for delivery exists.

CAUSES OF PRETERM DELIVERY

There are four main direct reasons for preterm births in the United States. These include: (1) spontaneous unexplained preterm labor with intact membranes, (2) idiopathic preterm premature rupture of membranes (PPROM), (3) delivery for maternal or fetal indications, and (4) twins and higher-order multifetal births. Of all preterm births, 30 to 35 percent are indicated, 40 to 45 percent are due to spontaneous preterm labor, and 30 to 35 percent follow preterm membrane rupture (Goldenberg, 2008). Indeed, much of the increase in the singleton preterm birth rate in the United States is explained by rising numbers of indicated preterm births (Ananth, 2005).

Reasons for preterm birth have multiple, often interacting, antecedents and contributing factors. This complexity has greatly confounded efforts to prevent and manage this complication. This is particularly true for preterm ruptured membranes and spontaneous preterm labor, which together lead

to 70 to 80 percent of preterm births. Last, according to data from Martin (2006), approximately one in six preterm births in the United States is from twins or higher-order multifetal pregnancies (Chap. 45, p. 891). For example, in 2004, there were 508,356 preterm births, and of these, 86,116 or 17 percent were from multifetal pregnancies. Many of these pregnancies were achieved using ovulation-inducing drugs and assisted reproductive technologies (ART).

Analogous to other complex disease processes, multiple coexistent genetic alterations and environment may lead to preterm birth (Esplin, 2005; Ward, 2008). There are polymorphisms in genes associated with inflammation and infection and in those associated with collagen turnover (Velez, 2008). Inherited mutations in genes regulating collagen assembly may predispose individuals to cervical insufficiency or prematurely ruptured membranes (Anum, 2009; Wang, 2006; Warren, 2007).

Basic Science of Spontaneous Preterm Labor

For both clinical and research purposes, pregnancies with intact fetal membranes and spontaneous preterm labor must be distinguished from those complicated by preterm prematurely ruptured membranes. Even so, those with spontaneous preterm labor do not constitute a homogeneous group characterized singularly by early initiation of parturition (American College of Obstetricians and Gynecologists, 2012b). This certainly is one reason why preventative therapies and clinical tools to assess the risks for preterm birth have been difficult to identify. Among the more common associated findings are

multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilatation, cervical insufficiency, hydramnios, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness as a result of infections, autoimmune diseases, and gestational hypertension also increases preterm labor risks.

Although there are unique aspects to each cause of preterm labor, these diverse processes culminate in a common end point, which is premature cervical dilatation and effacement and premature activation of uterine contractions. It seems important to emphasize that the actual process of preterm labor should be considered a final step—one that results from progressive or acute changes that could be initiated days or even weeks before labor onset. Indeed, many forms of spontaneous preterm labor that result from premature initiation of phase 2 of parturition may be viewed in this light (Chap. 21, p. 410). Although the end result in preterm birth is the same as at term, namely cervical ripening and myometrial activation, recent studies in animal models support the idea that preterm birth is not always an acceleration of the normal process. Diverse pathways to instigate parturition exist and are dependent on the etiology of preterm birth. Identification of both common and uncommon factors has begun to explain the physiological processes of human parturition at term and preterm. Four major causes of spontaneous preterm labor include uterine distention, maternal–fetal stress, premature cervical changes, and infection.

Uterine Distention

There is no doubt that multifetal pregnancy and hydramnios lead to an increased risk of preterm birth (Chap. 45, p. 913). It is likely that early uterine distention acts to initiate expression of contraction-associated proteins (CAPs) in the myometrium. The *CAP* genes that are influenced by stretch include those coding for gap-junction proteins such as connexin 43, for oxytocin receptors, and for prostaglandin synthase (Korita, 2002; Lyall, 2002; Sooranna, 2004). Recent reports suggest that gastrin-releasing peptides (GRPs) are increased with stretch to promote myometrial contractility and that GRP antagonists can inhibit uterine contractility (Tattershell, 2012). There is also a stretch-induced potassium channel—TREK-1—that is upregulated during gestation and downregulated in labor. This pattern of expression is consistent with a potential role in uterine relaxation during pregnancy (Buxton, 2010). Expression of TREK-1 splice variants that block function of the full-length TREK-1 have been recently identified in myometrium from women with preterm labor. This further implicates a role for TREK-1 in uterine quiescence (Wu, 2012). Although these and other regulatory factors remain to be validated, it is clear that excessive uterine stretch causes premature loss of myometrial quiescence.

Excessive uterine stretch also leads to early activation of the placental–fetal endocrine cascade shown in Figure 21-17 (p. 425). The resulting early rise in maternal corticotropin-releasing hormone and estrogen levels can further enhance the expression of myometrial *CAP* genes (Warren, 1990; Wolfe, 1988). Finally, the influence of uterine stretch should be considered with regard to the cervix. For example, cervical

length is an important risk factor for preterm birth in multifetal pregnancies (Goldenberg, 1996). Prematurely increased stretch and endocrine activity may initiate events that shift the timing of uterine activation, including premature cervical ripening.

Maternal–Fetal Stress

Stress is defined as a condition or adverse circumstance that disturbs the normal physiological or psychological functioning of an individual. But the complexities of measuring “stress” are what cause difficulty in defining its exact role (Lobel, 1994). That said, considerable evidence shows a correlation between some sort of maternal stress and preterm birth (Hedegaard, 1993; Hobel, 2003; Ruiz, 2003). Moreover, there is a correlation between maternal psychological stress and the placental–adrenal endocrine axis that provides a potential mechanism for stress-induced preterm birth (Lockwood, 1999; Petraglia, 2010; Wadhwa, 2001).

As discussed earlier, the last trimester is marked by rising maternal serum levels of placental-derived corticotropin-releasing hormone (CRH). This hormone works with adrenocorticotrophic hormone (ACTH) to increase adult and fetal adrenal steroid hormone production, including the initiation of fetal cortisol biosynthesis. Rising levels of maternal and fetal cortisol further increase placental CRH secretion, which develops a feed-forward endocrine cascade that does not end until delivery (Fig. 21-17, p. 425). Rising levels of CRH further stimulate fetal adrenal dehydroepiandrosterone sulfate (DHEA-S) biosynthesis, which acts as substrate to increase maternal plasma estrogens, particularly estriol.

It has been hypothesized that a premature rise in cortisol and estrogens results in an early loss of uterine quiescence. A number of studies have reported that spontaneous preterm labor is associated with an early rise in maternal CRH levels and that CRH determination may be a useful biomarker for preterm birth risk assessment (Holzman, 2001; McGrath, 2002; McLean, 1995; Moawad, 2002). Because of large variations in CRH levels among pregnant women, however, a single CRH measurement has low sensitivity (Leung, 2001; McGrath, 2002). It may be that the *rate of increase* in maternal CRH levels is possibly a more accurate predictor of preterm birth. Confounding factors include CRH variability among ethnic groups. Another is that placental CRH enters the fetal circulation—albeit at lower levels than in the maternal circulation. In vitro studies have shown that CRH can directly stimulate fetal adrenal production of DHEA-S and cortisol (Parker, 1999; Smith, 1998). Thus, current studies do not support the idea that CRH levels alone have a positive-predictive value for preterm birth risk.

If preterm delivery is associated with early activation of the fetal adrenal–placental endocrine cascade, maternal estrogen levels would likely be prematurely elevated. This is indeed the case. An early rise in serum estriol concentrations is noted in women with subsequent preterm labor (Heine, 2000; McGregor, 1995). Physiologically, this premature rise in estrogen levels may alter myometrial quiescence and accelerate cervical ripening.

Taken together, these observations suggest that preterm birth is associated, in many cases, with a maternal–fetal biological

stress response. The stressors that activate this cascade likely are broad, and the stress response is dependent on the stressor. For example, CRH or estriol levels are prematurely elevated in preterm birth due to infection and multifetal pregnancies but not in pregnant women with perceived stress (Gravett, 2000; Himes, 2011; Warren, 1990). Chronic, psychological stress—resulting for example from racial discrimination—appears to promote impaired cellular immune competence (Christian, 2012b). A growing body of work in the area of psychoneuroimmunology will perhaps enhance the understanding of pathways that link stress with adverse birth outcomes (Christian, 2012a).

Infection

There is great interest in the role of infection as a primary cause of preterm labor in pregnancies with intact membranes (Goncalves, 2002; Iams, 1987). In some cases, there is histological evidence of inflammation in the fetal membranes, decidua, or umbilical cord, whereas other cases are deemed “subclinical.” More recently, new technologies based on genomic analysis of a mixed population of microorganisms have shown that the nonpregnant vaginal tract hosts a complex microbial community that can differ widely between women who are all healthy (Gajer, 2012; White, 2011). The application of the field of *metagenomics* to understanding microbiome complexity in term and preterm birth and to identifying microbe populations that may mediate subclinical infection holds great promise. Aagaard and coworkers (2012) used metagenomics to determine how the vaginal microbiome changes during normal pregnancy. They reported that the diversity and richness of microbes is reduced through pregnancy. Compared with nonpregnant controls, there is an increased dominance of *Lactobacillus* species. These findings lay the foundation for future studies to identify microbial populations associated with “subclinical” infection-induced preterm birth.

Current data suggest that microbial invasion of the reproductive tract is sufficient to induce infection-mediated preterm birth—more specifically, there is ongoing “subclinical” infection. However, microorganisms certainly are not ubiquitous in the amniotic fluid of all women with preterm labor, and indeed, positive cultures are found in only 10 to 40 percent (Goncalves, 2002). This minority of women with amniotic fluid bacteria are more likely to develop clinical chorioamnionitis and preterm ruptured membranes compared with women with sterile cultures. Moreover, their neonates are also more likely to have complications (Hitti, 2001). Although infection is more severe when there is clinically obvious intraamniotic infection, inflammation in the absence of detectable microorganisms is also a risk factor for a fetal inflammatory response (Lee, 2007, 2008). The earlier the onset of preterm labor, the greater the likelihood of documented infection (Goldenberg, 2000; Watts, 1992). It is enigmatic that the incidence of culture-positive amniotic fluids collected by amniocentesis during spontaneous term labor is similar to that with preterm labor (Gomez, 1994; Romero, 1993). It has been suggested that at term, amniotic fluid is infiltrated by bacteria as a consequence of labor, whereas in preterm pregnancies, bacteria represent an important cause of labor. If true, this explanation questions the contribution of fetal infection as a major cause of preterm labor and delivery.

Despite these observations, there are considerable data that associate chorioamnionitis with preterm labor (Goldenberg, 2002; Üstün, 2001). In such infections, the microbes may invade maternal tissue only and not amniotic fluid. Despite this, endotoxins can stimulate amniotic cells to secrete cytokines that enter amniotic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amniotic fluid cytokines and preterm labor, in which microbes were not detectable in the amniotic fluid.

Sources for Intrauterine Infection. The patency of the female reproductive tract, although essential for achievement of pregnancy and delivery, is theoretically problematic during phase 1 of parturition. It has been suggested that bacteria can gain access to intrauterine tissues through: (1) transplacental transfer of maternal systemic infection, (2) retrograde flow of infection into the peritoneal cavity via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. The lower pole of the fetal membrane–decidual junction is contiguous with the cervical canal orifice, which is patent to the vagina. This anatomical arrangement provides a passageway for microorganisms, and ascending infection is considered to be the most common. A thoughtful description of the potential degrees of intrauterine infection has been provided by Goncalves and associates (2002). They categorize intrauterine infection into four stages of microbial invasion that include bacterial vaginosis—stage I, decidual infection—stage II, amniotic infection—stage III, and finally, fetal systemic infection—stage IV. As expected, progression of these stages is thought to increase rates of preterm birth and neonatal morbidity.

Based on these insights, it is straightforward to construct a theory for the pathogenesis of infection-induced preterm labor. Ascending microorganisms colonize the cervix, decidua, and possibly the membranes, where they then may enter the amniotic sac. Lipopolysaccharide (LPS) or other toxins elaborated by bacteria induce immune-cell recruitment into the reproductive tract and cytokine production by immune cells and by cells within the cervix, decidua, membranes, or fetus itself. Both LPS and cytokines then provoke prostaglandin release from the membranes, decidua, or cervix. These influence both cervical ripening and loss of myometrial quiescence (Challis, 2002; Keelan, 2003; Olson, 2003). Current evidence based on animal and human studies suggests that many aspects of infection-mediated preterm birth differ from pathways that regulate term parturition (Hamilton, 2012; Holt, 2011; Shynlova, 2013a,b).

Microbes Associated with Preterm Birth. Some microorganisms—examples include *Gardnerella vaginalis*, *Fusobacterium*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*—are detected more frequently than others in amniotic fluid of women with preterm labor (Gerber, 2003; Hillier, 1988; Yoon, 1998). This finding was interpreted by some as presumptive evidence that specific microorganisms are more commonly involved as pathogens in the induction of preterm labor. Another interpretation, however, is that given direct access to the membranes after cervical

dilatation, selected microorganisms, such as fusobacteria, that are more capable of burrowing through these exposed tissues will do so. Fusobacteria are found in the vaginal fluid of only 9 percent of women but in 28 percent of positive amniotic fluid cultures from pregnancies with preterm labor and intact membranes (Chaim, 1992). Knowledge from metagenomic studies will better define these interactions in the future. In addition, host responses to pathogens with respect to mucosal immunity, barrier protection of cervical and vaginal epithelia, and expression of antimicrobial peptides is likely to provide insights. Specifically, the mechanisms that render some women more susceptible to infection-mediated preterm birth may be found.

Intrauterine Inflammatory Response. The initial inflammatory response elicited by bacterial toxins is mediated, in large measure, by specific receptors on mononuclear phagocytes, decidual cells, cervical epithelia, and trophoblasts. These *Toll-like receptors* represent a family that has evolved to recognize pathogen-associated molecules (Janssens, 2003). Toll-like receptors are present in the placenta on trophoblast cells, in the cervical epithelia, and on fixed and invading leukocytes (Chuang, 2000; Gonzalez, 2007; Holmlund, 2002). Loss of specific Toll-like receptors results in delayed parturition in mouse models (Montalbano, 2013).

Under the influence of ligands such as bacterial LPS, these receptors increase chemokine, cytokine, and prostaglandin release as part of an inflammatory response. One example is interleukin-1 β (IL-1 β), which is produced rapidly after LPS stimulation (Dinarello, 2002). This cytokine in turn acts to promote a series of responses that include: (1) increased synthesis of others, that is, IL-6, IL-8, and tumor-necrosis factor alpha (TNF- α); (2) proliferation, activation, and migration of leukocytes; (3) modifications in extracellular matrix proteins; and (4) mitogenic and cytotoxic effects such as fever and acute-phase response (El-Bastawissi, 2000). Also, IL-1 promotes prostaglandin formation in many tissues, including myometrium, decidua, and amnion (Casey, 1990). The importance of prostaglandins to infection-mediated preterm birth is supported by the observation that prostaglandin inhibitors can reduce the rate of LPS-induced preterm birth in both the mouse and nonhuman primate (Gravett, 2007; Gross, 2000). Inhibition of cyclooxygenase-2 prevents inflammation-mediated preterm labor in the mouse. And immunomodulators plus antibiotics delay preterm delivery after experimental intraamniotic infection in a nonhuman primate model. Thus, there appears to be a cascade of events once an inflammatory response is initiated that can result in preterm labor.

Origin of Cytokines. Cytokines within the normal term uterus are likely important for normal and preterm labor. The transfer of cytokines such as IL-1 from decidua across the membranes into amniotic fluid appears to be severely limited. It is reasonable that cytokines produced in maternal decidua and myometrium will have effects on that side, whereas cytokines produced in the membranes or in cells within the amniotic fluid will not be transferred to maternal tissues. The human myometrium expresses chemokine receptors that decline during labor (Hua, 2013). Macrophages are reported to infiltrate the human and rat decidua before labor onset and

may be important for decidual activation (Hamilton, 2012). Still, the requirement of leukocytes for initiation of term labor in women remains inconclusive. In most cases of inflammation resulting from infection, resident and invading leukocytes produce the bulk of cytokines. Indeed, with infection, leukocytes—mainly neutrophils, macrophages, and T lymphocytes—infiltrate the cervix, lower uterine segment, fundus, and membranes at the time of labor. Thus, invading leukocytes may be the major source of cytokines in preterm labor. Along with proinflammatory cytokines, studies in women and animal models highlight the importance of the antiinflammatory limb of the immune response in parturition (Gotsch, 2008; Timmons, 2009).

Immunohistochemical studies in the term laboring uterus have shown that both invading leukocytes and certain parenchymal cells produce cytokines. These leukocytes appear to be the primary source of myometrial cytokines, including IL-1, IL-6, IL-8, and TNF- α (Young, 2002). By contrast, in the decidua, both stromal cells and leukocytes are likely to contribute because they have been shown to produce these same cytokines. In the cervix, glandular and surface epithelial cells appear to produce IL-6, IL-8, and TNF- α . Of these, IL-8 is considered a critical cytokine in cervical dilation, and it is produced in both cervical epithelial and stromal cells.

The presence of cytokines in amniotic fluid and their association with preterm labor has been well documented. But their exact cellular origin—with or without recoverable microorganisms—has not been well defined. Although the rate of IL-1 secretion from forebag decidual tissue is great, Kent (1994) found that there is negligible *in vivo* transfer of radiolabeled IL-1 across the membranes. Amniotic fluid IL-1 probably does not arise from amnion, fetal urine, or fetal lung secretions. It most likely is secreted by mononuclear phagocytes or neutrophils activated and recruited into the amniotic fluid. Therefore, IL-1 in amniotic fluid likely is generated *in situ* from newly recruited cells (Young, 2002). Thus, the amount of amniotic fluid IL-1 would be determined by the number of leukocytes recruited, their activation status, or the effect of amniotic fluid constituents on their IL-1 secretion rate.

Leukocyte infiltration may be regulated by fetal membrane synthesis of specific chemokines. In term labor, there are increased amniotic fluid concentrations of the potent chemoattractant and monocyte-macrophage activator *monocyte chemoattractant protein-1* (MCP-1), which is also called *chemokine (C-C motif) ligand 2* (CCL2). As is true for prostaglandins and other cytokines, the levels of MCP-1 are much higher in the forebag compared with the upper compartment (Esplin, 2003). Levels in preterm labor were significantly higher than those found in normal term amniotic fluid (Jacobsson, 2003). MCP-1 may initiate fetal leukocyte infiltration of the placenta and membranes, and its production may act as a marker for intraamniotic infection and inflammation.

Preterm Premature Rupture of Membranes

This term defines spontaneous rupture of the fetal membranes before 37 completed weeks and *before labor onset* (American College of Obstetricians and Gynecologists, 2013d). Such rupture likely has various causes, but intrauterine infection is

believed by many to be a major predisposing event (Gomez, 1997; Mercer, 2003). There are associated risk factors that include low socioeconomic status, body mass index ≤ 19.8 , nutritional deficiencies, and cigarette smoking. Women with prior preterm premature rupture of membranes (PPROM) are at increased risk for recurrence during a subsequent pregnancy (Bloom, 2001). Despite these known risk factors, none is identified in most cases of preterm rupture.

Molecular Changes

Preterm membrane rupture pathogenesis may be related to increased apoptosis of membrane cellular components and to increased levels of specific proteases in membranes and amniotic fluid. Most tensile strength of the membranes is provided by the amniotic extracellular matrix and interstitial amniotic collagens—primarily type I and III—which are produced in mesenchymal cells (Casey, 1996). For that reason, collagen degradation has been a focus of research. The matrix metalloproteinase (MMP) family is involved with normal tissue remodeling and particularly with collagen degradation. The MMP-1, MMP-2, MMP-3, and MMP-9 members of this family are found in higher concentrations in amniotic fluid from pregnancies with preterm prematurely ruptured membranes (Maymon, 2000; Park, 2003; Romero, 2002). MMP activity is in part regulated by tissue inhibitors of matrix metalloproteinases—TIMPs. Several of these inhibitors are found in lower concentrations in amniotic fluid from women with ruptured membranes. Elevated MMP levels found at a time when protease inhibitor expression decreases supports further that their expression alters amniotic tensile strength. Studies of amniochorion explants have demonstrated that the expression of MMPs can be increased by treatment with IL-1, TNF- α , and IL-6 (Fortunato, 1999a,b, 2002). Recent studies by Mogami (2013) provide a mechanism by which bacterial endotoxin or TNF- α elicits release of fetal fibronectin (fFN) by amnion epithelial cells. The fFN then binds Toll-like receptor 4 in the amnion mesenchymal cells to activate signaling cascades. These result in increased prostaglandin E (PGE₂) synthesis and elevated activity of MMP-1, MP-2, and MMP-9. Increased prostaglandin levels promote cervical ripening and uterine contractions. Increased MMPs allow collagen breakdown in the fetal membranes resulting in premature rupture.

In pregnancies with PPRM, the amnion exhibits a higher degree of cell death and more apoptosis markers than that in term amnion (Arechavaleta-Velasco, 2002; Fortunato, 2003). In vitro studies indicate that apoptosis is likely regulated by bacterial endotoxin, IL-1, and TNF- α . Last, there are proteins involved in the synthesis of mature cross-linked collagen or matrix proteins that bind collagen and thereby promote tensile strength. These proteins are altered in membranes with premature rupture (Wang, 2006). Taken together, these observations suggest that many PPRM cases result from collagen degradation, altered collagen assembly, and cell death, which all lead to a weakened amnion.

Infection

Several studies have been done to ascertain the incidence of infection-induced premature membrane rupture. Bacterial

cultures of amniotic fluid support a role for infection in a significant proportion. A review of 18 studies comprising almost 1500 women with PPRM found that in a third, bacteria were isolated from amniotic fluid (Goncalves, 2002). Accordingly, some have given prophylactic antimicrobial treatment to prevent premature rupture (Miyazaki, 2012; Phupong, 2012).

Overall, there is compelling evidence that infection causes a significant proportion of PPRM cases. The inflammatory response that leads to membrane weakening is currently being defined. Research is focused on mediators of this process with a goal to identify early risk markers for PPRM.

Multifetal Gestation

Twins and higher-order multifetal births account for approximately 3 percent of infants born in the United States (Martin, 2009a). The majority—95 percent—of these births are twins. Compared with 1980, the rates of multiple births increased steadily and peaked in 1998. Current rates have declined since then, but remain higher than the 1980s. The increased rate of multifetal births is due to the increased number of women having babies after the age of 30, at which time the risk to conceive multiples rises. In addition, the use of fertility treatments has contributed to the elevated rates of multifetal pregnancies. Preterm delivery continues to be the major cause of the excessive perinatal morbidity and mortality with multifetal pregnancies. The effects of uterine stretch discussed on page 837 are obvious in these pregnancies, and this likely is related to the increased incidence of preterm cervical dilatation. Many of these interrelationships are discussed in Chapter 45.

Summary of Preterm Labor Pathophysiology

Preterm labor is a pathological condition with multiple etiologies. Romero (2006) termed it the *preterm parturition syndrome*. Most research in this field has been focused on the role of infection in mediating preterm birth. It is possible that intrauterine infection causes some cases currently categorized as idiopathic spontaneous preterm labor. There are various sites for intrauterine infection—maternal, fetal, or both—and increasing evidence that the inflammatory response may have distinct and compartment-specific functions that differ between uterus, fetal membranes, and cervix in normal birth. Thus, determining the proportion of pregnancies that end prematurely because of infection is difficult.

Infection does not explain all causes of preterm birth. In recent years, our understanding of other influences on the parturition process, such as maternal nutrition before or during pregnancy, genetics, the vaginal microbiome, and dynamic regulation of the extracellular matrix, has led to new avenues of research and a broader understanding of this complicated and multifactorial process. The current and future application of genomic and bioinformatics as well as molecular and biochemical studies will shed light on pathways involved in term and preterm labor and identify processes critical to all phases of cervical remodeling and uterine function.

ANTECEDENTS AND CONTRIBUTING FACTORS

Myriad genetic and environmental factors affect the frequency of preterm labor.

Threatened Abortion

Vaginal bleeding in early pregnancy is associated with increased adverse outcomes later. Weiss (2004) reported outcomes with vaginal bleeding at 6 to 13 weeks in nearly 14,000 women. Both light and heavy bleeding were associated with subsequent preterm labor, placental abruption, and subsequent pregnancy loss before 24 weeks.

Lifestyle Factors

Cigarette smoking, inadequate maternal weight gain, and illicit drug use have important roles in both the incidence and outcome of low-birthweight neonates (Chap. 12, p. 253). Overweight and obese mothers have an elevated risk of preterm birth (Cnattingius, 2013). Other maternal factors implicated include young or advanced maternal age, poverty, short stature, and vitamin C deficiency (Casanueva, 2005; Gielchinsky, 2002; Kramer, 1995; Meis, 1995; Satin, 1994).

As discussed on page 837, psychological factors such as depression, anxiety, and chronic stress have been reported in association with preterm birth (Copper, 1996; Li, 2008; Littleton, 2007). Neggers and coworkers (2004) found a significant link between low birthweight and preterm birth in women injured by physical abuse (Chap. 47, p. 951).

Studies of work and physical activity related to preterm birth have produced conflicting results (Goldenberg, 2008). There is some evidence, however, that working long hours and hard physical labor are probably associated with increased risk of preterm birth (Luke, 1995).

Genetic Factors

The recurrent, familial, and racial nature of preterm birth has led to the suggestion that genetics may play a causal role. An accumulating literature on genetic variants buttresses this concept (Gibson, 2007; Hampton, 2006; Li, 2004; Macones, 2004). As discussed on page 839, several such studies have also implicated immunoregulatory genes in potentiating chorioamnionitis in cases of preterm delivery due to infection (Varner, 2005).

Birth Defects

In a secondary analysis of data from the First- and Second-Trimester Evaluation of Risk (FASTER) Trial, it was found that birth defects were associated with preterm birth and low birthweight (Dolan, 2007).

Periodontal Disease

Gum inflammation is a chronic anaerobic inflammation that affects as many as 50 percent of pregnant women in the United States (Goepfert, 2004). Vergnes and Sixou (2007) performed a metaanalysis of 17 studies and concluded that periodontal

disease was significantly associated with preterm birth—odds ratio 2.83. The researchers concluded, however, that the data were not robust enough to recommend screening and treatment of pregnant women (Stamilio, 2007).

To better study the relationship with periodontitis, Michalowicz (2006) randomly assigned 813 pregnant women between 13 and 17 weeks' gestation who had periodontal disease to treatment during pregnancy or postpartum. They found that treatment during pregnancy improved periodontal disease and that it is safe. However, treatment failed to significantly alter preterm birth rates.

Interval between Pregnancies

Short intervals between pregnancies have been known for some time to be associated with adverse perinatal outcomes. In a metaanalysis, Conde-Agudelo and colleagues (2006) reported that intervals < 18 months and > 59 months were associated with increased risks for both preterm birth and small-for-gestational age newborns.

Prior Preterm Birth

A major risk factor for preterm labor is prior preterm delivery (Spong, 2007). Shown in Table 42-6 is the incidence of recurrent preterm birth in nearly 16,000 women delivered at Parkland Hospital. The recurrent preterm delivery risk for women whose first delivery was preterm was increased three-fold compared with that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. Most—70 percent—of the recurrent births in this study occurred within 2 weeks of the gestational age of the prior preterm delivery. Importantly, the causes of prior preterm delivery also recurred.

Although women with prior preterm births are clearly at risk for recurrence, they contributed only 10 percent of the total preterm births in this study. Expressed another way, 90 percent of the preterm births at Parkland Hospital cannot be predicted based on a history of preterm birth. Extrapolating data from the 2003 revised birth certificates, it is estimated that approximately 2.5 percent of women delivered in 2004 had a history of prior preterm birth (Martin, 2007).

TABLE 42-6. Recurrent Spontaneous Preterm Births According to Prior Outcome

Birth Outcome ^a	Second Birth ≤ 34 Weeks (%)
First birth ≥ 35 weeks	5
First birth ≤ 34 weeks	16
First and second birth ≤ 34 weeks	41

^aData from 15,863 women delivering their first and subsequent pregnancies at Parkland Hospital. Adapted from Bloom, 2001.

Infection

As discussed, a link between preterm birth and infection seems irrefutable. Goldenberg and coworkers (2008) have reviewed this association. Intrauterine infections are believed to trigger preterm labor by activation of the innate immune system. In this hypothesis, microorganisms elicit release of inflammatory cytokines such as interleukins and TNF- α , which in turn stimulate the production of prostaglandin and/or matrix-degrading enzymes. Prostaglandins stimulate uterine contractions, whereas degradation of extracellular matrix in the fetal membranes leads to preterm rupture of membranes. It is estimated that 25 to 40 percent of preterm births result from intrauterine infection. The basic science of preterm birth due to infection is discussed at length beginning on page 838.

In several studies, antimicrobial treatment has been given to prevent preterm labor due to microbial invasion. Based on available data, these strategies especially targeted mycoplasma species. Morency and colleagues (2007) performed a metaanalysis of 61 articles and suggested that antimicrobials given in the second trimester may prevent subsequent preterm birth. Andrews and associates (2006) reported results of a double-blind interconceptional trial in which they gave a course of azithromycin plus metronidazole every 4 months to 241 nonpregnant women whose last pregnancy resulted in spontaneous delivery before 34 weeks. Approximately 80 percent of the women with subsequent pregnancies had received study drug within 6 months of their subsequent conception. Such interconceptional antimicrobial treatment did not reduce the rate of recurrent preterm birth. Tita and coworkers (2007) performed a subgroup analysis of these same data and concluded that such use of antimicrobials may be harmful. In another study, Goldenberg and colleagues (2006) randomized 2661 women at four African sites to placebo or metronidazole plus erythromycin between 20 and 24 weeks' gestation followed by ampicillin plus metronidazole during labor. This antimicrobial regimen did not reduce the rate of preterm birth or that of histological chorioamnionitis.

Bacterial Vaginosis

In this condition, normal, hydrogen peroxide-producing, lactobacillus-predominant vaginal flora is replaced with anaerobes that include *Gardnerella vaginalis*, *Mobiluncus* species, and *Mycoplasma hominis* (Hillier, 1995; Nugent, 1991). Its diagnosis and management are discussed in Chapter 65 (p. 1276). Using Gram staining, relative concentrations of the bacterial morphotypes characteristic of bacterial vaginosis are determined and graded as the *Nugent score*.

Bacterial vaginosis has been associated with spontaneous abortion, preterm labor, PPRM, chorioamnionitis, and amniotic fluid infection (Hillier, 1995; Kurki, 1992; Leitich, 2003a,b). Environmental factors appear to be important in bacterial vaginosis development. Exposure to chronic stress, ethnic differences, and frequent or recent douching have all been associated with increased rates of the condition (Culhane, 2002; Ness, 2002). A gene-environment interaction has been described (Macones, 2004). Women with bacterial vaginosis and a susceptible TNF- α genotype had a ninefold increased incidence of preterm birth. From all of these studies, there seems no doubt that

adverse vaginal flora is associated in some way with spontaneous preterm birth. Unfortunately, to date, screening and treatment have not been shown to prevent preterm birth. Indeed, microbial resistance or antimicrobial-induced change in the vaginal flora has been reported as a result of regimens intended to eliminate bacterial vaginosis (Beigi, 2004; Carey, 2005). Okun and associates (2005) performed a systematic review of antibiotics given for bacterial vaginosis and for *Trichomonas vaginalis*. They found no evidence to support such use for the prevention of preterm birth in either low-risk or high-risk women.

DIAGNOSIS

Preterm labor is primarily diagnosed by symptoms and physical examination. Sonography is used to identify asymptomatic cervical dilation and effacement.

Symptoms

Early differentiation between true and false labor is difficult before there is demonstrable cervical effacement and dilatation. Uterine activity alone can be misleading because of *Braxton Hicks contractions*, which are discussed in detail in Chapter 21 (p. 409). These contractions, described as irregular, nonrhythmical, and either painful or painless, can cause considerable confusion in the diagnosis of true preterm labor. Not infrequently, women who deliver before term have uterine activity that is attributed to Braxton Hicks contractions, prompting an incorrect diagnosis of false labor. Accordingly, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) define preterm labor to be regular contractions before 37 weeks that are associated with cervical change.

In addition to painful or painless uterine contractions, symptoms such as pelvic pressure, menstrual-like cramps, watery vaginal discharge, and lower back pain have been empirically associated with impending preterm birth. Such complaints are thought by some to be common in normal pregnancy and are therefore often dismissed by patients, clinicians, and nurses.

The importance of these symptoms as a harbinger of labor has been emphasized by some but not all investigators (Iams, 1990; Kragt, 1990). Iams and coworkers (1994) found that the signs and symptoms signaling preterm labor, including uterine contractions, appeared only within 24 hours of preterm labor.

Chao (2011) prospectively studied 843 women with singletons who presented to Parkland Hospital with preterm labor symptoms, between 24^{0/7} and 33^{6/7} weeks, intact membranes, and cervical dilation < 2 cm. These women underwent electronic fetal and uterine contraction monitoring for 2 hours. Those whose cervix remained < 2 cm were sent home with a diagnosis of false preterm labor. When analyzed compared with the general obstetrical population, women sent home had a similar and nonsignificant rate of birth before 34 weeks—2 versus 1 percent. However, these women had a significantly higher rate of birth between 34 and 36 weeks—5 percent compared with 2 percent. Women with cervical dilation of 1 cm at discharge were significantly more likely to deliver before 34 weeks

compared with women without cervical dilatation—5 percent versus 1 percent. Importantly, almost 90 percent of the 1-cm group delivered > 21 days after the initial presentation.

■ Cervical Change

Dilatation

Researchers have evaluated asymptomatic cervical changes that may presage and thus predict preterm labor. Asymptomatic cervical dilatation after midpregnancy is suspected to be a risk factor for preterm delivery, although some clinicians consider it to be a normal anatomical variant. Moreover, study results have suggested that parity alone is not sufficient to explain cervical dilatation discovered early in the third trimester. Cook (1996) longitudinally evaluated cervical status with transvaginal sonography between 18 and 30 weeks in both nulliparous and parous women who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. In a study from Parkland Hospital, routine digital cervical examinations were performed between 26 and 30 weeks in 185 women. Approximately 25 percent of women whose cervix was dilated 2 or 3 cm delivered before 34 weeks. Other investigators have verified cervical dilatation as a predictor of increased preterm delivery risk (Copper, 1995; Pereira, 2007).

Although women with dilatation and effacement in the third trimester are at increased risk for preterm birth, detection does not improve pregnancy outcome. Buekens and associates (1994) randomly assigned 2719 women to undergo routine cervical examinations at each prenatal visit and compared them with 2721 women in whom serial examinations were not performed. Knowledge of antenatal cervical dilatation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor. The investigators also reported that cervical examinations were not related to preterm membrane rupture. At this time, it seems that prenatal cervical examinations are neither beneficial nor harmful.

Length

Vaginal-probe sonographic cervical assessment has been evaluated extensively during the past two decades. When performed by trained operators, cervical length analysis using transvaginal sonography is safe, highly reproducible, and more predictive than transabdominal sonographic screening (American College of Obstetricians and Gynecologists, 2012b). Unlike the transabdominal approach, transvaginal cervical sonography is not affected by maternal obesity, cervix position, or shadowing from the fetal presenting part. Technique is important, and Yost and colleagues (1999) have cautioned that special expertise is needed. Iams and coworkers (1996) measured cervical length at approximately 24 weeks' gestation and again at 28 weeks in 2915 women not at risk for preterm birth. The mean cervical length at 24 weeks was approximately 35 mm, and those women with progressively shorter cervixes experienced increased rates of preterm birth.

Until recently, routine cervical length evaluation in women at low risk was not advocated because, like other factors associated

with potentially higher preterm birth risk, no effective treatments were available. Randomized trials done to investigate vaginal progesterone use in women with short cervix diagnosed during screening have stimulated consideration of whether or not such screening is warranted (Fonseca, 2007; Hassan, 2011). These trials are discussed subsequently on page 844.

■ Ambulatory Uterine Monitoring

An external tocodynamometer belted around the abdomen and connected to an electronic waist recorder allows a woman to ambulate while uterine activity is recorded. Results are transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress. The 1985 approval of this monitor by the Food and Drug Administration (FDA) prompted its widespread clinical use. Subsequently, the American College of Obstetricians and Gynecologists (1995) concluded that the use of this expensive, bulky, and time-consuming system does not reduce preterm birth rates. A subsequent study by the Collaborative Home Uterine Monitoring Study Group (1995) confirmed these conclusions. And Iams and associates (2002) analyzed data from almost 35,000 hours of daily home monitoring and verified that no contraction pattern efficiently predicted preterm birth. The American College of Obstetricians and Gynecologists (2012a) does not recommend home uterine activity monitoring.

■ Fetal Fibronectin

This glycoprotein is produced in 20 different molecular forms by various cell types, including hepatocytes, fibroblasts, endothelial cells, and fetal amnion. Present in high concentrations in maternal blood and in amniotic fluid, it is thought to function in intercellular adhesion during implantation and in maintenance of placental adherence to uterine decidua (Leeson, 1996). Fetal fibronectin is detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term. It appears to reflect stromal remodeling of the cervix before labor.

Lockwood (1991) reported that fibronectin detection in cervicovaginal secretions before membrane rupture was a possible marker for impending preterm labor. Fetal fibronectin is measured using an enzyme-linked immunosorbent assay, and values exceeding 50 ng/mL are considered positive. Sample contamination by amniotic fluid and maternal blood should be avoided. Interventional studies based on the use of fetal fibronectin screening in asymptomatic women have not demonstrated improved perinatal outcomes (Andrews, 2003; Grobman, 2004). The American College of Obstetricians and Gynecologists (2012b) does not recommend screening with fetal fibronectin tests.

PRETERM BIRTH PREVENTION

Prevention of preterm birth has been an elusive goal. Recent reports, however, suggest that prevention in selected populations may be achievable.

Cervical Cerclage

There are at least three circumstances when cerclage placement may be used to prevent preterm birth. Two are done prophylactically, and a third is done for treatment. The first prophylactic cerclage is used in women who have a history of recurrent midtrimester losses and who are diagnosed with cervical insufficiency (Chap. 18, p. 360). The second prophylactic cerclage is for women identified during sonographic examination to have a short cervix. The third indication is “rescue” cerclage, done emergently when cervical incompetence is recognized in women with threatened preterm labor.

For women with a short cervix detected by sonography, Berghella and colleagues (2005) reviewed several small trials of cerclage in this group and concluded that cerclage may reduce preterm birth rates in those women with a prior preterm birth. Owen (2009) randomly assigned 302 women with prior preterm birth from 16 centers with a short cervix—defined as length < 25 mm—to cerclage or no procedure. Women with a cervical length < 15 mm delivered before 35 weeks significantly less often following cerclage compared with women with no cerclage—30 versus 65 percent. This study suggests that recurrent preterm birth can be prevented in a subset of women who have a history of prior preterm births.

In a multinational study, To and associates (2004) screened 47,123 women and randomized the 253 women with cervixes < 15 mm to cerclage or no cerclage. The frequency of preterm delivery < 33 weeks was not significantly different between the treatment groups. Thus, cerclage for sonographically detected *short cervix alone* has not been found to be beneficial. In contrast, women with a very short cervix, that is, < 15 mm, and a history of prior preterm birth may benefit.

Prophylaxis with Progestin Compounds

Progesterone levels in most mammals fall rapidly before the onset of labor. This is termed *progesterone withdrawal* and is considered to be a parturition-triggering event. During human parturition, however, maternal, fetal, and amniotic fluid progesterone levels remain elevated with no decline. It has been proposed that human parturition involves functional progesterone withdrawal mediated by decreased progesterone activity of progesterone receptors (Ziyan, 2010). It follows conceptually that the administration of progesterone to maintain uterine quiescence may block preterm labor. This hypothesis has stimulated several studies in the past half century.

Prior Preterm Birth and Progestin Compounds

Initial Studies

Studies in the past 15 years have included several investigations to evaluate progestin compounds given prophylactically. A pivotal study was done by the MFMU Network to evaluate prophylactic progestin treatment for women at high-risk for recurrent preterm birth (Meis, 2003). In this trial, 310 women with a prior preterm birth were randomized to receive *17-hydroxyprogesterone caproate* (17-OHPC) (Romero, 2013).

Another 153 women received placebo, and these were administered as weekly intramuscular injections of either inert oil or 17-OHPC from 16 through 36 weeks' gestation. Delivery rates before 37, 35, and 32 weeks were all significantly reduced by 17-OHPC therapy. At the same time, however, similar studies of 17-OHPC in both twins and triplets done by the Network showed no improvement in preterm birth rates (Caritis, 2009; Rouse, 2007).

The 17-OHPC study by Meis and colleagues (2003) has been challenged because of the unexpectedly high preterm delivery rate in the placebo arm of the trial. Fifty-five percent delivered rather than the expected rate of 36 percent, which was derived from a pretrial cohort (Romero, 2013). The criticism is that 17-OHPC may have been shown to be effective only because the placebo group was distorted by this high 55-percent preterm delivery rate. This compared with the 36-percent rate, which was actually observed when women were treated with 17-OHPC in the trial. To further elucidate this disparity, a confirmation trial by the Network is underway.

Also in contrast to the 17-OHPC study by Meis and coworkers (2003), O'Brien and associates (2007) randomly assigned 659 women with a prior preterm birth to treatment with daily vaginal progesterone gel (90 mg) or placebo. They found no differences in preterm birth rates.

Subsequent Studies

Perhaps no other topic in contemporary obstetrics has generated as much interest and debate since the 23rd edition of *Williams Obstetrics* as has the use of progestins to prevent preterm birth. At the center of the controversy is whether or not progestins prevent preterm birth in women with a singleton pregnancy but without prior preterm birth—especially nulliparous women. If progestins are effective in women at low risk for preterm birth, this would justify sonographic screening of all pregnant women to detect short cervixes (Silver, 2011).

Three randomized trials are at the center of the controversy, and these are summarized in Table 42-7. Fonseca and colleagues (2007) randomly assigned 250 women with sonographically short cervixes—15 mm or less—identified during routine prenatal care. Women were given nightly 200-mg micronized progesterone vaginal capsules or placebo from 24 to 34 weeks' gestation. As shown in Table 42-7, spontaneous delivery before 34 weeks was significantly reduced by progesterone therapy. Importantly, this trial included not only nulliparous women but also those with twins or prior preterm birth.

Hassan and coworkers (2011) randomly assigned 465 women with a sonographically short cervix—10 to 20 mm—to vaginal progesterone gel, 90 mg daily or placebo. As shown in Table 42-7, this trial also included nulliparous women as well as women with prior preterm births. Unlike the Fonseca (2007) trial, however, twin gestations were excluded. This trial was performed in 44 hospitals located in 10 countries including the United States. The FDA rejected progesterone gel for use in the United States because the results did not meet the level of statistical significance required to show efficacy in the subjects recruited in this country. Neither the Fonseca (2007) nor the

TABLE 42-7. Randomized Trials of Progestin Compounds Given Prophylactically to Prevent Preterm Labor

Investigator	Women Randomized	Cervical Length ^a	Progestin Compound	Progestin vs Placebo
Fonseca (2007)	n = 250; 5% nulliparous, 10% twins, 15% prior PTB; 8 hospitals: UK, Greece, Brazil, Chile	< 15 mm	Progesterone, 200-mg vaginal capsules daily	Delivery < 34 weeks: 19% vs 34%, <i>p</i> = .02
Hassan (2011)	n = 465; singletons only; 55% nulliparous; 13% prior PTB; 44 hospitals in 10 countries	10–20 mm	Progesterone, 90-mg vaginal gel daily	Delivery < 33 weeks: 9% vs 16%, <i>p</i> = .02
Grobman (2012)	n = 657; singletons only; nulliparous only; 14 centers across US	< 30 mm	17-OHPC, 250 mg IM weekly	Delivery < 37 weeks: 25% vs 24%, <i>p</i> = NS

^aDetermined sonographically.

Hassan (2011) studies report subset analyses exclusive to nulliparas (Parry, 2012). According to Likis and colleagues (2012), the heterogeneity of these two studies that included women with varied indications for progestin treatment, combined with the fact that outcomes were not reported by risk factors such as nulliparity, makes it impossible to interpret the efficacy of progesterone for specific indications. Based on these studies, the American College of Obstetricians and Gynecologists (2012a,b) concluded that it could not “mandate universal cervical length screening in women without a prior preterm birth, but that this screening strategy may be considered.”

The most recently published study that addresses use of progestins to prevent preterm birth in nulliparas included 657 randomly assigned to 17-OHPC or placebo (Grobman, 2012). This study was limited to women with singletons and

sonographic cervical length < 30 mm detected between 16 and 22^{3/7} weeks. Treatment with 17-OHPC given weekly did not reduce the frequency of preterm birth before 37 weeks. Subgroup analyses by cervical length and gestational age at delivery are summarized in Table 42-8. Regardless of cervical length, 17-OHPC was ineffective.

Another interesting development vis-à-vis progestin therapy for preterm birth since the last edition of *Williams Obstetrics* was the marketing of 17-OHPC by KV Pharmaceuticals under the brand name *Makena*. The original retail price was \$1500 per 250-mg injectable dose. Thus, a 20-week course for one woman would cost \$30,000. This caused an uproar among the leadership of organizations in obstetrics and gynecology. The United States Congress became involved, and the FDA permitted continued availability of 17-hydroxyprogesterone

TABLE 42-8. Comparison of 17-OHPC versus Placebo to Prevent Preterm Birth at < 37 and < 34 Weeks

Variable	17-OHPC N = 327	Placebo N = 330	RR (95% CI)	<i>p</i> value ^a
Preterm birth < 37 wk:

Data from Grobman, 2012.

compounded by pharmacies as an alternative to *Makena*. In Dallas in 2013, a 250-mg injectable dose of compounded 17-OHPC cost about \$18. KV Pharmaceuticals filed for Chapter 11 bankruptcy 4 in August 2012. The company cited that it had been unable to realize the full value of its most important drug, *Makena* (St Louis Business Journal, 2012).

So, how does the clinician reconcile the conflicting evidence as to the efficacy of progestins across the spectrum of the various specific indications? Romero and Stanczyk (2013) argue that one explanation for the conflicting evidence is that progesterone is not the same as 17-hydroxyprogesterone caproate (Figure 42-9). Progesterone is a natural steroid produced by the corpus luteum and the placenta, whereas 17-hydroxyprogesterone caproate is a synthetic steroid. These authors reviewed the basic science of natural and synthetic progestins vis-à-vis effects on the uterus and cervix in pregnant women, animals, and in vitro experiments. For example, natural progesterone suppresses myometrial contractility in strips that were obtained at cesarean delivery, whereas synthetic 17-OHPC did not. This report is an excellent source of information on the issues involved with progestin use in preterm birth.

The evidence for or against the preventive efficacy of progestins for preterm birth is clearly complex. As outlined in this section, virtually all evidence supporting use for a specific indication can be challenged in some way. Currently, at Parkland Hospital, we are prescribing weekly injections of 17-hydroxyprogesterone compounded by a local pharmacy for women with a prior preterm birth. In our view, all other indications for the use of progestin in the prevention of preterm birth are investigational.

Geographic-Based Public Health-Care Programs

A well-organized prenatal system results in a decreased preterm birth rate in high-risk indigent populations. The decreasing preterm birth rate at Parkland Hospital between 1988 and 2006 shown in Figure 42-10 coincided with a substantial increase in prenatal care utilization. In the early 1990s, a concerted effort was made to improve access to and use of prenatal care. The intention was to develop a program of seamless care beginning with enrollment during the prenatal period and extending through delivery and into the puerperium. Prenatal clinics are placed strategically throughout Dallas County to provide convenient access for indigent women. When possible, these clinics were colocated with comprehensive medical and pediatric clinics that enhance patient use. Because the entire clinic system is operated by Parkland Hospital, administrative and medical oversight is seamless. For example, prenatal protocols are used by nurse practitioners at all clinic sites to guarantee homogeneous care. Women with high-risk pregnancy complications are referred to the hospital-based central clinic system. Here, high-risk pregnancy clinics operate each weekday, with specialty clinics for women with prior preterm birth, gestational diabetes, infectious diseases, multifetal pregnancy,

FIGURE 42-9 Chemical structure of progesterone and 17 α -hydroxyprogesterone caproate.

and hypertensive disorders. Clinics are staffed by residents and midwives supervised by maternal-fetal medicine fellows and faculty. Because Parkland Hospital has a closed medical staff, all attending physicians are employed by the University of Texas Southwestern Department of Obstetrics and Gynecology. These faculty members adhere to agreed-upon practice guidelines using an evidence-based outcomes approach. Thus, prenatal care is considered one component of a comprehensive and orchestrated public health care system that is community-based. Putting this together, we hypothesize that the decrease in preterm births experienced at our inner-city hospital was attributable to a geographically based public health-care program specifically targeting minority populations of pregnant women. A similar obstetrical care system for indigent women at the University of Alabama at Birmingham has also produced salutary results (Tita, 2011).

MANAGEMENT OF PRETERM PREMATURELY RUPTURED MEMBRANES

Methods used to diagnose ruptured membranes are detailed in Chapter 22 (p. 448). A history of vaginal leakage of fluid, either as a continuous stream or as a gush, should prompt a

FIGURE 42-10 Percentage of births before 37 weeks' gestation at Parkland Hospital from 1988 to 2006 compared with that in the United States from 1996 to 2002. Analysis in both cohorts was limited to singleton live births ≥ 500 g who received prenatal care. (Redrawn from Leveno, 2009, with permission.)

speculum examination to visualize gross vaginal pooling of amniotic fluid, clear fluid from the cervical canal, or both. Confirmation of ruptured membranes is usually accompanied by sonographic examination to assess amniotic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Amniotic fluid is slightly alkaline (pH 7.1–7.3) compared with vaginal secretions (pH 4.5–6.0). This is the basis of frequently used pH testing for ruptured membranes. Blood, semen, antiseptics, or bacterial vaginosis, however, are all also alkaline and can give false-positive results.

Natural History

Cox and associates (1988) described pregnancy outcomes of 298 consecutive women who gave birth following spontaneously ruptured membranes between 24 and 34 weeks at Parkland Hospital. Although this complication was identified in only 1.7 percent of pregnancies, it contributed to 20 percent of all perinatal deaths. By the time they presented, 75 percent of the women were already in labor, 5 percent were delivered for other complications, and another 10 percent delivered within 48 hours. In only 7 percent was delivery delayed 48 hours or more after membrane rupture. This last subgroup, however, appeared to benefit from delayed delivery because there were no neonatal deaths. This contrasted with a neonatal death rate of 80 per 1000 in preterm newborns delivered within 48 hours of membrane rupture. Nelson (1994) reported similar results.

The time from PPRM to delivery is inversely proportional to the gestational age when rupture occurs (Carroll, 1995). As shown in [Figure 42-11](#), very few days were gained when membranes ruptured during the third trimester compared with midpregnancy.

FIGURE 42-11 Relationship of time between preterm membrane rupture and delivery in 172 singleton pregnancies. (Redrawn from Carroll, 1995, with permission.)

Hospitalization

Most clinicians hospitalize women with PPRM. Concerns regarding the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and coworkers (1993) randomly assigned 67 women with ruptured membranes to home or hospital management. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home—14 versus 7 days. Importantly, the investigators emphasized that this study was too small to conclude that home management was safe vis-à-vis umbilical cord prolapse.

Intentional Delivery

Before the mid-1970s, labor was usually induced in women with preterm ruptured membranes because of fear of sepsis. Two randomized trials compared labor induction with expectant management in such pregnancies. Mercer and associates (1993) randomly assigned 93 women with pregnancies between 32 and 36 weeks to undergo delivery or expectant management. Fetal lung maturity, as evidenced by mature surfactant profiles, was present in all cases. Intentional delivery reduced the length of maternal hospitalization and also reduced infection rates in both mothers and neonates. Cox and coworkers (1995) similarly apportioned 129 women between 30 and 34 weeks. Fetal lung maturity was not assessed. One fetal death resulted from sepsis in the pregnancies managed expectantly. Among those intentionally delivered, there were three neonatal deaths—two from sepsis and one from pulmonary hypoplasia. Thus, neither management approach proved to be superior for perinatal outcomes.

Expectant Management

Despite extensive literature concerning expectant management of PPRM, tocolysis has been used in few studies. In randomized studies, women were assigned to receive either tocolysis or expectant management. The investigators concluded that active interventions did not improve perinatal outcomes (Garite, 1981, 1987; Nelson, 1985).

Other considerations with expectant management involve the use of digital cervical examination and cerclage. Alexander and colleagues (2000) analyzed findings in women expectantly managed between 24 and 32 weeks' gestation. They compared those who had one or two digital cervical examinations with women who were not examined digitally. Women who were examined had a rupture-to-delivery interval of 3 days compared with 5 days in those who were not examined. This difference did not worsen maternal or neonatal outcomes.

There is uncertainty regarding ruptured membranes in the woman

who has undergone cervical cerclage. McElrath and associates (2002) studied 114 women with cerclage in place who later had ruptured membranes before 34 weeks. They were compared with 288 controls who had not received a cerclage. Pregnancy outcomes were equivalent in both groups. As discussed in Chapter 18 (p. 363), such management is controversial.

Risks of Expectant Management

Maternal and fetal risks vary with the gestational age at membrane rupture. Morales (1993b) expectantly managed 94 singleton pregnancies with ruptured membranes before 25 weeks. The average time gained was 11 days. *Although 41 percent of infants survived to age 1 year, only 27 percent were neurologically normal.* Similar results were reported by Farooqi (1998) and Winn (2000) and their colleagues. Lieman and associates (2005) found no improved neonatal outcomes with expectant management beyond 33 weeks. In contrast, McElrath and coworkers (2003) found that prolonged latency after membrane rupture was not associated with an increased incidence of fetal neurological damage.

The volume of amniotic fluid remaining after rupture appears to have prognostic importance in pregnancies before 26 weeks. Hadi and colleagues (1994) described 178 pregnancies with ruptured membranes between 20 and 25 weeks. Forty percent of women developed oligohydramnios, defined by the absence of fluid pockets 2 cm or larger. Virtually all women with oligohydramnios delivered before 25 weeks, whereas 85 percent with adequate amniotic fluid volume were delivered in the third trimester. Carroll and coworkers (1995) observed no cases of pulmonary hypoplasia in fetuses born after membrane rupture at 24 weeks or beyond. This suggests that 23 weeks or less is the threshold for development of lung hypoplasia. Further, when contemplating early expectant management, consideration is also given to oligohydramnios and resultant limb compression deformities (Chap. 11, p. 237).

Other risk factors have also been evaluated. In neonates born to women with active herpetic lesions who were expectantly managed, the infectious morbidity risk appeared to be outweighed by risks associated with preterm delivery (Major, 2003). Lewis and associates (2007) found that expectant management of women with preterm ruptured membranes and noncephalic presentation was associated with an increased rate of umbilical cord prolapse, especially before 26 weeks.

Clinical Chorioamnionitis

Most authors report that prolonged membrane rupture is associated with increased fetal and maternal sepsis (Ho, 2003). If chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Fever is the only reliable indicator for this diagnosis, and temperature of 38°C (100.4°F) or higher accompanying ruptured membranes implies infection. Maternal leukocytosis alone has not been found to be reliable. During expectant management, monitoring for sustained maternal or fetal tachycardia, for uterine tenderness, and for a malodorous vaginal discharge is warranted.

With chorioamnionitis, fetal and neonatal morbidity is substantively increased. Alexander and colleagues (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with similar newborns without clinical infection. Those in the infected group had a higher incidence of sepsis, respiratory distress syndrome, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. The investigators concluded that these very-low-birthweight neonates were vulnerable to neurological injury attributable to chorioamnionitis.

Although Locatelli and coworkers (2005) have challenged this finding, there is other evidence that very small newborns are at increased risk for sepsis. Yoon and colleagues (2000) found that intraamniotic infection in preterm neonates was related to increased rates of cerebral palsy. Petrova and associates (2001) studied more than 11 million singleton live births in the United States from 1995 to 1997. During labor, 1.6 percent of all women had fever, and this was a strong predictor of infection-related death in both term and preterm neonates. Bullard and colleagues (2002) reported similar results.

Accelerated Pulmonary Maturation

Various clinical events—some well defined—were once proposed to accelerate fetal surfactant production (Gluck, 1979). These included chronic renal or cardiovascular disease, hypertensive disorders, heroin addiction, fetal-growth restriction, placental infarction, chorioamnionitis, and preterm ruptured membranes. Although this view was widely held for many years, subsequent observations do not support this association (Hallak, 1993; Owen, 1990).

Antimicrobial Therapy

The proposed microbial pathogenesis for spontaneous preterm labor or ruptured membranes has prompted investigators to give various antimicrobials in an attempt to forestall delivery. Mercer and associates (1995) reviewed 13 randomized trials performed before 35 weeks. Metaanalysis indicated that only three of 10 outcomes were *possibly* benefited: (1) fewer women developed chorioamnionitis, (2) fewer newborns developed sepsis, and (3) pregnancy was more often prolonged 7 days in women given antimicrobials. Neonatal survival, however, was unaffected, as was the incidence of necrotizing enterocolitis, respiratory distress, or intracranial hemorrhage.

To further address this issue, the MFMU Network designed a trial to study expectant management combined with a 7-day treatment with ampicillin, amoxicillin plus erythromycin, or placebo. The women had membrane rupture between 24 and 32 weeks. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer newborns with respiratory distress syndrome, necrotizing enterocolitis, and composite adverse outcomes (Mercer, 1997). The latency period was significantly longer. Specifically, 50 percent of women given an antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of

those given placebo. There was also significant prolongation of pregnancy at 14 and 21 days. Cervicovaginal group B streptococcal colonization did not alter these results.

More recent studies have examined the efficacy of shorter treatment lengths and other antimicrobial combinations. Three-day treatment compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appeared equally effective in regard to perinatal outcomes (Lewis, 2003; Segel, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The amoxicillin-clavulanate regimen was not recommended, however, because of its association with an increased incidence of necrotizing enterocolitis (Kenyon, 2004).

Some predicted that prolonged antimicrobial therapy in such pregnancies might have unwanted consequences. Carroll (1996) and Mercer (1999) and their coworkers cautioned that such therapy potentially increased the risk for resistant bacteria. Stoll and associates (2002) studied 4337 neonates weighing from 400 to 1500 g and born from 1998 to 2000. Their outcomes were compared with those of 7606 neonates of similar birthweight born from 1991 to 1993. The overall rate of early-onset sepsis did not change between these two epochs. But the rate of group B streptococcal sepsis decreased from 5.9 per 1000 births in the 1991 to 1993 group to 1.7 per 1000 births in the 1998 to 2000 group. Comparing these same epochs, the rate of *Escherichia coli* sepsis increased from 3.2 to 6.8 per 1000 births. Almost 85 percent of coliform isolates from the more recent cohort were ampicillin resistant. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms. Kenyon and coworkers (2008a) found that antimicrobials given for women with PPROM had no effect on the health of children at age 7 years.

Corticosteroids to Accelerate Fetal Lung Maturity

The National Institutes of Health (NIH) (2000) in their Consensus Development Conference recommended a single course of antenatal corticosteroids for women with preterm membrane rupture before 32 weeks and in whom there was no evidence of chorioamnionitis. Since then, several metaanalyses have addressed this issue, and according to the American College of Obstetricians and Gynecologists (2013d), single-dose therapy is recommended from 24 to 32 weeks. There is no consensus regarding treatment between 32 and 34 weeks. Corticosteroid therapy is not recommended before 24 weeks.

Membrane Repair

Tissue sealants have been used for various purposes in medicine and have become important in maintaining surgical hemostasis and stimulating wound healing. Devlieger and colleagues (2006) have reviewed the efficacy of sealants in the repair of fetal membrane defects such as in preterm ruptured membranes.

Management Recommendations

The management scheme recommended by the American College of Obstetricians and Gynecologists (2013d) is summarized in [Table 42-9](#). This management is similar to that practiced at Parkland Hospital.

MANAGEMENT OF PRETERM LABOR WITH INTACT MEMBRANES

Women with signs and symptoms of preterm labor with intact membranes are managed much the same as described above for

TABLE 42-9. Recommended Management of Preterm Ruptured Membranes

Gestational Age	Management
34 weeks or more	Proceed to delivery, usually by induction of labor Group B streptococcal prophylaxis is recommended
32 weeks to 33 completed weeks	Expectant management unless fetal pulmonary maturity is documented Group B streptococcal prophylaxis is recommended Corticosteroids—no consensus, but some experts recommend Antimicrobials to prolong latency if no contraindications
24 weeks to 31 completed weeks	Expectant management Group B streptococcal prophylaxis is recommended Single-course corticosteroid use is recommended Tocolytics—no consensus Antimicrobials to prolong latency if no contraindications
Before 24 weeks ^a	Patient counseling Expectant management or induction of labor Group B streptococcal prophylaxis is not recommended Corticosteroids are not recommended Antimicrobials—there are incomplete data on use in prolonging latency

^aThe combination of birthweight, gestational age, and sex provides the best estimate of chances of survival and should be considered in individual cases.

those with preterm ruptured membranes. If possible, delivery before 34 weeks is delayed. Drugs used to abate or suppress preterm uterine contractions are subsequently discussed.

■ Amniocentesis to Detect Infection

Several tests have been used to diagnose intraamniotic infection. Romero and coworkers (1993) evaluated the diagnostic value of amniotic fluid containing an elevated leukocyte count, a low glucose level, a high IL-6 concentration, or a positive Gram stain result in 120 women with preterm labor and intact membranes. Women with positive amniotic fluid culture results were considered infected. These investigators found that a negative Gram stain result was 99-percent specific to exclude amniotic fluid bacteria. A high IL-6 level was 82-percent sensitive for detection of amniotic fluid containing bacteria. Other investigators have also found good correlation between amniotic fluid IL-6 or leukocyte levels and chorioamniotic infection (Andrews, 1995; Yoon, 1996). Despite these correlations, amniocentesis to diagnose infection does not improve pregnancy outcomes in women with or without membrane rupture (Feinstein, 1986). The American College of Obstetricians and Gynecologists (2012a) has concluded that there is no evidence to support routine amniocentesis to identify infection.

■ Corticosteroids for Fetal Lung Maturation

Because glucocorticosteroids were found to accelerate lung maturation in preterm sheep fetuses, Liggins and Howie (1972) evaluated them to treat women. Corticosteroid therapy was effective in lowering the incidence of respiratory distress syndrome and neonatal mortality rates if birth was delayed for at least 24 hours after *initiation* of betamethasone. Infants exposed to corticosteroids in these early studies have now been followed to age 31 years with no ill effects detected. In 1995, an NIH Consensus Development Conference panel recommended corticosteroids for fetal lung maturation in threatened preterm birth.

In a subsequent meeting, the NIH Consensus Development Conference (2000) concluded that data were insufficient to assess corticosteroid effectiveness in pregnancies complicated by hypertension, diabetes, multifetal gestation, fetal-growth restriction, and fetal hydrops. It concluded, however, that it was reasonable to administer corticosteroids in women with these complications.

The issue of the fetal and neonatal safety with single versus repeat courses of intramuscular corticosteroids for lung maturation has been the topic of two major trials. Although both found repeated courses to be beneficial in reducing neonatal respiratory morbidity rates, the long-term consequences were much different. Specifically, Crowther and associates (2007) studied outcomes in 982 women who were given a single weekly dose of 11.4 mg of betamethasone. These investigators found no adverse effects in the infants followed to age 2 years. Wapner and colleagues (2007) studied infants born to 495 women who were randomly assigned to receive a single corticosteroid course or repeated courses that were given weekly. With each round, a 12-mg betamethasone dose was injected, followed by a second

given 24 hours later. A nonsignificant rise in cerebral palsy rates was identified in infants exposed to repeated courses. The twice-as-large betamethasone dose in this study was worrisome because some experimental evidence supports the view that adverse corticosteroid effects are dose dependent. Bruschettini and coworkers (2006) studied the equivalent of 12-mg versus 6-mg betamethasone given to pregnant cats. They reported that the lower dose had less severe effects on somatic growth without affecting fetal brain cell proliferation. Stiles (2007) summarized these two human studies as “early gain, long-term questions.” We agree, and at Parkland Hospital, we follow the recommendation by the American College of Obstetricians and Gynecologists (2013c) for single-course therapy.

“Rescue Therapy”

This refers to administration of a repeated corticosteroid dose when delivery becomes imminent and more than 7 days have elapsed since the initial dose. The 2000 NIH Consensus Development Conference recommended that rescue therapy should not be routinely used and that it should be reserved for clinical trials. The first randomized trial, reported by Peltoniemi and coworkers (2007), allocated 326 women to placebo or 12-mg betamethasone single-dose rescue regimens. Paradoxically, these researchers found that the rescue dose of betamethasone increased the risk of respiratory distress syndrome! In a multicenter study of 437 women < 33 weeks who were randomly assigned to rescue therapy or placebo, Kurtzman and associates (2009) reported significantly decreased rates of respiratory complications and neonatal composite morbidity with rescue corticosteroids. There were, however, no differences in perinatal mortality rates and other morbidities. In another trial, McEvoy and colleagues (2010) showed that treated infants had improved respiratory compliance.

Garite and coworkers (2009) randomly assigned 437 women with singletons or twins < 33 weeks' gestation and with intact membranes to one “rescue” course of either betamethasone or dexamethasone or placebo. These women had all previously completed a single course of corticosteroids before 30 weeks' gestation and at least 14 days before the “rescue” course. Respiratory distress syndrome developed in 41 percent of the infants given corticosteroids compared with 62 percent of those randomized to placebo. There were no differences in other morbidities attributable to prematurity. In a metaanalysis, Crowther and colleagues (2011) concluded that a single course of corticosteroids should be considered in women whose prior course was administered at least 7 days previously and were < 34 weeks' gestation. The American College of Obstetricians and Gynecologists (2012a) has taken the position that a single rescue course of antenatal corticosteroids *should be considered* in women before 34 weeks whose prior course was administered at least 7 days previously.

Choice of Corticosteroid

As summarized by Murphy (2007), there is a 10-year question as to whether betamethasone is superior to dexamethasone for fetal lung maturation. Elimian and associates (2007) randomly assigned 299 women between 24 and 33 weeks to betamethasone or dexamethasone. These two drugs were comparable in reducing rates of major neonatal morbidities in preterm infants.

Antimicrobials

As with preterm ruptured membranes, antimicrobials have been given in an attempt to arrest preterm labor. Results have been disappointing. A Cochrane metaanalysis by King and colleagues (2000) found no difference in the rates of newborn respiratory distress syndrome or sepsis between placebo- and antimicrobial-treated groups. They did find, however, increased perinatal morbidity in the antimicrobial-treated group. Kenyon (2001) reported the ORACLE Collaborative Group study of 6295 women with spontaneous preterm labor, intact membranes, but without evidence of infection. Women were randomly assigned to receive antimicrobial or placebo therapy. The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In his review, Goldenberg (2002) also concluded that antimicrobial treatment of women with preterm labor for the sole purpose of preventing delivery is generally not recommended. In a follow-up of the ORACLE II trial, Kenyon and associates (2008b) reported that fetal exposure to antimicrobials in this clinical setting was associated with an increased cerebral palsy rate at age 7 years compared with that of children without fetal exposure.

Bed Rest

This is one of the most often prescribed interventions during pregnancy, yet one of the least studied. Goldenberg (1994) reviewed the available literature on bed rest in pregnancy and found no evidence supporting or refuting the benefit of either bed rest or hospitalization for women with threatened preterm labor. Moreover, Sosa and colleagues (2004) searched the Cochrane Database and concluded that evidence neither supported nor refuted bed rest to prevent preterm birth.

Goulet and coworkers (2001) randomly assigned 250 Canadian women to either home care or hospitalization after treatment of an acute episode of preterm labor and also found no benefits. Yost and associates (2005) attempted a randomized study at Parkland Hospital but terminated the study after 6 years due to low recruitment. In this study, bed rest in the hospital compared with bed rest at home had no effect on pregnancy duration in women with threatened preterm labor before 34 weeks. Kovacevich and coworkers (2000) reported that bed rest for 3 days or more increased thromboembolic complications to 16 per 1000 women compared with only 1 per 1000 with normal ambulation. Promislow and colleagues (2004) observed significant bone loss in pregnant women prescribed outpatient bed rest.

Most recently there were three articles on bed rest in the journal *Obstetrics & Gynecology*. Grobman and associates (2013) found that nearly 40 percent of women enrolled in a trial to study the efficacy of 17-OHPC in those with a sonographically short cervix had some form of activity restriction. Women with activity restriction were nearly 2.5 times more likely to have a preterm birth before 34 weeks. This finding, however, may reflect ascertainment bias in that women with restricted activity may have received bed rest because they were viewed to be at more imminent risk of preterm delivery. In the same journal issue, McCall and coworkers (2013) summarized the literature

on bed rest. They found insufficient evidence to support the use of bed rest and found several studies showing harm with its use. They opined that it is unethical to continue to prescribe bed rest. In an accompanying editorial, Biggio (2013) called for appropriate trials to settle these issues.

Cervical Pessaries

There is increasing interest in the use of cervical pessaries to prevent preterm birth. Silicone rings, also known as the *Arabin pessary*, are being used to support the cervix in women with a sonographically short cervix. For 385 Spanish women with cervical lengths ≤ 25 mm, Goya and colleagues (2012) provided a silicone pessary or expectant management. There was spontaneous delivery before 34 weeks' gestation in 6 percent of women in the pessary group compared with 27 percent in the expectant management group. Hui and associates (2013) randomly assigned approximately 100 women with cervixes < 25 mm at 20 to 24 weeks to silicone pessaries or expectant management. The prophylactic use of silicone pessary did not reduce the rate of delivery before 34 weeks. These two studies with conflicting results are the only randomized trials to date. Currently, the MFMU Network is designing a trial to study pessary use to prevent preterm labor in twin pregnancies.

Emergency or Rescue Cerclage

There is support for the concept that cervical incompetence and preterm labor lie on a spectrum leading to preterm delivery. Consequently, investigators have evaluated cerclage performed after preterm labor begins to manifest clinically. More than 30 years ago, Harger (1983) concluded that if cervical incompetence is recognized with threatened preterm labor, then emergency cerclage can be attempted, albeit with an appreciable risk of infection and pregnancy loss. Althuisius and colleagues (2003) randomly assigned 23 women with cervical incompetence before 27 weeks to bed rest, with or without emergency McDonald cerclage. Delivery delay was significantly greater in the cerclage group compared with that assigned to bed rest alone—54 versus 24 days. Terkildsen and coworkers (2003) studied 116 women who underwent second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage before 22 weeks were associated with a significantly decreased chance of pregnancy continuation to 28 weeks or beyond.

Tocolysis to Treat Preterm Labor

Although several drugs and other interventions have been used to prevent or inhibit preterm labor, none has been shown to be completely effective. The American College of Obstetricians and Gynecologists (2012a) has concluded that tocolytic agents do not markedly prolong gestation but may delay delivery in some women for up to 48 hours. This may allow transport to a regional obstetrical center and permit time for corticosteroid therapy. Beta-adrenergic agonists, calcium-channel blockers, or indomethacin are the recommended tocolytic agents for such short-term use—up to 48 hours. In contrast, the College has

concluded that “Maintenance therapy with tocolytics is ineffective for preventing preterm birth and improving neonatal outcome and is not recommended for this purpose.” Moreover, the College recommends that women with preterm contractions without cervical change, especially those with cervical dilation of less than 2 cm, generally should not be treated with tocolytics.

β-Adrenergic Receptor Agonists

Several compounds react with β-adrenergic receptors to reduce intracellular ionized calcium levels and prevent activation of myometrial contractile proteins (Chap. 21, p. 421). In the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine had been approved for preterm labor by the FDA.

Ritodrine. According to the Federal Register, ritodrine was voluntarily withdrawn from the United States market in 2003. A discussion is included here because knowledge concerning β-mimetic drugs accrued with its use. In an early multicenter trial, neonates whose mothers were treated with ritodrine for threatened preterm labor had lower rates of preterm birth, death, and respiratory distress (Merkatz, 1980). In a randomized trial at Parkland Hospital, Leveno and associates (1986) found that intravenous drug treatment delayed delivery for 24 hours but without other benefits. Additional studies of parenteral β-agonists confirmed a delivery delay up to 48 hours (Canadian Preterm Labor Investigators Group, 1992).

Unfortunately, this delay in preterm delivery provided no fetal benefits. Macones and colleagues (1995) used metaanalysis to assess the efficacy of *oral* β-agonist therapy and found no benefits. Keirse (1995b) suggested that this brief delay may aid maternal transport to tertiary care or permit fetal lung maturation with corticosteroids. Although this intuitive reasoning is logical, there are no data to support this.

β-Agonist infusion has resulted in frequent and, at times, serious and even fatal maternal side effects. Pulmonary edema is a special concern, and its contribution to morbidity is discussed in Chapter 47 (p. 942). Tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry, 1998). The cause of pulmonary edema is multifactorial. Risk factors include tocolytic therapy with β-agonists, multifetal gestation, concurrent corticosteroid therapy, tocolysis for more than 24 hours, and large intravenous crystalloid volume infusion. Because β-agonists cause retention of sodium and water, with time—usually 24 to 48 hours, these can cause volume overload (Hankins, 1988). The drugs have been implicated in increased capillary permeability, cardiac rhythm disturbances, and myocardial ischemia.

Terbutaline. This β-agonist is commonly used to forestall preterm labor. Like ritodrine, it can cause pulmonary edema (Angel, 1988). Low-dose terbutaline can be administered long-term by subcutaneous pump (Lam, 1988). Marketed between 1987 and 1993, these pumps were used in nearly 25,000 women with suspected preterm labor (Perry, 1995). Adverse reports describe a sudden maternal death and a newborn

with myocardial necrosis after the mother used the pump for 12 weeks (Fletcher, 1991; Hudgens, 1993). Elliott and associates (2004) used continuous terbutaline subcutaneous infusion in 9359 patients and reported that only 12 women experienced severe adverse events—primarily pulmonary edema.

However, randomized trials have reported no benefit for terbutaline pump therapy. Wenstrom and coworkers (1997) randomly assigned 42 women with preterm labor to a terbutaline pump, to a saline pump, or to oral terbutaline. In another trial, Guinn and colleagues (1998) randomly treated 52 women with terbutaline or with saline pump therapy. Terbutaline did not significantly prolong pregnancy, prevent preterm delivery, or improve neonatal outcomes in either of these studies.

Oral terbutaline therapy to prevent preterm delivery has also not been effective (How, 1995; Parilla, 1993). In a double-blind trial, Lewis and coworkers (1996) studied 203 women with arrested preterm labor at 24 to 34 weeks. Women were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours. Delivery rates at 1 week were similar in both groups, as was median latency, mean gestational age at delivery, and the incidence of recurrent preterm labor. In 2011, the FDA issued a warning regarding use of terbutaline to treat preterm labor because of reports of serious maternal side effects.

Magnesium Sulfate

Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. Its role is presumably that of a calcium antagonist, and when given in pharmacological doses, it may inhibit labor. Steer and Petrie (1977) concluded that intravenous magnesium sulfate—a 4-g loading dose followed by a continuous infusion of 2 g/hr—usually arrests labor. The pharmacology and toxicology of magnesium are considered in more detail in Chapter 40 (p. 759). Samol and associates (2005) reported 67 cases—8.5 percent—of pulmonary edema among 789 women given tocolysis with magnesium sulfate at their hospital.

There have been only two randomized placebo-controlled studies of tocolysis with magnesium sulfate. Cotton and colleagues (1984) compared magnesium sulfate, ritodrine, and placebo in 54 women in preterm labor. They identified few differences in outcomes. Cox and coworkers (1990) randomly assigned 156 women to receive magnesium sulfate or normal saline infusions. Magnesium-treated women and their fetuses had identical outcomes compared with those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital. Grimes (2006) reviewed this tocolytic agent and concluded it was ineffective and potentially harmful.

Recently, the FDA (2013) warned against prolonged use of magnesium sulfate given to arrest preterm labor due to bone thinning and fractures in fetuses exposed for more than 5 to 7 days. This was attributed to low calcium levels in the fetus.

Prostaglandin Inhibitors

Prostaglandins are intimately involved in contractions of normal labor (Chap. 21, p. 426). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs. A group of enzymes collectively termed *prostaglandin*

synthase is responsible for the conversion of free arachidonic acid to prostaglandins (Fig. 21-16, p. 422). Several drugs block this system, including acetylsalicylate and indomethacin.

Indomethacin was first used as a tocolytic for 50 women by Zuckerman and associates (1974). Studies that followed reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench, 2003; Niebyl, 1980). Morales and coworkers (1989, 1993a), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery. Berghella and associates (2006) reviewed four trials of indomethacin given to women with sonographically short cervixes and found such therapy ineffective.

Indomethacin is administered orally or rectally. A dose of 50 to 100 mg is followed at 8-hour intervals not to exceed a total 24-hour dose of 200 mg. Serum concentrations usually peak 1 to 2 hours after oral administration, whereas levels after rectal administration peak slightly earlier. Most studies have limited indomethacin use to 24 to 48 hours because of concerns for oligohydramnios, which can develop with these doses. If amniotic fluid is monitored, oligohydramnios can be detected early, and it is reversible with drug discontinuation.

Case-control studies have assessed neonatal effects of exposure to indomethacin given for preterm labor. In a study of neonates born before 30 weeks, Norton and coworkers (1993) identified necrotizing enterocolitis in 30 percent of 37 indomethacin-exposed newborns compared with 8 percent of 37 control newborns. Higher incidences of intraventricular hemorrhage and patent ductus arteriosus were also documented in the indomethacin group. The impact of treatment duration and its timing in relation to delivery were not reported. In contrast, several investigators have challenged the association between indomethacin exposure and necrotizing enterocolitis (Muench, 2001; Parilla, 2000). Finally, Gardner (1996) and Abbasi (2003) and their colleagues found no link between indomethacin use and intraventricular hemorrhage, patent ductus arteriosus, sepsis, necrotizing enterocolitis, or neonatal death.

Schmidt and associates (2001) followed 574 newborns who were randomly assigned to receive either indomethacin or placebo to prevent pulmonary hypertension from patent ductus arteriosus. The infants, who weighed 500 to 1000 g, were followed to a corrected age of 18 months. Those given indomethacin had a significantly *reduced* incidence of both patent ductus arteriosus and severe intraventricular hemorrhage. Survival without impairment, however, was similar in both groups. Peck and coworkers (2003) reported that indomethacin therapy for 7 or more days before 33 weeks does not increase the risk of neonatal or childhood medical problems. Two metaanalyses of the effects of antenatal indomethacin on neonatal outcomes had conflicting findings (Amin, 2007; Loe, 2005).

Calcium-Channel Blockers

Myometrial activity is directly related to cytoplasmic free calcium, and a reduction in its concentration inhibits contractions (Chap. 21, p. 417). Calcium-channel blockers act to inhibit, by various mechanisms, calcium entry through cell membrane channels. Although they were developed to treat hypertension, their ability to arrest preterm labor has been evaluated.

Using the Cochrane Database, Keirse (1995a) compared nifedipine and β -agonists. They concluded that although nifedipine treatment reduced births of neonates weighing < 2500 g, significantly more of these were admitted for intensive care. Other investigators have also concluded that calcium-channel blockers, especially nifedipine, are safer and more effective tocolytic agents than are β -agonists (King, 2003; Papatonis, 1997). Lyell and colleagues (2007) randomized 192 women at 24 to 33 weeks to either magnesium sulfate or nifedipine and found no substantial differences in efficacy or adverse effects. Salim and associates (2012) randomly assigned 145 women in preterm labor between 24 and 33 weeks to nifedipine or atosiban. No clear superiority of either to delay delivery was identified, and otherwise, neonatal morbidity was equivalent. Importantly, no randomized trial has compared nifedipine to placebo for *acute tocolysis*.

The combination of nifedipine with magnesium for tocolysis is potentially dangerous. Ben-Ami (1994) and Kurtzman (1993) and their coworkers reported that nifedipine enhances the neuromuscular blocking effects of magnesium that can interfere with pulmonary and cardiac function. How and associates (2006) randomly provided 54 women between 32^{0/7} and 34^{6/7} weeks with magnesium sulfate plus nifedipine or no tocolytic and found neither benefit nor harm.

Atosiban

This nonapeptide oxytocin analogue is a competitive antagonist of oxytocin-induced contractions. Goodwin and colleagues (1995) described its pharmacokinetics in pregnant women. In randomized clinical trials, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Moutquin, 2000; Romero, 2000). The FDA has denied approval of atosiban because of concerns regarding efficacy and fetal–newborn safety. Goodwin (2004) has reviewed the history of atosiban both in the United States and in Europe, where this drug is approved and widely used as a tocolytic.

Nitric Oxide Donors

These potent smooth-muscle relaxants affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously was not effective or showed no superiority to other tocolytics. In addition, maternal hypotension was a common side effect (Bisits, 2004; Clavin, 1996; El-Sayed, 1999; Lees, 1999).

Summary of Tocolysis for Preterm Labor

In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. In a metaanalysis of tocolytic therapy, Gyetvai and associates (1999) concluded that although delivery may be delayed long enough for administration of corticosteroids, treatment does not result in improved perinatal outcome. Berkman and colleagues (2003) reviewed 60 reports and concluded that tocolytic therapy can prolong gestation, but that β -agonists are no better than other drugs and pose potential maternal danger. They also concluded that there are no benefits of maintenance tocolytic therapy.

In general, if tocolytics are given, they should be administered concomitantly with corticosteroids. The gestational age

range for their use is debatable. However, because corticosteroids are not generally used after 33 weeks and because the perinatal outcomes in preterm neonates are generally good after this time, most practitioners do not recommend use of tocolytics at or after 33 weeks (Goldenberg, 2002).

■ Labor

Whether labor is induced or spontaneous, abnormalities of fetal heart rate and uterine contractions should be sought. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, is suggestive of sepsis. There is some evidence that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Low and colleagues (1995) observed that intrapartum acidosis—umbilical artery blood pH less than 7.0—had an important role in neonatal complications (Chap. 32, p. 629). Similarly, Kimberlin and coworkers (1996) found that increasing umbilical artery blood acidemia was related to more severe respiratory disease in preterm neonates. Despite this, no effects were found in short-term neurological outcomes that included intracranial hemorrhages.

Group B streptococcal infections are common and dangerous in the preterm neonate. Accordingly, as discussed in Chapter 64 (p. 1249), prophylaxis should be provided.

■ Delivery

In the absence of a relaxed vaginal outlet, an episiotomy for delivery may be necessary once the fetal head reaches the perineum. Perinatal outcome data do not support routine forceps delivery to protect the “fragile” preterm fetal head. Staff proficient in resuscitative techniques commensurate with the gestational age and fully oriented to any specific problems should be present at delivery. Principles of resuscitation described in Chapter 32 are applicable. The importance of specialized personnel and facilities for preterm newborn care is underscored by the improved survival rates of these neonates when delivered in tertiary-care centers.

■ Prevention of Neonatal Intracranial Hemorrhage

Preterm newborns frequently have intracranial germinal matrix bleeding that can extend to more serious intraventricular hemorrhage (Chap. 34, p. 656). It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by most subsequent studies. Malloy (1991) analyzed 1765 newborns with birthweights less than 1500 g and found that cesarean delivery did not lower the risk of mortality or intracranial hemorrhage. Anderson (1988), however, made an interesting observation regarding the role of cesarean delivery in intracranial hemorrhage prevention. These hemorrhages correlated with exposure to active-phase labor. However, they emphasized that avoidance of active-phase labor is impossible in most preterm births because decisions for delivery route are not required until active labor is firmly established.

Magnesium Sulfate for Fetal Neuroprotection

In intriguing reports, very-low-birthweight neonates whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia were found to have a reduced incidence of cerebral palsy at 3 years (Grether, 2000; Nelson, 1995). Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, randomized trials were designed to investigate this hypothesis. An Australian randomized trial by Crowther and coworkers (2003) included 1063 women at imminent risk of delivery before 30 weeks and who were given magnesium sulfate or placebo. These investigators showed that magnesium exposure improved some perinatal outcomes. Rates of both neonatal death and cerebral palsy were lower in the magnesium-treated group—but this study was not sufficiently powered. The multicenter French trial reported by Marret and associates (2008) had similar problems.

More convincing evidence for magnesium neuroprotection came from the NICHD MFMU Network study reported by Rouse and colleagues (2008). The *Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—Study* was a placebo-controlled trial in 2241 women at imminent risk for preterm birth between 24 and 31 weeks. Almost 87 percent had preterm ruptured membranes, and almost a fifth had previously received magnesium sulfate for tocolysis. Women randomized to magnesium sulfate were given a 6-g bolus over 20 to 30 minutes followed by a maintenance infusion of 2 g per hour. Magnesium sulfate was actually infusing at the time of delivery in approximately half of the treated women. A 2-year follow-up was available for 96 percent of the children. Selected results are shown in [Table 42-10](#). This trial can be interpreted differently depending on statistical philosophy. Some opt to interpret these findings to mean that magnesium sulfate infusion prevents cerebral palsy regardless of the gestational age at which the therapy is given. Those with a differing view conclude that this trial only supports use of magnesium sulfate for prevention of cerebral palsy before 28 weeks. What is certain, however, is that maternally administered magnesium sulfate infusions cannot be implicated in increased perinatal deaths as reported by Mittendorf (1997).

Subsequent to these studies, Doyle and associates (2009) performed a Cochrane review of the five available randomized trials to assess neuroprotective effects of magnesium sulfate. A total of 6145 infants were studied, and as expected, most came from the three larger Australian, French, and MFMU Network multicenter studies. These reviewers reported that magnesium exposure compared with no exposure significantly decreased risks for cerebral palsy, with a relative risk of 0.68. There were no significant effects on rates of pediatric mortality or other neurological impairments or disabilities. It was calculated that treatment given to 63 women would prevent one case of cerebral palsy.

There was debate regarding magnesium efficacy for neuroprotection at the 2011 annual meeting of the Society for Maternal-Fetal Medicine. Rouse (2011) spoke for the benefits of magnesium sulfate, whereas Sibai (2011) challenged that the reported benefits vis-à-vis neuroprotection were false positive due to random statistical error in the Doyle (2009) metaanalysis.

TABLE 42-10. Magnesium Sulfate for the Prevention of Cerebral Palsy^a

Perinatal Outcome ^a	Treatment		
	Magnesium Sulfate No. (%)	Placebo No. (%)	Relative Risk (95% CI)
Infants with 2-year follow-up	1041 (100)	1095 (100)	—
Fetal or infant death	99 (9.5)	93 (8.5)	1.12 (0.85–1.47)
Moderate or severe cerebral palsy:			
Overall	20/1041 (1.9)	3/1095 (3.4)	0.55 (0.32–0.95)
< 28–31 weeks ^b	12/442 (2.7)	30/496 (6)	0.45 (0.23–0.87)
≥ 24–27 weeks ^b	8/599 (1.3)	8/599 (1.3)	1.00 (0.38–2.65)

^aSelected results from the Beneficial Effects of Antenatal Magnesium Sulfate (BEAM) Study.^bWeeks' gestation at randomization.

Data from Rouse, 2008.

The American College of Obstetricians and Gynecologists (2013a) recognized that “none of the individual studies found a benefit with regard to their primary outcome.” It was concluded that “Physicians electing to use magnesium sulfate for fetal neuroprotection should develop specific guidelines regarding inclusion criteria, treatment regimen. ...” Subsequently, the American College of Obstetricians and Gynecologists (2012a) issued a *Patient Safety Checklist* that could be used if magnesium sulfate is given for neuroprotection.

Because of these findings, at Parkland Hospital our policy is to provide magnesium sulfate for threatened preterm delivery from 24^{0/7} to 27^{6/7} weeks. A 6-g loading dose is followed by an infusion of 2 g per hour for at least 12 hours.

CHAPTER 43

Postterm Pregnancy

ESTIMATED GESTATIONAL AGE USING MENSTRUAL DATES 862

INCIDENCE 863

PERINATAL MORTALITY 863

PATHOPHYSIOLOGY 864

COMPLICATIONS 866

MANAGEMENT 867

INTRAPARTUM MANAGEMENT 869

The adjectives *postterm*, *prolonged*, *postdates*, and *postmature* are often loosely used interchangeably to describe pregnancies that have exceeded a duration considered to be the upper limit of normal. We do not recommend use of the term *postdates* because the real issue in many postterm pregnancies is “post-*what* dates?” *Postmature* is reserved for the relatively uncommon specific clinical fetal syndrome in which the infant has recognizable clinical features indicating a pathologically prolonged pregnancy. Therefore, *postterm* or *prolonged* pregnancy is our preferred expression for an extended pregnancy.

The international definition of prolonged pregnancy, endorsed by the American College of Obstetricians and Gynecologists (2013a), is 42 completed weeks—294 days—or more from the first day of the last menstrual period. It is important to emphasize the phrase “42 completed weeks.” Pregnancies between 41 weeks 1 day and 41 weeks 6 days, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. Thus, technically speaking, prolonged pregnancy could begin either on day 294 or on day 295 following the onset of the last menses. Which is it? Day 294 or 295? We cannot resolve this question, and emphasize this dilemma only to ensure that litigators and others understand that some

imprecision is inevitable when there is biological variation such as with prolonged pregnancy. Amersi and Grimes (1998) have cautioned against use of ordinal numbers such as “42nd week” because of imprecision. For example, “42nd week” refers to 41 weeks and 1 through 6 days, whereas the cardinal number “42 weeks” refers to precisely 42 completed weeks.

ESTIMATED GESTATIONAL AGE USING MENSTRUAL DATES

The definition of postterm pregnancy as one that persists for 42 weeks or more from the onset of a menstrual period assumes that the last menses was followed by ovulation 2 weeks later. That said, some pregnancies may not actually be postterm, but rather are the result of an error in gestational age estimation because of faulty menstrual date recall or delayed ovulation. Thus, there are two categories of pregnancies that reach 42 completed weeks: (1) those truly 40 weeks past conception, and (2) those of less-advanced gestation but with inaccurately estimated gestational age. Even with precisely recalled menstrual dates, there is still not precision. Specifically, Munster and associates (1992) reported that large variations in menstrual cycle lengths are common in normal women. Boyce and coworkers (1976) studied 317 French women with periconceptional basal body temperature profiles. Almost 70 percent who completed 42 postmenstrual weeks had a less-advanced gestation based on ovulation dates. These variations in the menstrual cycle may partially explain why a relatively small proportion of fetuses delivered postterm have evidence of *postmaturity syndrome*. Even so, because there is no accurate method to identify the truly prolonged pregnancy, all those judged to have reached 42 completed weeks should be managed as if abnormally prolonged. Sonographic evaluation of gestational age during pregnancy has been used to add precision. Blondel and colleagues (2002) studied 44,623 women delivered at the Royal Victoria Hospital in Montreal. Postterm pregnancy rates were analyzed

according to six algorithms for gestational age based on the last menstrual period, sonographic evaluation at 16 to 18 weeks, or both. The proportion of births at 42 weeks or longer was 6.4 percent when based on the last menstrual period alone, but was 1.9 percent when based on sonographic measurements alone. Similarly, sonographic pregnancy dating at ≤ 12 weeks resulted in a 2.7-percent incidence of postterm gestation compared with 3.7 percent in a group assessed at 13 to 24 weeks (Caughey, 2008). These findings suggest that menstrual dates are frequently inaccurate in predicting postterm pregnancy. Other clinical studies confirmed these observations (Bennett, 2004; Joseph, 2007; Wingate, 2007).

INCIDENCE

From a review, the incidence of postterm pregnancy ranged from 4 to 19 percent (Divon, 2008). Using criteria that likely overestimate the incidence, approximately 6 percent of 4 million infants born in the United States during 2009 were estimated to have been delivered at 42 weeks or more (Martin, 2011). The trend toward fewer births at 42 weeks suggests earlier intervention. Specifically, in 2000, 7.2 percent of births in this country were 42 weeks or beyond compared with 5.5 percent in 2009. Zhang and colleagues (2010) studied live births in this country from 1992 through 2003 and reported dramatic increases in labor induction rates at 41 and 42 weeks' gestation (Fig. 43-1). This significantly increased use of labor induction was posited to contribute to a downward shift of the overall mean birthweight for these infants born in the United States.

There are contradictory findings concerning maternal demographic factors such as parity, prior postterm birth, socioeconomic class, and age as risks for postterm pregnancy. Olesen and associates (2006) analyzed various risk factors in 3392 participants in the 1998 to 2001 Danish Birth Cohort. Only pre-pregnancy body mass index (BMI) ≥ 25 and nulliparity were significantly associated with prolonged pregnancy. Caughey (2009) and Arrowsmith (2011) and their coworkers also reported similar associations.

FIGURE 43-1 Rates of induction by gestational age among non-Hispanic white singleton livebirths ≥ 37 weeks from 1992 through 2003. (Redrawn from Zhang, 2010, with permission.)

The tendency for some mothers to have repeated postterm births suggests that some prolonged pregnancies are biologically determined. And Mogren and colleagues (1999) reported that prolonged pregnancy recurred across generations in Swedish women. When mother and daughter had a prolonged pregnancy, the risk for the daughter to have a subsequent postterm pregnancy was increased two- to threefold. In another Swedish study, Laursen and associates (2004) found that maternal, but not paternal, genes influenced prolonged pregnancy. As noted in Chapter 21 (p. 426), rare fetal-placental factors that have been reported as predisposing to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (MacDonald, 1965).

PERINATAL MORTALITY

Perinatal mortality rates increase after the expected due date has passed. This is best seen when perinatal mortality rates are analyzed from times before widespread intervention for postterm pregnancies. In two large Swedish studies shown in Figure 43-2, after reaching a nadir at 39 to 40 weeks, the perinatal mortality rate increased as pregnancy exceeded 41 weeks. This trend has also been reported for the United States (MacDorman, 2009). Another study in this country of more than 2.5 million births has similar findings (Cheng, 2008). The major causes of death in these pregnancies included gestational hypertension, prolonged labor with cephalopelvic disproportion, “unexplained anoxia,” and malformations. Similar outcomes were reported by Olesen and colleagues (2003) in 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark. Moster and associates (2010) found increased rates of cerebral palsy in postterm births, and Yang and coworkers (2010) reported lower intelligence quotient (IQ) scores at age 6.5 years in children born ≥ 42 weeks' gestation. Conversely, autism was not associated with postterm birth (Gardener, 2011).

FIGURE 43-2 Perinatal mortality rates in late pregnancy according to gestational age in Sweden of all births during 1943-1952 compared with those during 1977-1978. The partially compressed scale is used for convenience in depiction. (Adapted from Bakketeig, 1991, and Lindell, 1956.)

TABLE 43-1. Pregnancy Outcomes in 56,317 Consecutive Singleton Pregnancies Delivered at or Beyond 40 Weeks at Parkland Hospital from 1988 through 1998

Outcome	Weeks' Gestation			<i>p</i> value ^a
	40 (n = 29,136)	41 (n = 16,386)	42 (n = 10,795)	
Maternal outcomes (%)				
Labor induction	2	7	35	< .001
Cesarean delivery				
Dystocia	7	6	9	< .001
Fetal distress	2	3	4	< .001
Perinatal outcomes (per 1000)				
Neonatal ICU	4	5	6	< .001
Neonatal seizures	1	1	2	.12
Stillbirth	2	1	2	.84
Neonatal death	0.2	0.2	0.6	.17

^a*p* value is for the trend using 42 weeks as the referent.

ICU = intensive care unit.

Adapted from Alexander, 2000a.

Alexander and colleagues (2000a) reviewed 56,317 consecutive singleton pregnancies delivered at ≥ 40 weeks between 1988 and 1998 at Parkland Hospital. As shown in Table 43-1, labor was induced in 35 percent of pregnancies completing 42 weeks. The rate of cesarean delivery for dystocia and fetal distress was significantly increased at 42 weeks compared with earlier deliveries. More infants of postterm pregnancies were admitted to intensive care units. Importantly, the incidence of neonatal seizures and deaths doubled at 42 weeks. Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality in a given week consists of all ongoing pregnancies rather than just the births in a given week. Figure 43-3 shows perinatal mortality rates calculated using only births in a given week of gestation from 37 to 43

completed weeks compared with the cumulative probability—the perinatal index—of death when all ongoing pregnancies are included in the denominator. As shown, delivery at 38 weeks had the lowest risk index for perinatal death.

PATHOPHYSIOLOGY

Postmaturity Syndrome

The postmature infant presents a unique appearance such as shown in Figure 43-4. Features include wrinkled, patchy, peeling skin; a long, thin body suggesting wasting; and advanced maturity in that the infant is open-eyed, unusually alert, and appears old and worried. Skin wrinkling can be particularly prominent on the palms and soles. The nails are typically long. Most postmature infants are not technically growth restricted because their birthweight seldom falls below the 10th percentile for gestational age. On the other hand, severe growth restriction—which logically must have preceded completion of 42 weeks—may be present.

The incidence of postmaturity syndrome in infants at 41, 42, or 43 weeks, respectively, has not been conclusively determined. In one of the rare contemporary reports that chronicle postmaturity, Shime and colleagues (1984) found this syndrome in approximately 10 percent of pregnancies between 41 and 43 weeks. The incidence increased to 33 percent at 44 weeks. Associated oligohydramnios substantially increases the likelihood of postmaturity. Trimmer and associates (1990) reported that 88 percent of infants were postmature if there was oligohydramnios defined by a sonographic maximal vertical amniotic fluid pocket that measured ≤ 1 cm at 42 weeks.

Placental Dysfunction

Clifford (1954) proposed that the skin changes of postmaturity were due to loss of the protective effects of vernix caseosa. He also

FIGURE 43-3 Perinatal mortality rate and perinatal risk index for births between 37 and 43 weeks in Scotland from 1985 through 1996. The perinatal mortality rate is the number of perinatal deaths with delivery in a given gestational week divided by the total number of births in that week multiplied by 1000. The perinatal risk index is the cumulative probability of perinatal death multiplied by 1000. (Redrawn from Smith, 2001, with permission.)

FIGURE 43-4 Postmaturity syndrome. Infant delivered at 43 weeks' gestation with thick, viscous meconium coating the desquamating skin. Note the long, thin appearance and wrinkling of the hands.

attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity is due to placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen, 1995; Rushton, 1991). There are findings that placental apoptosis—programmed cell death—was significantly increased at 41 to 42 completed weeks compared with that at 36 to 39 weeks (Smith, 1999). Several proapoptotic genes such as kisspeptin were shown to be upregulated in postterm placental explants compared with the same genes in term placental explants (Torricelli, 2012). The clinical significance of such apoptosis is currently unclear.

Jazayeri and coworkers (1998) investigated cord blood erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. The only known stimulator of erythropoietin is decreased partial oxygen pressure. Thus, they sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. All women had an uncomplicated labor and delivery. These investigators reported that cord blood erythropoietin levels were significantly increased in pregnancies reaching 41 weeks or more. Although Apgar scores and acid-base studies were normal, these researchers concluded that there was decreased fetal oxygenation in some postterm gestations.

Another scenario is that the postterm fetus may continue to gain weight and thus be unusually large at birth. This at least suggests that placental function is not severely compromised. Indeed, continued fetal growth is the norm—albeit at a slower

FIGURE 43-5 Mean daily fetal growth during previous week of gestation. (From Hendricks, 1964.)

rate beginning at 37 completed weeks (Fig. 43-5). Nahum and colleagues (1995) confirmed that fetal growth continues until at least 42 weeks, however, Link and associates (2007) showed that umbilical blood flow did not increase concomitantly.

Fetal Distress and Oligohydramnios

The principal reasons for increased risks to postterm fetuses were described by Leveno and associates (1984). Both antepartum fetal jeopardy and intrapartum fetal distress were found to be the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum fetal distress detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in Figure 43-6 preceded three fourths of emergency cesarean deliveries for nonreassuring fetal heart rate tracings. In all but two cases, there were also variable decelerations (Fig. 43-7). Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline shown in Figure 43-8. As described in Chapter 24 (p. 484), these findings are consistent with cord occlusion as the proximate cause of the nonreassuring tracings. Other correlates included oligohydramnios and viscous meconium. Schaffer and colleagues (2005) implicated a nuchal cord in abnormal intrapartum fetal heart rate patterns, meconium, and compromised newborn condition in prolonged pregnancies.

The volume of amniotic fluid normally continues to decrease after 38 weeks and may become problematic (Fig. 11-1, p. 233). Moreover, meconium release into an already reduced amniotic fluid volume results in thick, viscous meconium that may cause *meconium aspiration syndrome* (Chap. 33, p. 637).

Trimmer and coworkers (1990) sonographically measured hourly fetal urine production using sequential bladder volume measurements in 38 pregnancies of ≥ 42 weeks. Diminished urine production was found to be associated with oligohydramnios. They hypothesized that decreased fetal urine flow was likely the result of preexisting oligohydramnios that limited fetal swallowing. Oz and associates (2002), using Doppler waveforms, concluded that fetal renal blood flow is reduced in those postterm pregnancies complicated by oligohydramnios.

FIGURE 43-7 Severe—less than 70 bpm for 60 seconds or longer—variable decelerations in a postterm pregnancy with oligohydramnios. (Redrawn from Leveno, 1984, with permission.)

FIGURE 43-8 Saltatory baseline fetal heart rate showing oscillations exceeding 20 bpm and associated with oligohydramnios in a postterm pregnancy. (Redrawn from Leveno, 1984, with permission.)

The study mentioned above, by Link and associates (2007), showed that umbilical blood flow did not increase past term.

Fetal-Growth Restriction

It was not until the late 1990s that the clinical significance of fetal-growth restriction in the otherwise uncomplicated pregnancy became more fully appreciated. Divon (1998) and Clausson (1999) and their coworkers analyzed births between 1991 and 1995 in the National Swedish Medical Birth Registry. As shown in [Table 43-2](#), stillbirths were more common among growth-restricted infants who were delivered after 42 weeks. Indeed, a third of postterm stillborn infants were growth restricted. During this time in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks. In a study from Parkland Hospital, Alexander and colleagues (2000d) analyzed outcomes for 355 infants who were ≥ 42 weeks and whose birthweights were < 3 rd percentile. They compared these with outcomes of 14,520 similarly aged infants above the 3rd percentile and found that morbidity and mortality rates were significantly increased in the growth-restricted infants. Notably, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted infants.

COMPLICATIONS

Oligohydramnios

Most clinical studies support the view that diminished amniotic fluid determined by various sonographic methods identifies a postterm fetus with increased risks. Indeed, decreased amniotic fluid in any pregnancy signifies increased fetal risk (Chap. 11, p. 238). Unfortunately, lack of an exact method to define “decreased amniotic fluid” has limited investigators, and many different criteria for sonographic diagnosis have been proposed. Fischer and colleagues (1993) attempted to determine which criteria were most predictive of normal versus abnormal outcomes in postterm pregnancies. As shown in [Figure 43-9](#), the smaller the amniotic fluid pocket, the greater the likelihood that there was clinically significant oligohydramnios. Importantly, normal

TABLE 43-2. Effects of Fetal-Growth Restriction by Gestational Age on Stillbirth Rates in 537,029 Swedish Women Delivered before and after 42 Weeks

Fetal Outcome	Pregnancy Duration	
	37–41 Weeks	≥ 42 Weeks
Births (No.)	469,056	40,973
Growth restriction ^a n (%)	10,312 (2)	1,558 (4)
Stillbirth n (per 1000)		
Appropriate growth	650 (1.4)	69 (1.8)
Growth restriction	116 (11)	23 (15)

^aDefined as birthweight two standard deviations below mean birthweights for fetal gender and gestational age. Data from Clausson, 1999.

amniotic fluid volume did not preclude abnormal outcomes. Alfirevic and coworkers (1997) randomly assigned 500 women with postterm pregnancies to assessment using either the amniotic fluid index (AFI) or the deepest vertical pocket (Chap. 11, p. 232). They concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.

Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found an increased incidence of some sort of “fetal distress” during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of “normal” amniotic fluid volume is tenuous. This may be related to how quickly pathological oligohydramnios develops. Although such cases are unusual,

FIGURE 43-9 Comparison of the prognostic value of various sonographic estimates of amniotic fluid volume in prolonged pregnancies. Abnormal outcomes include cesarean or operative vaginal delivery for fetal jeopardy, 5-minute Apgar score ≤ 6, umbilical arterial blood pH < 7.1, or admission to the neonatal intensive care unit. (Adapted from Fischer, 1993.)

Clement and coworkers (1987) described six postterm pregnancies in which amniotic fluid volume diminished abruptly over 24 hours, and in one of these, the fetus died.

Macrosomia

The velocity of fetal weight gain peaks at approximately 37 weeks as shown in Figure 43-5. Although growth velocity slows at that time, most fetuses continue to gain weight. For example, the percentage of fetuses born in 2009 whose birthweight exceeded 4000 g was 8.2 percent at 37 to 41 weeks and increased to 11.0 percent at 42 weeks or more (Martin, 2011). However, in some studies, brachial plexus injury was not related to postterm gestation (Walsh, 2011). Intuitively at least, it seems that both maternal and fetal morbidity associated with macrosomia would be mitigated with timely induction to preempt further growth. This does not appear to be the case, however, and the American College of Obstetricians and Gynecologists (2013b) has concluded that current evidence does not support such a practice in women at term with suspected fetal macrosomia. Moreover, the College concluded that in the absence of diabetes, vaginal delivery is not contraindicated for women with an estimated fetal weight up to 5000 g. Cesarean delivery was recommended for estimated fetal weights greater than 4500 g if there is prolonged second-stage labor or arrest of descent. Obvious problems with all such recommendations are substantive variations in fetal weight estimation (Chap. 44, p. 885).

Medical or Obstetrical Complications

In the event of a medical or other obstetrical complication, it is generally not recommended that a pregnancy be allowed to continue past 42 weeks. Indeed, in many such instances, *earlier* delivery is indicated. Common examples include gestational hypertensive disorders, prior cesarean delivery, and diabetes.

MANAGEMENT

Although some form of intervention is considered to be indicated for prolonged pregnancies, the types and timing of interventions are not unanimous (Divon, 2008). The decision centers on whether labor induction is warranted or if expectant management with fetal surveillance is best. In a survey done 10 years ago, Cleary-Goldman and associates (2006) reported that 73 percent of members of the American College of Obstetricians and Gynecologists routinely induced women at 41 weeks. Most of the remainder performed twice weekly fetal testing until 42 weeks.

Prognostic Factors for Successful Induction

Unfavorable Cervix

Although all obstetricians know what an “unfavorable cervix” is, the term unfortunately defies precise objective definition. Thus, various investigators have used different criteria for studies of prolonged pregnancies. For example, Harris and coworkers (1983) defined an unfavorable cervix by a Bishop

score < 7 and reported this in 92 percent of women at 42 weeks. Hannah and colleagues (1992) found that only 40 percent of 3407 women with a 41-week pregnancy had an “undilated cervix.” In a study of 800 women undergoing induction for postterm pregnancy at Parkland Hospital, Alexander and associates (2000b) reported that women in whom there was no cervical dilatation had a twofold increased cesarean delivery rate for “dystocia.” Yang and coworkers (2004) found that cervical length ≤ 3 cm measured with transvaginal sonography was predictive of successful induction. In a similar study, Vankayalapati and associates (2008) found that cervical length ≤ 25 mm was predictive of spontaneous labor or successful induction.

Cervical Ripening. A number of investigators have evaluated prostaglandin E₂ (PGE₂) for induction in women with an unfavorable cervix and prolonged pregnancies. The study by the National Institute of Child Health and Human Development Network of Maternal–Fetal Medicine Units (1994) found that PGE₂ gel was not more effective than placebo. Alexander and associates (2000c) treated 393 women with a postterm pregnancy with PGE₂, regardless of cervical “favorability,” and reported that almost half of the 84 women with cervical dilatation of 2 to 4 cm entered labor with prostaglandin E₂ use alone. The American College of Obstetricians and Gynecologists (2011) previously concluded that PGE₂ gel could be used safely in postterm pregnancies. In another study, mifepristone was reported to increase uterine activity without uterotonic agents in women beyond 41 weeks (Fasset, 2008). Prostaglandins and other agents used for cervical ripening are discussed in Chapter 26 (p. 525).

Sweeping or stripping of the membranes to induce labor and thereby prevent postterm pregnancy was studied in 15 randomized trials during the 1990s. Boulvain and coworkers (1999) performed a metaanalysis of these and found that membrane stripping at 38 to 40 weeks decreased the frequency of postterm pregnancy. Moreover, maternal and neonatal infection rates were not increased by cervical manipulation. However, this practice did not modify the cesarean delivery risk. Since then, randomized trials by Wong (2002), Kashanian (2006), Hill (2008), and their coworkers found that sweeping membranes did not reduce the need to induce labor. Drawbacks of membrane stripping included pain, vaginal bleeding, and irregular contractions without labor.

Station of Vertex

The station of the fetal head within the pelvis is another important predictor of successful postterm pregnancy induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks. The cesarean delivery rate was directly related to station. It was 6 percent if the vertex before induction was at –1 station; 20 percent at –2; 43 percent at –3; and 77 percent at –4.

■ Induction versus Fetal Testing

Because of marginal benefits for induction with an unfavorable cervix as discussed above, some clinicians prefer to use the

alternative strategy of fetal testing beginning at 41 completed weeks. There now are several quality studies designed to resolve these important questions.

In a Canadian study, 3407 women were randomly assigned at 41 or more weeks to induction or to fetal testing (Hannah, 1992). In the surveillance group, evaluation included: (1) counting fetal movements during a 2-hour period each day, (2) nonstress testing three times weekly, and (3) amniotic fluid volume assessment two to three times weekly with pockets < 3 cm considered abnormal. Labor induction resulted in a small but significant reduction in cesarean delivery rate compared with fetal testing—21 versus 24 percent, respectively. This difference was due to fewer procedures for fetal distress. Importantly, the only two stillbirths were in the fetal testing group.

The Maternal–Fetal Medicine Network performed a randomized trial of induction versus fetal testing beginning at 41 weeks (Gardner, 1996). Fetal surveillance included nonstress testing and sonographic estimation of amniotic fluid volume performed twice weekly in 175 women. Perinatal outcomes were compared with those of 265 women also at 41 weeks randomly assigned to induction with or without cervical ripening. There were no perinatal deaths, and the cesarean delivery rate was not different between management groups. The results of this study could be used to support the validity of either of these management schemes. Similar results were subsequently reported from a Norwegian randomized trial of 508 women (Heimstad, 2007).

In an analysis of 19 trials in the Cochrane Pregnancy and Childbirth Trials Registry, Gulmezoglu and colleagues (2006) found that induction after 41 weeks was associated with fewer perinatal deaths without significantly increasing the cesarean delivery rate. In a review of two metaanalyses and a recent randomized controlled study, similar conclusions were reached (Mozurkewich, 2009).

In an attempt to “lower” the number of postterm pregnancies, Harrington and associates (2006) randomly assigned 463 women to pregnancy dating with sonography between 8 and 12 weeks versus no first-trimester sonographic evaluation. Their primary end point was the labor induction rate for prolonged pregnancy, and they found no advantages to early sonographic pregnancy dating.

At 42 weeks, labor induction has a higher cesarean delivery rate compared with spontaneous labor. From Parkland Hospital, Alexander and coworkers (2001) evaluated pregnancy outcomes in 638 such women in whom labor was induced and compared them with outcomes of 687 women with postterm pregnancies who had spontaneous labor. Cesarean delivery rates were significantly increased—19 versus 14 percent—in the induced group because of failure to progress. When these investigators corrected for risk factors, however, they concluded that intrinsic maternal factors, rather than the induction itself, led to the higher rate. These factors included nulliparity, an unfavorable cervix, and epidural analgesia.

Evidence to substantiate intervention—whether induction or fetal testing—commencing at 41 versus 42 weeks is limited. Most evidence used to justify intervention at 41 weeks is from the randomized Canadian and American investigations cited earlier. No randomized studies have specifically assessed intervention at 41 weeks versus an identical intervention used

at 42 weeks. But there have been observational studies. In one, Usher and colleagues (1988) analyzed outcomes in 7663 pregnancies in women at 40, 41, or 42 weeks confirmed by early sonographic evaluation. After correction for malformations, perinatal death rates were 1.5, 0.7, and 3.0 per 1000 at 40, 41, and 42 weeks, respectively. These results could be used to challenge the concept of routine intervention at 41 instead of 42 weeks.

Management Recommendations

Because of the studies discussed above, the American College of Obstetricians and Gynecologists (2013a) defines postterm pregnancies as having completed 42 weeks. There is insufficient evidence to recommend a management strategy between 40 and 42 completed weeks. Thus, although not considered mandatory, initiation of fetal surveillance at 41 weeks is a reasonable option. After completing 42 weeks, recommendations are for either antenatal testing or labor induction. These are summarized in [Figure 43-10](#).

At Parkland Hospital, based on results discussed above, we consider 41-week pregnancies without other complications to be normal. Thus, no interventions are practiced solely based on fetal age until 42 completed weeks. If there are complications such as hypertension, decreased fetal movement, or oligohydramnios, then labor induction is carried out. It is our view that large, randomized trials should be performed before otherwise uncomplicated 41-week gestations are routinely considered pathologically prolonged. In women in whom a *certain* gestational age is known, labor is induced at the completion of 42 weeks. Almost 90 percent of such women are induced successfully or enter labor within 2 days of induction. For those who do not deliver with the first induction, a second induction is performed within 3 days. Almost all women are delivered

using this management plan, but in the unusual few who are not delivered, management decisions involve a third—or even more—induction versus cesarean delivery. Women classified as having *uncertain* postterm pregnancies are managed with weekly nonstress fetal testing and assessment of amniotic fluid volume. Women with an AFI ≤ 5 cm or with reports of diminished fetal movement undergo labor induction.

INTRAPARTUM MANAGEMENT

Labor is a particularly dangerous time for the postterm fetus. Therefore, women whose pregnancies are known or suspected to be postterm should come to the hospital as soon as they suspect labor. While being evaluated for active labor, we recommend that fetal heart rate and uterine contractions be monitored electronically for variations consistent with fetal compromise.

The decision to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can certainly enhance the possibility of cord compression. Conversely, amniotomy aids identification of thick meconium, which may be dangerous to the fetus if aspirated. Also, after membrane rupture, a scalp electrode and intrauterine pressure catheter can be placed. These usually provide more precise data concerning fetal heart rate and uterine contractions.

Identification of thick meconium in the amniotic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (Chap. 33, p. 637). Because of this, amnioinfusion during labor has been proposed as a way of diluting meconium to decrease the incidence of aspiration syndrome (Wenstrom, 1989). As discussed in Chapter 24 (p. 494), the benefits of amnioinfusion remain controversial. In a large randomized trial by Fraser and colleagues (2005), amnioinfusion did not reduce the risk of meconium aspiration syndrome or perinatal death. According to the American College of Obstetricians and Gynecologists (2012), amnioinfusion does not prevent meconium aspiration, however, it remains a reasonable treatment approach for repetitive variable decelerations.

The likelihood of a successful vaginal delivery is reduced appreciably for the nulliparous woman who is in early labor with thick, meconium-stained amniotic fluid. Therefore, if the woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

Until recently, it was taught—including at Parkland Hospital—that aspiration of meconium could be minimized but not eliminated by suctioning the pharynx as soon as the head was delivered. According to the American Academy of Pediatrics guidelines, this is no longer recommended (Perlman, 2010). The American College of Obstetricians and Gynecologists (2013c) does not recommend routine intrapartum suctioning. Alternatively, if the depressed newborn has meconium-stained fluid, then intubation is carried out. The American Academy of Pediatrics states that tracheal suctioning is neither supported nor refuted (Perlman, 2010).

CHAPTER 44

Fetal-Growth Disorders

FETAL GROWTH 872

FETAL-GROWTH RESTRICTION..... 874

FETAL OVERGROWTH 884

Nearly 20 percent of the almost 4 million infants born in the United States are at the low and high extremes of fetal growth. In 2010, 8.2 percent of infants weighed < 2500 g at birth, whereas 7.6 percent weighed > 4000 g. And although most low-birthweight infants are born preterm, approximately 3 percent are term. The proportion of infants with birthweight < 2500 g has increased by more than 20 percent since 1984, and at the same time, the incidence of birthweight > 4000 g continues to decline (Martin, 2012). This shift away from the upper extreme is difficult to explain because it coincides with the epidemic prevalence of obesity (Morisaki, 2013).

FETAL GROWTH

Human fetal growth is characterized by sequential patterns of tissue and organ growth, differentiation, and maturation. However, the “obstetrical dilemma” postulates a conflict between the need to walk upright—requiring a narrow pelvis—and the need to think—requiring a large brain, and thus a large head. Some have speculated that there may be evolutionary pressure to restrict growth late in pregnancy (Dunsworth, 2012; Espinoza, 2012). Thus, the ability to *growth restrict* may be adaptive rather than pathological.

Fetal growth has been divided into three phases. The initial phase of hyperplasia occurs in the first 16 weeks and is characterized by a rapid increase in cell number. The second phase, which extends up to 32 weeks’ gestation, includes both cellular hyperplasia and hypertrophy. After 32 weeks,

fetal growth is by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen are accumulated. The corresponding fetal-growth rates during these three phases are 5 g/day at 15 weeks’ gestation, 15 to 20 g/day at 24 weeks, and 30 to 35 g/day at 34 weeks (Williams, 1982). As shown in [Figure 44-1](#), there is considerable biological variation in the velocity of fetal growth.

Fetal development is determined by maternal provision of substrate, placental transfer of these substrates, and fetal growth potential governed by the genome. However, the precise cellular and molecular mechanisms by which normal fetal growth ensues are incompletely understood. That said, there is considerable evidence that insulin and insulin-like growth factors, particularly insulin-like growth factor-I (IGF-I), have an important role in regulation of fetal growth and weight gain (Luo, 2012; Murray, 2013). These growth factors are produced by virtually all fetal organs and are potent stimulators of cell division and differentiation.

Other hormones implicated in fetal growth have been identified in recent years, particularly hormones derived from adipose tissue. These hormones are known broadly as *adipokines* and include leptin, the protein product of the *obesity gene*. Fetal leptin concentrations increase during gestation, and they correlate with birthweight (Forhead, 2009; Karakosta, 2011). This relationship, however, is controversial in growth-restricted fetuses (Kyriakakou, 2008; Mise, 2007). Other adipokines under investigation include adiponectin, ghrelin, follistatin, resistin, visfatin, vaspin, omentin-1, apelin, and chemerin. Data for these adipokines are often conflicting, and their roles in normal and disordered fetal growth are still being elucidated (Chap. 48, p. 961).

Fetal growth is also dependent on an adequate supply of nutrients. As discussed in Chapter 4 (p. 53), glucose transfer has been extensively studied during pregnancy. Both excessive and diminished maternal glucose availability affect fetal growth. Reducing maternal glucose levels may result in a lower

FIGURE 44-1 Increments in fetal weight gain in grams per day from 24 to 42 weeks' gestation. The black line represents the mean and the outer blue lines depict ± 2 standard deviations. Data from pregnancies managed at Parkland Hospital. (Image courtesy of Dr. Don McIntire.)

birthweight. Still, growth-restricted neonates do not typically show pathologically low glucose concentrations in their cord blood (Pardi, 2006). Fetal-growth restriction in response to glucose deprivation generally results only after long-term severe maternal caloric deprivation (Lechtig, 1975).

Excessive glycemia produces macrosomia. Varying levels of glucose affect fetal growth via insulin and its associated insulin-like growth factors discussed earlier. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) Study Cooperative Research Group (2008) found that elevated cord C-peptide levels, which reflect fetal hyperinsulinemia, have been associated with increased birthweight. This relationship was noted even in women with maternal glucose levels below the threshold for diabetes. Overgrowth does occur in the fetuses of euglycemic women. Its etiology is thus likely more complicated than a paradigm of dysregulated glucose metabolism resulting in fetal hyperinsulinemia (Catalano, 2011).

Excessive transfer of lipids to the fetus has also been postulated to result in fetal overgrowth (Higa, 2013). Free or non-esterified fatty acids in maternal plasma may be transferred to the fetus via facilitated diffusion or after liberation of fatty acids from triglycerides by trophoblastic lipases (Gil-Sánchez, 2012). Generally speaking, lipolytic activity is increased in pregnancy, and fatty acids have been reported to be increased in nonobese women during the third trimester (Diderholm, 2005). In obese women without diabetes who were fed a controlled diet, neonatal adiposity was strongly linked both with fasting triglyceride levels in early pregnancy and with free fatty acid levels at 26 to 28 weeks' gestation (Harmon, 2011). Other studies have correlated maternal triglyceride levels with birthweight in both early and late pregnancy (Di Cianni, 2005; Vrijkotte, 2011). Overgrown infants have higher placental levels of certain fatty acids, particularly omega-3, and this has been associated with increased trophoblastic lipase expression (Varastehpour, 2006). Conversely, growth restriction in the third trimester has been associated with decreased maternal lipolysis (Diderholm, 2006). This may be related to

dysregulation of the triglyceride lipase gene family, which has been reported in placentas from pregnancies complicated by fetal-growth restriction (Gauster, 2007).

Amino acids undergo active transport from maternal blood to the fetus, which explains the normally higher fetal concentrations. This concentration differential is decreased in growth restriction because of lower fetal amino acid levels and higher maternal amino acid concentrations (Cetin, 1996). The etiology of this altered ratio is uncertain, but there are multiple points at which dysregulation can occur. Amino acids that reach the fetus must first cross the microvillus membrane at the maternal interface, traverse the trophoblastic cell, and finally cross the basal membrane into fetal blood (Chap. 5, p. 92). This process is incompletely understood, particularly with respect to trophoblast metabolism of amino acids and export mechanisms from the trophoblast to the fetus. Jansson and colleagues (2013) have linked expression and activity of particular amino-acid transporters at the microvillous membrane with increasing birthweight and maternal body mass index (BMI). Expression of particular amino acid efflux transporters has been positively correlated with multiple measures of fetal and neonatal growth (Cleal, 2011).

Normal Birthweight

Normative data for fetal growth based on birthweight vary with ethnicity and geographic region. For example, infants born to women who reside at high altitudes are smaller than those born at sea level. Term infants average 3400 g at sea level, 3200 g at 5000 feet, and 2900 g at 10,000 feet. Accordingly, researchers have developed fetal-growth curves using various populations and geographic locations throughout the United States (Brenner, 1976; Ott, 1993; Overpeck, 1999; Williams, 1975). Because these curves are based on specific ethnic or regional groups, they are not representative of the entire population.

To address this, data such as those shown in [Table 44-1](#) were derived on a nationwide basis in both the United States and Canada (Alexander, 1996; Kramer, 2001). Data from more than 3.1 million mothers with singleton liveborn infants in the United States during 1991 were used to derive the growth curve by Alexander and colleagues, colored red in [Figure 44-2](#). Also shown, the previously published regional fetal-growth curve data in general underestimated birthweights compared with national data. Importantly, there are significant ethnic and racial variations in neonatal mortality rates within the national neonatal mortality rate and within national birthweight and gestational age categories (Alexander, 1999, 2003).

The work of Alexander and associates (1996) is most accurately termed a population *reference*, rather than a *standard*. Iams (2010) emphasizes the problems that result from blending a population reference for fetal growth with a fetal-growth standard. A population reference incorporates pregnancies of varying risks, along with the resulting outcomes, both normal and abnormal. In contrast, a *standard* incorporates normal pregnancies with normal outcomes. Because population *references* include preterm births, which are more likely to be growth restricted, it has been argued that the associated birthweight data underestimate deficient fetal growth (Mayer, 2013; Zhang, 2010). That said, there is not a widely accepted *standard* for the United States.

TABLE 44-1. Smoothed Percentiles of Birthweight (g) for Gestational Age in the United States Based on 3,134,879 Singleton Live Births

Fetal Growth versus Birthweight

Most of what is known regarding normal and abnormal human fetal growth is actually based on birthweights that are assembled as references for fetal growth at particular gestational ages. This is problematic, however, because birthweight does not define the *rate* of fetal growth. Indeed, such birthweight curves reveal compromised growth only at the extreme of impaired growth. Thus, they cannot be used to identify the fetus who fails to achieve an expected size but whose birthweight is above the 10th percentile. For example, a fetus with a birthweight in the 40th percentile may not have achieved its genomic growth potential for a birthweight in the 80th percentile. The rate or *velocity* of fetal growth can be estimated by serial sonographic anthropometry. For example, Milovanovic (2012) demonstrated that the growth rate of intrinsically small-for-gestational age newborns approximates that of appropriate-for-gestational age neonates. Diminished growth velocity has been linked to perinatal morbidity and adverse postnatal metabolic changes that are independent of birthweight (Beltrand, 2008; Owen, 1997, 1998). Conversely, an excessive fetal-growth velocity, particularly of the abdominal circumference—which may be correlated with increased hepatic blood flow—is associated with an overgrown neonate. This is especially true when detected earlier in pregnancy (Ebbing, 2011; Kessler, 2011; Mulder, 2010).

FETAL-GROWTH RESTRICTION

Definition

Low-birthweight newborns who are small for gestational age are often designated as having *fetal-growth restriction*. In 1963, Lubchenco and coworkers published detailed comparisons of gestational ages with birthweights to derive norms for expected fetal size at a given gestational week. Battaglia and Lubchenco (1967) then classified *small-for-gestational-age* (SGA) neonates as those whose weights were below the 10th percentile for their gestational age. Such infants were shown to be at increased risk for neonatal death. For example, the neonatal mortality rate of SGA infants born at 38 weeks was 1 percent compared with 0.2 percent in those with appropriate birthweights.

Many infants with birthweights < 10th percentile, however, are not pathologically growth restricted, but are small simply because of normal biological factors. As many as 25 to 60 percent of SGA infants are thought to be appropriately grown when maternal ethnic group, parity, weight, and height are considered (Gardosi, 1992; Manning, 1991). These small but normal infants also do not show evidence of the postnatal metabolic derangements commonly associated with deficient fetal growth. Moreover, intrinsically SGA infants remain significantly smaller during surveillance to 2 years compared with appropriate-for-gestational age neonates, but they do not show differences in measures of metabolic risk (Milovanovic, 2012).

FIGURE 44-2 Comparison of fetal-growth curves for infants born in different regions of the United States and compared with those of the nation at large. (Modified from Alexander, 1996.)

FIGURE 44-3 Relationship between birthweight percentile and perinatal mortality and morbidity rates in 1560 small-for-gestational age fetuses. A progressive increase in both mortality and morbidity rates is observed as birthweight percentile falls. (Data from Manning, 1995.)

Because of these disparities, other classifications have been developed. Seeds (1984) suggested a definition based on birthweight < 5th percentile. Usher and McLean (1969) suggested that fetal-growth standards should be based on mean weights-for-age, with normal limits defined by ± 2 standard deviations. This definition would limit SGA infants to 3 percent of births instead of 10 percent. In a population-based analysis of 122,754 births at Parkland Hospital, McIntire and colleagues (1999) showed this definition to be clinically meaningful. Also, as shown in Figure 44-3, most adverse outcomes are in infants < 3rd percentile.

More recently, individual or customized fetal-growth potential has been proposed in place of a population-based cutoff. In this model, a fetus that deviates from its individual optimal size at a given gestational age is considered either overgrown or growth restricted (Bukowski, 2008). Such optimal projections are based on maternal race or ethnicity. However, the superiority of customized growth curves has not been established (Hutcheon, 2011a,b; Larkin, 2012; Zhang, 2011).

Symmetrical versus Asymmetrical Growth Restriction

Campbell and Thoms (1977) described the use of the sonographically determined *head-to-abdomen circumference ratio* (HC/AC) to differentiate growth-restricted fetuses. Those who were *symmetrical* were proportionately small, and those who were *asymmetrical* had disproportionately lagging abdominal growth. Furthermore, the onset or etiology of a particular fetal insult has been hypothetically linked to either type of growth restriction. In the instance of *symmetrical growth restriction*, an early insult could result in a relative decrease in

cell number and size. For example, global insults such as from chemical exposure, viral infection, or cellular maldevelopment with aneuploidy may cause a proportionate reduction of both head and body size. *Asymmetrical growth restriction* might follow a late pregnancy insult such as placental insufficiency from hypertension. Resultant diminished glucose transfer and hepatic storage would primarily affect cell size and not number, and fetal abdominal circumference—which reflects liver size—would be reduced. Such somatic-growth restriction is proposed to result from preferential shunting of oxygen and nutrients to the brain. This allows normal brain and head growth, that is—*brain sparing*. Accordingly, the ratio of brain weight to liver weight during the last 12 weeks—usually about 3 to 1—may be increased to 5 to 1 or more in severely growth-restricted infants.

Because of brain-sparing effects, asymmetrical fetuses were thought to be preferentially protected from the full effects of growth restriction. Considerable evidence has since accrued that fetal-growth patterns are much more complex. For example, Nicolaides and coworkers (1991) observed that fetuses with aneuploidy typically had disproportionately large head sizes and thus were *asymmetrically* growth restricted, which was contrary to contemporaneous thinking. Moreover, most preterm infants with growth restriction due to preeclampsia and associated uteroplacental insufficiency were found to have more symmetrical growth impairment—again, a departure from accepted principles (Salafia, 1995).

More evidence of the complexity of growth patterns was presented by Dashe and associates (2000). These investigators analyzed 8722 consecutive liveborn singletons who had undergone sonographic examination within 4 weeks of delivery. Although only 20 percent of growth-restricted fetuses demonstrated sonographic head-to-abdomen asymmetry, these fetuses were at increased risk for intrapartum and neonatal complications. Symmetrically growth-restricted fetuses were not at increased risk for adverse outcomes compared with those appropriately grown. These investigators concluded that asymmetrical fetal-growth restriction represented significantly disordered growth, whereas symmetrical growth restriction more likely represented normal, genetically determined small stature.

Finally, data from Holland further challenge the concept of “brain sparing.” Roza and associates (2008) provided surveillance of 935 Rotterdam toddlers enrolled between 2003 and 2007 in the Generation R Study. Using the Child Behavior Checklist at age 18 months, they found that infants with circulatory redistribution—*brain sparing*—had a higher incidence of behavioral problems. In another study, evidence of brain sparing was found in half of 62 growth-restricted fetuses with birthweight < 10th percentile and who showed abnormal umbilical artery Doppler flow studies (Figueras, 2011a). Compared with controls, these neonates had significantly lower neurobehavioral scores in multiple areas, suggesting profound brain injury.

Placental Abnormalities

Fetal-growth restriction was included by Brosens and colleagues (2011) as one of the “great obstetrical syndromes” associated

with defects in early placentation. Rogers and coworkers (1999) had observed that implantation site disorders such as incomplete trophoblastic invasion are associated with both fetal-growth restriction and hypertensive disorders. They concluded that implantation site disorders may be both a cause and consequence of hypoperfusion at the placental site. These disorders ultimately lead to pregnancy complications such as fetal-growth restriction with or without maternal hypertension. This comports with the association of certain placental angiogenic factors with pregnancy hypertensive disorders (Chap. 40, p. 735). Thus, it may be that placentas from pregnancies complicated by hypertension elaborate these angiogenic factors in response to placental site hypoperfusion, whereas pregnancies complicated by fetal-growth restriction without hypertension do not (Jeyabalan, 2008).

Mechanisms leading to abnormal trophoblastic invasion are likely multifactorial, and both vascular and immunological etiologies have been proposed. Recently, *atrial natriuretic peptide converting enzyme*, also known as *corrin*, has been shown to play a critical role in trophoblastic invasion and remodeling of the uterine spiral arteries. These processes are impaired in corrin-deficient mice, which also develop evidence of preeclampsia. Moreover, mutations in the gene for corrin have also been reported in women with preeclampsia (Cui, 2012).

Notably, several immunological abnormalities have been associated with fetal-growth restriction. This raises the prospect of maternal rejection of the “paternal semiallograft.” Rudzinski and colleagues (2013) studied C4d, a component of complement that is associated with humoral rejection of transplanted tissues. They found this to be highly associated with chronic villitis—88 percent of cases versus only 5 percent of controls—and with reduced placental weight. Greer and associates (2012) studied 10,204 placentas and reported that chronic villitis was associated with placental hypoperfusion, fetal acidemia, and fetal-growth restriction and its sequelae. Kovo and coworkers (2010) found that chronic villitis is more strongly associated with fetal-growth restriction than with preeclampsia. Redline (2007) described the findings of activated maternal lymphocytes among fetal trophoblast. However, this author notes uncertainty as to whether these pathological changes represent maternal immunological rejection.

■ Morbidity and Mortality

Perinatal Risk

As shown in Figure 44-3, fetal-growth restriction is associated with substantive perinatal morbidity and mortality rates. Rates of stillbirth, birth asphyxia, meconium aspiration, and neonatal hypoglycemia and hypothermia are all increased, as is the prevalence of abnormal neurological development (Jacobsson, 2008; Paz, 1995). This is true for both term and preterm growth-restricted infants (McIntire, 1999; Wu, 2006). Smulian and colleagues (2002) reported that SGA infants had a higher 1-year infant mortality rate compared with that of normally grown infants. Boulet and associates (2006) demonstrated that for a fetus at the 10th percentile, the risk of neonatal death is increased but varies with gesta-

tional age. Risk is increased threefold at 26 weeks' gestation compared with only a 1.13-fold increased risk at 40 weeks. More recently, in an analysis of 123,383 nonanomalous singleton live births, Chen and coworkers (2011) reported that SGA infants had a twofold risk for early and late neonatal death but not for postneonatal demise.

Long-Term Sequelae

Fetal Undergrowth. In his book *Fetal and Infant Origins of Adult Disease*, Barker (1992) hypothesized that adult mortality and morbidity are related to fetal and infant health. This includes both under- and overgrowth. In the context of fetal-growth restriction, there are numerous reports of a relationship between suboptimal fetal nutrition and an increased risk of subsequent adult hypertension, atherosclerosis, type 2 diabetes, and metabolic derangement (Gluckman, 2008). The degree to which low birthweight mediates adult disease is controversial. For example, it is unclear whether poor health in adulthood is mainly modulated by low birthweight, postnatal compensatory growth, or an interaction of the two (Crowther, 2008; Kerkhof, 2012; Leunissen, 2008; Nobili, 2008; Ong, 2007).

There is increasing evidence that fetal-growth restriction may affect organ development, particularly that of the heart. Individuals with low birthweight demonstrate cardiac structural changes and dysfunction persisting through childhood, adolescence, and adulthood. Crispi and coworkers (2012) studied 50 children aged between 3 and 6 years who were born small-for-gestational age at > 34 weeks and compared them with 100 normally grown children. The heart shape was altered in children born SGA. They had a more globular ventricle that resulted in systolic and diastolic dysfunction. Hietalampi and associates (2012) performed echocardiography in 418 adolescents at a mean age of 15 years and found that low birthweight was associated with increased left ventricular posterior wall thickness. Importantly, current weight and physical activity affected measurements. In another study, 102 adults previously born preterm at a mean gestational age of 30.3 weeks underwent cardiac magnetic resonance (MR) imaging. Their ventricular mass was increased compared with that of 132 adults who were delivered at term (Lewandowski, 2013). Adults previously born preterm also had persistent structural remodeling and had reduced systolic and diastolic function.

Deficient fetal growth is also associated with postnatal structural and functional renal changes. Ritz and colleagues (2011) reviewed the numerous studies associating low birthweight with disordered nephrogenesis, renal dysfunction, chronic kidney disease, and hypertension. They found that although a low nephron number is associated with hypertension in white individuals, this association does not hold true for blacks.

Fetal Overgrowth. On the other end of the spectrum, fetal overgrowth, particularly in women with diabetes and elevated cord blood levels of IGF-I, is associated with increased neonatal fat mass and morphological heart changes. Aman and coworkers (2011) reported interventricular septal hypertrophy

in overgrown neonates of mothers with well-controlled diabetes in pregnancy. Garcia-Flores (2011) also reported increased fetal cardiac intraventricular septal thickness using sonography in women with well-controlled diabetes. Large-for-gestational age infants delivered of women without impaired glucose tolerance show higher insulin levels in childhood (Evagelidou, 2006). Not surprisingly, fetal overgrowth has been associated with development of the metabolic syndrome even in childhood (Boney, 2005).

■ Accelerated Lung Maturation

Numerous reports describe accelerated fetal pulmonary maturation in complicated pregnancies associated with growth restriction (Perelman, 1985). One possible explanation is that the fetus responds to a stressed environment by increasing adrenal glucocorticoid secretion, which leads to accelerated fetal lung maturation (Laatikainen, 1988). Although this concept pervades modern perinatal thinking, there is negligible evidence to support it.

To examine this hypothesis, Owen and associates (1990) analyzed perinatal outcomes in 178 women delivered because of hypertension. They compared these with outcomes in infants of 159 women delivered because of spontaneous preterm labor or ruptured membranes. They concluded that a “stressed” pregnancy did not confer an appreciable survival advantage. Similar findings were reported by Friedman and colleagues (1995) in women with severe preeclampsia. Two studies from Parkland Hospital also substantiate that the preterm infant accrues no apparent advantages from fetal-growth restriction (McIntire, 1999; Tyson, 1995).

■ Risk Factors and Etiologies

Risk factors for impaired fetal growth include potential abnormalities in the mother, fetus, and placenta. These three “compartments” are depicted in [Figure 44-4](#). Some of these factors are known causes of fetal-growth restriction and may

affect more than one compartment. For instance, infectious causes such as cytomegalovirus may affect the fetus directly. In contrast, bacterial infections such as tuberculosis may have significant maternal effects that lead to poor fetal growth. Malaria, a protozoal infection, possibly creates placental dysfunction (Umbers, 2011). Importantly, many causes of diminished fetal growth are prospectively considered risk factors, because impaired fetal growth is not consistent in all affected women.

Constitutionally Small Mothers

It is axiomatic that small women typically have smaller newborns. If a woman begins pregnancy weighing less than 100 pounds, the risk of delivering an SGA infant is increased at least twofold (Simpson, 1975). As discussed subsequently, both prepregnancy weight and gestational weight gain modulate this risk. Durie and colleagues (2011) showed that the risk of delivering an SGA neonate was highest among underweight women who gained less weight than recommended by the Institute of Medicine (Chap. 9, p. 177). Also, both maternal and paternal size influences birthweight. In a Swedish study of 137,538 term singleton mother-father-child units, researchers estimated that the maternal and paternal birthweights explained 6 and 3 percent of variance in birthweight, respectively (Mattsson, 2013).

Gestational Weight Gain and Nutrition

In the woman of average or low BMI, poor weight gain throughout pregnancy may be associated with fetal-growth restriction (Rode, 2007). In the study by Durie cited above, gestational weight gain during the second and third trimesters that was less than that recommended by the Institute of Medicine was associated with SGA neonates in women of all weight categories except class II or III obesity. Conversely, excessive gestational weight gain was associated with an overgrown newborn in all weight categories.

As perhaps expected, eating disorders are associated with significantly increased risks of low birthweight and preterm birth (Pasternak, 2012). This is discussed further in Chapter 61 (p. 1211). Marked weight gain restriction after midpregnancy should not be encouraged even in obese women (Chap. 9, p. 177). Even so, it appears that food restriction to < 1500 kcal/day adversely affects fetal growth minimally (Lechtig, 1975). The best documented effect of famine on fetal growth was in the *Hunger Winter* of 1944 in Holland. For 6 months, the German Occupation army restricted dietary intake to 500 kcal/day for civilians, including pregnant women. This resulted in an average birthweight decline of only 250 g (Stein, 1975).

It is unclear whether undernourished women may benefit from micronutrient supplementation. In the study by the Supplementation with Multiple Micronutrients Intervention Trial (SUMMIT) Study Group (2008), almost 32,000 Indonesian women were randomized to receive micronutrient supplementation or only iron and folate tablets. Infants of those receiving the supplement had lower risks of early infant mortality and low birthweight and had improved childhood motor and cognitive abilities (Prado, 2012). Conversely, Liu and coworkers

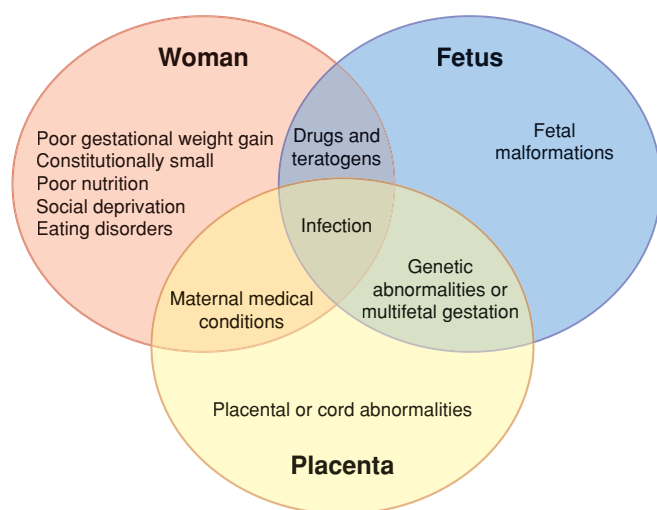

FIGURE 44-4 Risk factors and causes of impaired fetal growth centering on the mother, her fetus, and the placenta.

(2013) randomized 18,775 nulliparous pregnant women to folic acid alone; folic acid and iron; or folic acid, iron, and 13 other micronutrients. Folic acid and iron with or without the additional micronutrients resulted in a 30-percent reduction in risk of third-trimester anemia. However, it did not affect other maternal or neonatal outcomes. The importance of antenatal vitamins and trace metals is further discussed in Chapter 9 (p. 179).

Social Deprivation

The effect of social deprivation on birthweight is interconnected to the influence of associated lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. Importantly, Coker and associates (2012) found that women screened during pregnancy for psychosocial risk factors had more appropriate interventions. These women were significantly less likely to deliver a low-birthweight infant and also had fewer preterm births and other pregnancy complications.

Women who are immigrants may be at particular risk in pregnancy. Poeran and colleagues (2013) studied 56,443 singleton pregnancies in Rotterdam between 2000 and 2007 and found that social deprivation was associated with adverse perinatal outcomes that included SGA infants among socially deprived women. However, a similar linkage was not noted in socially deprived women of non-Western origin. The effect of immigration, however, is complex and dependent on the population studied. A paradoxical relationship between pregnancy outcomes in foreign-born Latina women delivering in the United States compared with Latina women born in the United States has been described (Flores, 2012). In particular, foreign-born Latina women appear to have lower risks of preterm birth and SGA neonates.

Vascular Disease

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly causes growth restriction (Chap. 50, p. 1004). Preeclampsia may cause fetal-growth failure, which can be an indicator of its severity (Backes, 2011). In a study of more than 2000 women, vascular disease as evidenced by abnormal uterine artery Doppler velocimetry early in pregnancy was associated with increased rates of preeclampsia, SGA neonates, and delivery before 34 weeks (Groom, 2009). Roos-Hesselink and coworkers (2013) described pregnancy outcomes in women with heart disease, and only 25 of the 1321 women had ischemic heart disease, emphasizing its rareness. But these women had the worst outcomes, with significantly lower neonatal birthweights and the highest rates of preterm birth and perinatal mortality.

Renal Disease

Chronic renal insufficiency is frequently associated with underlying hypertension and vascular disease. Nephropathies are commonly accompanied by restricted fetal growth (Bramham, 2011; Cunningham, 1990; Vidaeff, 2008). These relationships are considered further in Chapter 53 (p. 1059).

Pregestational Diabetes

Fetal-growth restriction in women with diabetes may be related to congenital malformations or may follow substrate

deprivation from advanced maternal vascular disease (Chap. 57, p. 1128). Also, the likelihood of restricted growth increases with development of nephropathy and proliferative retinopathy—especially in combination (Haeri, 2008). That said, the prevalence of serious vascular disease associated with diabetes in pregnancy is low, and the primary effect of overt diabetes, especially type 1, is fetal *overgrowth*. For example, Murphy and coworkers (2011) performed a prospective study of 682 consecutive pregnancies complicated by diabetes. Women with type 1 diabetes had significantly fewer of the traditional risk factors for fetal overgrowth, such as increased age, multiparity, and obesity. Yet, they were significantly more likely than women with type 2 diabetes to have a neonate weighing > 90th and 97.7th percentiles. Additionally, women with type 1 diabetes were significantly less likely to deliver an SGA newborn. Similarly, in a smaller study by Cyganek and colleagues (2011), the rate of macrosomia was higher among pregnancies complicated by type 1 diabetes. However, the rates of low birthweight were similar for those with type 1 and type 2 diabetes.

Chronic Hypoxia

Conditions associated with chronic uteroplacental hypoxia include preeclampsia, chronic hypertension, asthma, smoking, and high altitude. When exposed to a chronically hypoxic environment, some fetuses have significantly reduced birthweight. Gonzales and Tapia (2009) constructed growth charts based on 63,620 Peruvian live births between 26 and 42 weeks' gestation. They reported that mean birthweight was significantly decreased at higher altitudes compared with lower altitudes— 3065 ± 475 g versus 3280 ± 525 grams. At low altitude, the rate of birthweight < 2500 g was 6.2 percent, and it was 9.2 percent at high altitude. In contrast, the rate of birthweight > 4000 g was 6.3 percent at low altitude and 1.6 percent at high altitude. As discussed in Chapter 49 (p. 985), severe hypoxia from maternal cyanotic heart disease frequently is associated with severely growth-restricted fetuses (Patton, 1990).

Anemia

In most cases, maternal anemia does not cause restricted fetal growth. Exceptions include sickle-cell disease and some other inherited anemias (Chakravarty, 2008; Tongsong, 2009). Conversely, curtailed maternal blood-volume expansion has been linked to fetal-growth restriction (Duvekot, 1995; Scholten, 2011). This is further discussed in Chapter 40 (p. 737).

Antiphospholipid Antibody Syndrome

Adverse obstetrical outcomes including fetal-growth restriction have been associated with three species of antiphospholipid antibodies: *anticardiolipin antibodies*, *lupus anticoagulant*, and *antibodies against beta-2-glycoprotein-I*. Mechanistically, a “two-hit” hypothesis suggests that initial endothelial damage is then followed by intervillous placental thrombosis. More specifically, oxidative damage to certain membrane proteins such as beta-2-glycoprotein I is followed by antiphospholipid antibody binding, which leads to immune complex formation and ultimately to thrombosis (Giannakopoulos, 2013). This syndrome is considered in detail in Chapters 52 (p. 1033) and

59 (p. 1173). Pregnancy outcomes in women with these antibodies may be poor and include early-onset preeclampsia and fetal demise (Levine, 2002). The primary autoantibody that predicts obstetrical antiphospholipid syndrome appears to be lupus anticoagulant (Lockshin, 2012).

Inherited Thrombophilias

Numerous investigators have evaluated the role of genetic polymorphisms in the mother or fetus and their relationship to growth restriction (Lockwood, 2002; Stonek, 2007). Most suggest that inherited thrombophilias are not a significant factor in fetal-growth restriction (Infante-Rivard, 2002; Rodger, 2008). Facco and colleagues (2009) attribute positive associations primarily to publication bias.

Infertility

Pregnancies in women with prior infertility with or without infertility treatment have an increased risk of SGA newborns (Zhu, 2007). Kondapalli and Perales-Puchalt (2013) have recently reviewed possible links between low birthweight and infertility with its various interventions. They concluded that the association remains unexplained.

Placental and Cord Abnormalities

Several placental abnormalities may cause poor fetal growth. These are discussed further throughout Chapter 6 and include chronic placental abruption, extensive infarction, chorioangioma, marginal or velamentous cord insertion, placenta previa, and umbilical artery thrombosis. Growth failure in these cases is presumed secondary to uteroplacental insufficiency.

Abnormal placental implantation leading to endothelial dysfunction may also result in limited fetal growth (Brosens, 2011). This pathology has been implicated in pregnancies complicated by preeclampsia as discussed in Chapter 40 (p. 732).

If the placenta is implanted outside the uterus, the fetus is usually growth restricted (Chap. 19, p. 388). Also, some uterine malformations have been linked to impaired fetal growth (Chap. 3, p. 40).

Multiple Fetuses

As shown in Figure 44-5, pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses compared with that with normal singletons (Chap. 45, p. 899).

Drugs with Teratogenic and Fetal Effects

Several drugs and chemicals are capable of limiting fetal growth. Some are teratogenic and affect the fetus before organogenesis is complete. Some exert—or continue to exert—fetal effects after embryogenesis ends at 8 weeks. Many of these are considered in detail in Chapter 12, and some examples include anticonvulsants and antineoplastic agents. Some immunosuppressive drugs used for organ transplantation maintenance are also implicated in poor fetal growth (Mastrobattista, 2008). In addition, cigarette smoking, opiates and related drugs, alcohol, and cocaine may cause growth

FIGURE 44-5 Birthweight and gestational age relationships in multifetal gestations delivered at Parkland Hospital without malformations. (Data courtesy of Dr. Don McIntire.)

restriction, either primarily or by decreasing maternal food intake. There is a possible link with caffeine use throughout pregnancy and fetal-growth restriction (CARE Study Group, 2008). According to the American College of Obstetricians and Gynecologists (2013c), however, this relationship remains speculative (Chap. 9, p. 187).

Maternal and Fetal Infections

Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of fetal-growth restriction cases and are discussed throughout Chapters 64 and 65. The best known of these are *rubella* and *cytomegalovirus infection*. Both promote calcifications in the fetus that are associated with cell death, and infection earlier in pregnancy correlates with worse outcomes. Picone and associates (2013) described 238 primary cytomegalovirus infections and reported that no severe cases were observed when infection occurred after 14 weeks' gestation.

Tuberculosis and *syphilis* have both been associated with poor fetal growth. As discussed in Chapter 51 (p. 1020), both extrapulmonary and pulmonary tuberculosis have been linked with low birthweight (Jana, 1994, 1999). The etiology is uncertain. However, the adverse effect of tuberculosis on maternal health, compounded by effects of poor nutrition and poverty, is important (Jana, 2012). Congenital or transplacental tuberculosis is rare, whereas congenital syphilis is more common. Paradoxically, with syphilis, the placenta is almost always larger and heavier due to edema and perivascular inflammation. Congenital syphilis is also strongly linked with preterm birth and thus low-birthweight infants (Sheffield, 2002).

Toxoplasma gondii can also cause congenital infection, and Paquet and Yudin (2013) describe its classic association with fetal-growth restriction. Despite this, an analysis of 386 women who seroconverted during pregnancy from toxoplasma infection found no connection with low birthweight (Freeman, 2005). *Congenital malaria* has also been implicated, and malaria prophylaxis is associated with a decreased risk of low birthweight in Sub-Saharan Africa (Kayentao, 2013).

Congenital Malformations

In a study of more than 13,000 fetuses with major structural anomalies, 22 percent had accompanying growth restriction (Khoury, 1988). In their study of 115 pregnancies complicated by fetal gastroschisis, Tam Tam and coworkers (2011) identified low birthweights in 63 percent and fetal-growth restriction in 45 percent of affected newborns. As a general rule, the more severe the malformation, the more likely the fetus is to be SGA. This is especially evident in fetuses with chromosomal abnormalities or those with serious cardiovascular malformations.

Chromosomal Aneuploidies

Depending on which chromosome is redundant, there may be associated poor growth in fetuses with autosomal trisomies. For example, in *trisomy 21*, fetal-growth restriction is generally mild. By contrast, fetal growth in *trisomy 18* is virtually always significantly limited. Growth failure has been documented as early as the first trimester using crown-rump length (Baken, 2013). Bahado-Singh (1997) and Schemmer (1997) and their associates found that crown-rump length in fetuses with trisomy 18 and 13, unlike that with trisomy 21, was shorter than expected. By the second trimester, long-bone measurements typically are < 3rd percentile.

As discussed in Chapter 13 (p. 269), aneuploidic patches in the placenta—*confined placental mosaicism*—can cause placental insufficiency that may account for many previously unexplained growth-restricted fetuses (Wilkins-Haug, 2006). Although addition of an X chromosome in confined placental mosaicism can be associated with diminished fetal growth, this is not so with Klinefelter syndrome (47,XXY). Conversely, monosomy X or Turner syndrome has been associated with a low embryo volume during first-trimester sonography (Baken, 2013). This early finding manifests as growth restriction at delivery. Hagman and colleagues (2010) compared 494 children with monosomy X with normal girls and found a 6.6-fold increased risk for SGA in newborns with Turner syndrome.

First-trimester prenatal screening programs to identify women at risk for aneuploidy may incidentally identify pregnancies at risk for fetal-growth restriction unrelated to karyotype. In their analysis of 8012 women, Krantz and associates (2004) identified an increased risk for growth restriction in eukaryotic fetuses with extremely low free β -human chorionic gonadotropin (β -hCG) and pregnancy-associated plasma protein-A (PAPP-A) levels. From her review, Dugoff (2010) concluded that although most studies have found that a low PAPP-A level is strongly associated with poor fetal growth, studies of free β -hCG are conflicting. Second-trimester analytes, including elevated alpha-fetoprotein and inhibin A levels and low unconjugated serum estriol concentrations, are significantly associated with birthweight < 5th percentile. An even greater risk of poor growth has been associated with certain combinations of these analytes. Still, these markers are poor screening tools for complications such as fetal-growth restriction due to low sensitivity and positive predictive values (Dugoff, 2010). Nuchal translucency has also not been shown to be predictive of fetal-growth restriction. These markers are discussed further in Chapter 14 (p. 289).

Recognition of Fetal-Growth Restriction

Early establishment of gestational age, ascertainment of maternal weight gain, and careful measurement of uterine fundal growth throughout pregnancy will identify many cases of abnormal fetal growth in low-risk women. Risk factors, including a *previous growth-restricted fetus*, have an increased risk for recurrence of nearly 20 percent (Berghella, 2007). In women with risks, serial sonographic evaluation is considered. Although examination frequency varies depending on indications, an initial early dating examination followed by an examination at 32 to 34 weeks, or when otherwise clinically indicated, will identify many growth-restricted fetuses. Even so, *definitive diagnosis* frequently cannot be made until delivery.

Identification of the inappropriately growing fetus remains a challenge. There are, however, both simple clinical techniques and more complex technologies that may prove useful.

Uterine Fundal Height

According to a recent systematic review, insufficient evidence supports the utility of fundal height measurement to detect fetal-growth restriction (Robert Peter, 2012). Nonetheless, carefully performed serial fundal height measurements are recommended as a simple, safe, inexpensive, and reasonably accurate *screening* method to detect growth-restricted fetuses (Figueras, 2011b). As a screening tool, its principal drawback is imprecision (Jelks, 2007). For example, Sparks and coworkers (2011) reported sensitivities < 35 percent for detecting excessive or deficient fetal growth. Specificity, however, was reported to be > 90 percent.

The method used by most for fundal height measurement is described in Chapter 9 (p. 176). Between 18 and 30 weeks' gestation, the uterine fundal height in centimeters coincides within 2 weeks of gestational age. Thus, if the measurement is more than 2 to 3 cm from the expected height, inappropriate fetal growth is suspected.

Sonographic Measurements of Fetal Size

One argument in the debate regarding routine sonographic evaluation of all pregnancies is the potential for diagnosis of growth restriction. Typically, such routine screening incorporates an early initial sonographic examination—usually at 16 to 20 weeks' gestation, but increasingly in the first trimester—to establish gestational age and identify anomalies. Proponents of this view then repeat sonographic evaluation at 32 to 34 weeks to evaluate fetal growth (Chap. 10, p. 198). Although fetal-growth restriction can be detected during the first trimester, its detection using an initial sonogram from the second trimester is more likely to correspond to a birthweight that is small-for-gestational age (Baken, 2013; Mook-Kanamori, 2010; Tuuli, 2011). At Parkland Hospital, we provide midpregnancy sonographic screening examination of all pregnancies. Additional sonographic evaluations of fetal growth are performed as clinically indicated.

With sonography, the most common method for identifying poor fetal growth is estimation of weight using multiple fetal biometric measurements. Combining head, abdomen, and femur dimensions has been shown to optimize accuracy, whereas little incremental improvement is gained by adding other biometric

FIGURE 44-6 Correlation of sonographic fetal weight estimation using abdominal circumference (AC) and actual birthweight. Data from pregnancies managed at Parkland Hospital. (Image courtesy of Dr. Don McIntire.)

measurements (Platz, 2008). Of the dimensions, femur length measurement is technically the easiest and the most reproducible. Biparietal diameter and head circumference measurements are dependent on the plane of section and may also be affected by deformative pressures on the skull. Last, abdominal circumference measurements are more variable. However, these are most frequently abnormal with fetal-growth restriction because soft tissue predominates in this dimension (Fig. 44-6). Shown in Figure 44-7 is an example of a severely growth-restricted newborn.

FIGURE 44-7 A 36-week newborn with severe fetal-growth restriction. (Photograph contributed by Dr. Roxane Holt.)

Some studies have reported a significant predictive value for small abdominal circumference with respect to lagging fetal growth. However, newer data indicate that abnormal Doppler velocimetry of the umbilical arteries and a combined estimated fetal weight < 3rd percentile are most strongly associated with poor obstetrical outcome (Unterscheider, 2013).

Importantly, sonographic estimates of fetal weight and actual weight may be discordant by 20 percent or more, leading to both false-positive and false-negative findings. Dashe and associates (2000) studied 8400 live births at Parkland Hospital in which fetal sonographic evaluation had been performed within 4 weeks of delivery. They reported that 30 percent of growth-restricted fetuses were not detected. In a study of 1000 high-risk fetuses, Larsen and coworkers (1992) performed serial sonographic examinations beginning at 28 weeks and then every 3 weeks subsequently. Reporting results compared with withholding results from clinicians significantly increased the diagnosis of SGA fetuses. Elective delivery rates were increased in the group whose providers received sonographic reports, but there was no overall improvement in neonatal outcomes.

Amniotic Fluid Volume Measurement

An association between pathological fetal-growth restriction and oligohydramnios has long been recognized (Chap. 11, p. 236). Chauhan and colleagues (2007) found oligohydramnios in nearly 10 percent of pregnancies suspected of growth restriction. This group of women was two times more likely to undergo cesarean delivery for nonreassuring fetal heart rate patterns. Petrozella and associates (2011) reported that decreased amniotic fluid volume between 24 and 34 weeks' gestation was significantly associated with malformations. In the absence of malformations, a birthweight < 3rd percentile was seen in 37 percent of pregnancies with oligohydramnios, in 21 percent with borderline amniotic fluid volume, but in only 4 percent with normal volumes. Hypoxia and diminished renal blood flow has been hypothesized as an explanation for oligohydramnios. However, Magann and coworkers (2011) reviewed the literature and determined that the etiology of oligohydramnios is likely more complex and possibly involves altered intramembranous absorption as well.

Doppler Velocimetry

With this technique, early changes in placenta-based growth restriction are detected in peripheral vessels such as the umbilical and middle cerebral arteries. Late changes are characterized by abnormal flow in the ductus venosus and fetal aortic and pulmonary outflow tracts and by reversal of umbilical artery flow.

Of these, abnormal umbilical artery Doppler velocimetry findings—characterized by absent or reversed end-diastolic flow—have been uniquely linked with fetal-growth restriction (Chap. 10, p. 220). These abnormalities highlight early versus severe fetal-growth restriction and represent the transition from fetal adaptation to failure. Thus, persistently absent or reversed end-diastolic flow has long been correlated with hypoxia, acidosis, and fetal death (Pardi, 1993; Woo, 1987). Umbilical artery Doppler velocimetry is considered standard in the evaluation and management of the growth-restricted fetus (Fig. 44-8). The

FIGURE 44-8 Umbilical arterial Doppler velocimetry studies, ranging from normal to markedly abnormal. **A.** Normal velocimetry pattern with a systolic to diastolic (S/D) ratio of < 3 . **B.** The diastolic velocity approaching zero reflects increased placental vascular resistance. **C.** During diastole, arterial flow is reversed (negative S/D ratio), which is an ominous sign that may precede fetal demise.

American College of Obstetricians and Gynecologists (2013a) notes that umbilical-artery Doppler velocimetry has been shown to improve clinical outcomes. It is recommended in the management of fetal-growth restriction as an adjunct to standard surveillance techniques such as nonstress testing and biophysical profile.

As noted earlier, other Doppler assessments have been proposed but are still investigational. The ductus venosus was evaluated in a series of 604 neonates < 33 weeks who had an abdominal circumference < 5 th percentile (Baschat, 2007). Investigators found that the ductus venosus Doppler parameters were the primary cardiovascular factor in predicting neonatal outcome. These late changes are felt to reflect myocardial deterioration and acidemia, which are major contributors to adverse perinatal and neurological outcome. In their longitudinal evaluation of 46 growth-restricted fetuses, Figueras and coworkers (2009) determined that Doppler flow abnormalities at the aortic valve isthmus preceded those in the ductus venosus by 1 week. Turan and associates (2008), in their evaluation of several fetal vessels, described the sequence of changes characteristic of mild placental dysfunction, progressive placental dysfunction, and severe early-onset placental dysfunction.

Prevention

Prevention of fetal-growth restriction ideally begins before conception, with optimization of maternal medical conditions,

medications, and nutrition as discussed throughout Chapter 8. Smoking cessation is critical. Other risk factors should be tailored to the maternal condition, such as antimalarial prophylaxis for women living in endemic areas and correction of nutritional deficiencies. Studies have shown that treatment of mild to moderate hypertension does not reduce the incidence of growth-restricted infants (Chap. 50, p. 1005).

Accurate dating is essential during early pregnancy. Serial sonographic evaluations are typically used, but the best interval between assessments has not been clearly established. Given that a history of SGA is associated with other adverse outcomes in a subsequent pregnancy, particularly stillbirth and preterm birth, surveillance during a subsequent pregnancy may be beneficial (Gordon, 2012; Spong, 2012). According to the American College of Obstetricians and Gynecologists (2013a), if growth is normal during a pregnancy following a prior pregnancy complicated by fetal-growth restriction, Doppler velocimetry and fetal surveillance are not indicated. Prophylaxis with low-dose aspirin beginning early in gestation is not recommended because of its poor efficacy to reduce growth restriction (American College of Obstetricians and Gynecologists, 2013a; Berghella, 2007).

Management

If fetal-growth restriction is suspected, then efforts are made to confirm the diagnosis, assess fetal condition, and search for possible causes. Early-onset growth restriction is easier to recognize but presents challenging issues of management (Miller, 2008). In pregnancies in which there is a strong suspicion of fetal anomalies, patient counseling and prenatal diagnostic testing are indicated (American College of Obstetricians and Gynecologists, 2013a).

One algorithm for management is shown in Figure 44-9. In pregnancies with suspected fetal-growth restriction, antepartum fetal surveillance should include periodic Doppler velocimetry of the umbilical arteries in addition to more frequent fetal testing. At Parkland Hospital, if fetal viability has been reached, we hospitalize these women. Daily fetal heart rate tracings, weekly Doppler velocimetry, and sonographic assessment of fetal growth every 3 to 4 weeks are initiated. Other modalities of Doppler velocimetry, such as middle cerebral arteries or ductus venosus assessment, are considered experimental. The American College of Obstetricians and Gynecologists (2013a) recommends that pregnancies complicated by fetal-growth restriction and at risk for birth before 34 weeks receive antenatal corticosteroids for pulmonary maturation. According to Vidaeff and Blackwell (2011), growth-restricted fetuses may not tolerate the metabolic effects of corticosteroids in the same way as an unstressed fetus. They suggest increased surveillance during administration.

The timing of delivery is crucial, and the risks of fetal death versus the hazards of preterm delivery must be considered. Unfortunately, there are no studies that have elucidated the optimal timing of delivery. For the preterm fetus, the only randomized trial of delivery timing is the Growth Restriction Intervention Trial (GRIT) reported by Thornton and colleagues (2004). This trial was carried out in 13 European countries and

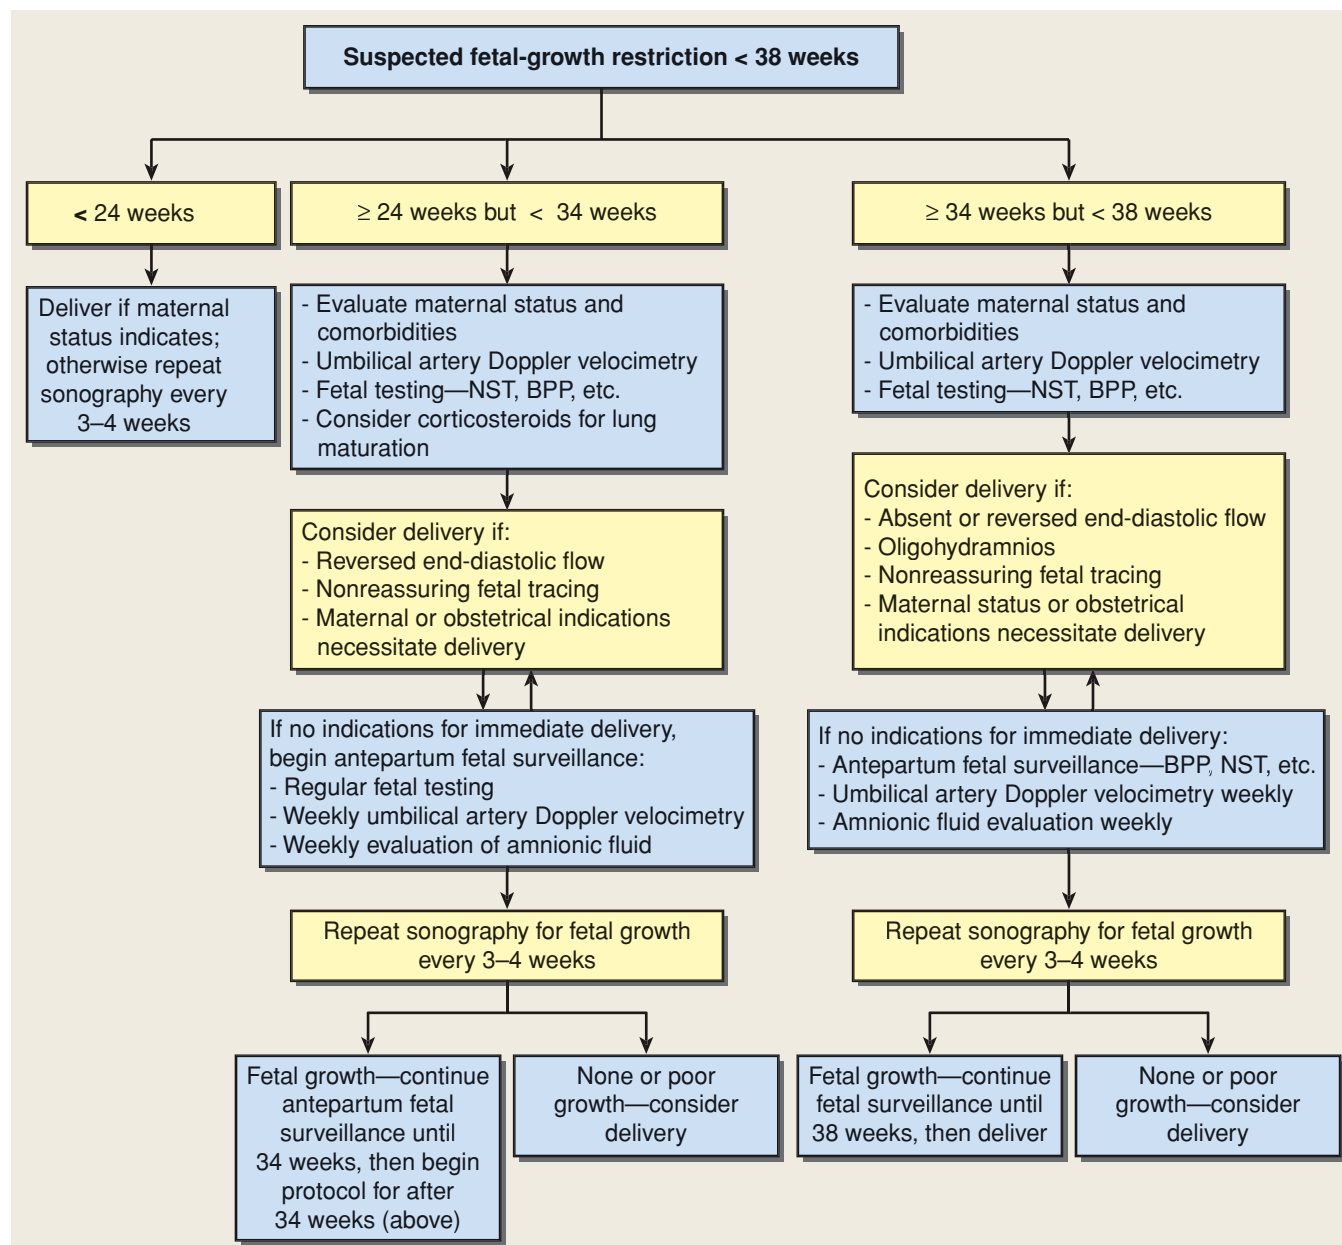

FIGURE 44-9 Algorithm for management of fetal-growth restriction at Parkland Hospital. BPP = biophysical profile; NST = nonstress test.

involved 548 women between 24 and 36 weeks' gestation with clinical uncertainty regarding delivery timing. Women were randomly assigned to immediate delivery or to delayed delivery until the situation worsened. The primary outcome was perinatal death or disability after reaching age 2 years. There were no differences in mortality rates through 2 years of age. Moreover, children aged 6 to 13 years did not show clinically significant differences between the two groups (Walker, 2011).

The DIGITAT—Disproportionate Intrauterine Growth Intervention Trial at Term—was designed to study delivery timing of growth-restricted fetuses who were 36 weeks' gestation or older. There were no differences in composite neonatal morbidity in 321 women with fetal-growth restriction and a gestational age of at least 36^{0/7} weeks who were randomly assigned to induction or to expectant management (Boers, 2010). Secondary analyses included assessment of neurodevel-

opmental and behavioral outcomes that did not differ at age 2 years (Van Wyk, 2012).

Management of the Near-Term Fetus

As shown in Figure 44-9, delivery of a suspected growth-restricted fetus with normal umbilical artery Doppler velocimetry, normal amniotic fluid volume, and reassuring fetal heart rate testing can likely be deferred until 38 weeks' gestation. Said another way, uncertainty regarding the diagnosis should preclude intervention until fetal lung maturity is assured. Expectant management can be guided using antepartum fetal surveillance techniques described in Chapter 17. Most clinicians, however, recommend delivery at 34 weeks or beyond if there is clinically significant oligohydramnios. Consensus statements by the Society of Maternal-Fetal Medicine (Spong, 2011) and the American College of Obstetricians and Gynecologists

(2013d) are similar. These recommend delivery between 34 and 37 weeks when there are concurrent conditions such as oligohydramnios. With a reassuring fetal heart rate pattern, vaginal delivery is planned. However, some of these fetuses do not tolerate labor, necessitating cesarean delivery.

Management of the Fetus Remote from Term

If growth restriction is identified in an anatomically normal fetus before 34 weeks, and amniotic fluid volume and fetal surveillance findings are normal, then observation is recommended. Screening for toxoplasmosis, cytomegalovirus infection, rubella, herpes, and other infections is recommended by some. However, we and others have not found this to be productive (Yamamoto, 2013).

As long as there is interval fetal growth and fetal surveillance test results are normal, pregnancy is allowed to continue until fetal lung maturity is reached (see Fig. 44-9). Reassessment of fetal growth is typically made no sooner than 3 to 4 weeks. Weekly assessment of umbilical artery Doppler velocimetry and amniotic fluid volume is combined with periodic non-stress testing, although the optimal frequency has not been determined. As mentioned, we hospitalize these women in our High-Risk Pregnancy Unit and monitor their fetuses daily. If interval growth, amniotic fluid volume, and umbilical artery Doppler velocimetry are normal, then the mother is discharged with intermittent outpatient surveillance.

With growth restriction remote from term, no specific treatment ameliorates the condition. For example, there is no evidence that diminished activity and bed rest result in accelerated growth or improved outcomes. Despite this, many clinicians intuitively advise a program of modified rest. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin have all been shown to be ineffective (American College of Obstetricians and Gynecologists, 2013a).

In most cases diagnosed before term, neither a precise etiology nor a specific therapy is apparent. Management decisions hinge on assessment of the relative risks of fetal death during expectant management versus the risks from preterm delivery. Although reassuring fetal testing may allow observation with continued maturation, long-term neurological outcome is a concern (Baschat, 2011; Thornton, 2004). Baschat and associates (2009) showed that neurodevelopmental outcome at 2 years in growth-restricted fetuses was best predicted by birthweight and gestational age. Doppler abnormalities are generally not associated with poor cognitive development scores among low-birthweight children delivered in the third trimester (Llurba, 2013). These findings emphasize that adverse neurodevelopmental outcomes cannot always be predicted.

Labor and Delivery

Fetal-growth restriction is commonly the result of placental insufficiency due to faulty maternal perfusion, reduction of functional placenta, or both. If present, these conditions are likely aggravated by labor. Equally important, diminished amniotic fluid volume increases the likelihood of cord compression

during labor. For these reasons, a woman with a suspected growth-restricted fetus should undergo “high-risk” intrapartum monitoring (Chap. 22, p. 450). For these and other reasons, the frequency of cesarean delivery is increased.

The risk of neonatal hypoxia or meconium aspiration is also increased. Thus, care for the newborn should be provided immediately by an attendant who can skillfully clear the airway and ventilate an infant as needed (Chap. 32, p. 625). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. In addition, low-birthweight infants are at increased risk for motor and other neurological disabilities. Risk is greatest at the lowest extremes of birthweight (Baschat, 2007, 2009, 2011; Llurba, 2013).

FETAL OVERGROWTH

The term *macrosomia* is used rather imprecisely to describe a very large fetus or neonate. Although there is general agreement among obstetricians that newborns weighing < 4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia.

Newborn weight rarely exceeds 11 pounds (5000 g), and excessively large infants are a curiosity. The largest newborn cited in the *Guinness Book of World Records* was a 23-lb 12-oz (10,800 g) infant boy born to a Canadian woman, Anna Bates, in 1879 (Barnes, 1957). In the United States in 2010, of more than 4 million births, 6.6 percent weighed 4000 to 4499 g; 1 percent weighed 4500 to 4999 g; and 0.1 percent were born weighing 5000 g or more (Martin, 2012). To be sure, the incidence of excessively large infants increased during the 20th century. According to Williams (1903), at the beginning of the 20th century, the incidence of birthweight > 5000 g was 1 to 2 per 10,000 births. This compares with 16 per 10,000 at Parkland Hospital from 1988 through 2008 and 11 per 10,000 in the United States in 2010.

The influence of increasing maternal obesity is overwhelming, and its association with diabetes is well known. Of Parkland mothers with infants born weighing > 5000 g, more than 15 percent were diabetic. Henriksen (2008) searched the Cochrane Database and reported that the rapid increase in the prevalence of large infants was due to maternal obesity and type 2 diabetes. Importantly however, review of data from the National Center for Health Statistics indicates that the rate of birthweight \geq 4000 g has steadily declined more than 30 percent since 1990—from 10.9 percent to 7.6 percent in 2010 (Martin, 2012). This is discussed further in Chapters 48 (p. 967) and 57 (p. 1140).

Definition

Because there are no widely accepted and precise definitions of pathological fetal overgrowth, several terms are currently used clinically. The most common of these—*macrosomia*—is defined by birthweights that exceed certain percentiles for a given population. Another commonly used scheme is to define macrosomia by an empirical birthweight threshold.

TABLE 44-2. Birthweight Distribution of 354,509 Liveborn Infants at Parkland Hospital between 1988 and 2012

Birthweight (g)	Births		Maternal Diabetes	
	Number	Percent	Number	Percent
500–3999	322,074	90.9	13,365	4
4000–4249	19,106	5.4	1043	5
4250–4499	8391	2.4	573	7
4500–4649	3221	0.9	284	9
4750–4999	1146	0.3	134	12
5000–5249	385	0.1	57	15
5250–5499	127	0.04	31	24
5500 or more	59	0.02	14	24
Total	354,509		15,501

Birthweight Distribution

Frequently, macrosomia is defined based on mathematical distributions of birthweight. Those infants exceeding the 90th percentile for a given gestational week are usually used as the threshold for macrosomia or large-for-gestational age (LGA) birthweight. For example, the 90th percentile at 39 weeks is 4000 g. If, however, birthweights that are 2 standard deviations above the mean are used, then thresholds lie at the 97th percentile. Thus, substantially larger infants are considered macrosomic compared with those at the 90th percentile. Specifically, the birthweight threshold at 39 weeks to be macrosomic would be approximately 4500 g for the 97th percentile rather than 4000 g for the 90th percentile.

Empirical Birthweight

Newborn weight exceeding 4000 g—8 lb 13 oz—is also a frequently used threshold to define macrosomia. Others use 4250 g or even 4500 g—10 lb. As shown in [Table 44-2](#), birthweights of 4500 g or more are uncommon. During a 30-year period at Parkland Hospital, during which there were more than 350,000 singleton births, only 1.4 percent of newborns weighed 4500 g or more. We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely two standard deviations above the mean, representing perhaps 3 percent of births. At 40 weeks, such a threshold would correspond to approximately 4500 g. The American College of Obstetricians and Gynecologists (2013b) concluded that the term *macrosomia* was an appropriate appellation for newborns who weigh 4500 g or more at birth.

Risk Factors

Some factors associated with fetal overgrowth are listed in [Table 44-3](#). Many are interrelated and thus likely are additive. For example, advancing age is usually related to multiparity and diabetes, and obesity is obviously related to diabetes. Koyanagi and coworkers (2013) reported that the incidence of macrosomia exceeds 15 to 20 percent in Africa, Asia, and Latin America when women have diabetes, are obese, or have a postterm

TABLE 44-3. Risk Factors for Fetal Overgrowth

Advancing maternal age
Previous macrosomic infant
Racial and ethnic factors

pregnancy. Of these, maternal diabetes is an important risk factor for fetal overgrowth (Chap. 57, p. 1129). As shown in [Table 44-2](#), the incidence of maternal diabetes increases as birthweight > 4000 g increases. It should be emphasized, however, that maternal diabetes is associated with only a small percentage of the total number of such large infants.

Maternal and Perinatal Morbidity

The adverse consequences of excessive fetal growth are considerable. Neonates with a birthweight of at least 4500 g have been reported to have cesarean delivery rates exceeding 50 percent (Das, 2009; Gyurkovits, 2011; Weissmann-Brenner, 2012). The rate of shoulder dystocia has been reported to be as high as 17 percent for neonates with birthweights of at least 4500 g, and 23 percent for neonates with birthweights of at least 5000 g (Stotland, 2004). Rates of postpartum hemorrhage, perineal laceration, and maternal infection, which are related complications, are also increased in mothers delivering overgrown neonates. Maternal and neonatal outcomes by birthweight for large babies > 4000 g and delivered at Parkland Hospital are shown in [Table 44-4](#).

Diagnosis

Because there are no current methods to estimate excessive fetal size accurately, macrosomia cannot be definitively diagnosed until delivery. Inaccuracy in clinical estimates of fetal weight by physical examination is often attributable, at least in part, to maternal obesity. Numerous attempts have been made to improve the accuracy of sonographic fetal-weight estimation. Several formulas have been proposed to calculate fetal weight using measurements of the head, femur, and abdomen. Estimates provided by these computations, although reasonably accurate for predicting the weight of small, preterm fetuses, are less valid in predicting the weight of large fetuses. Rouse and coworkers (1996) reviewed 13 studies completed between 1985 and 1995 to assess the accuracy of sonographic prediction for suspected fetal macrosomia. They found only fair sensitivity—60 percent—in the accurate diagnosis of macrosomia, but higher specificity—90 percent—in excluding excessive fetal size. Thus, sonographic estimation of fetal weight is unreliable, and its routine use to identify macrosomia is not recommended. Indeed, the findings of several studies indicate that clinical fetal-weight estimates are as reliable as, or even superior to, those made from sonographic measurements (Mattsson, 2007; Noumi, 2005; O'Reilly-Green, 2000).

TABLE 44-4. Maternal and Fetal Outcomes for 176,844 Pregnancies Delivered at Parkland Hospital from 1998 Through 2012

Outcome ^a	< 4000 g n = 187,119	4000–4499 g n = 17,750	4500–4999 g n = 2849	≥ 5000 g n = 372	p value

Management

Several interventions have been proposed to interdict fetal overgrowth. Some include prophylactic labor induction for poorly defined indications such as “impending macrosomia,” or elective cesarean delivery to avoid difficult delivery and shoulder dystocia. For women with diabetes in pregnancy, insulin therapy and close attention to good glycemic control reduces birthweight, but this has not consistently translated into reduced cesarean delivery rates (Crowther, 2005; Naylor, 1996). Irrespective of diabetes mellitus, fetal overgrowth among women is strongly associated with maternal obesity and excessive gestational weight gain (Durie, 2011; Johnson, 2013; Vesco, 2011). Dietary intervention to limit fetal overgrowth by curbing gestational weight gain is an active area of research. However, data to safely guide efforts to limit fetal overgrowth among at-risk women are lacking.

“Prophylactic” Labor Induction

Some clinicians have proposed labor induction when fetal macrosomia is suspected in nondiabetic women. This approach is suggested to obviate further fetal growth and thereby reduce potential delivery complications. Such prophylactic induction should theoretically reduce the risk of shoulder dystocia and cesarean delivery. Gonen and colleagues (1997) randomly assigned 273 nondiabetic women with sonographic fetal weight estimates of 4000 to 4500 g to either induction or expectant management. Labor induction did not decrease the rate of cesarean delivery or shoulder dystocia. Similar results were reported by Leapheart and associates (1997), who found that

induction unnecessarily increased the cesarean delivery rate. In their systematic review of 11 studies of expectant management versus labor induction for suspected macrosomia, Sanchez-Ramos and coworkers (2002) found that labor induction results in increased cesarean delivery rates without improved perinatal outcomes.

A review of early term births indicates that elective delivery before 39 weeks’ gestation does not improve maternal outcomes and is associated with worse neonatal outcomes (Wetta, 2012). We agree with the American College of Obstetricians and Gynecologists (2013b,d) that current evidence does not support a policy for early labor induction before 39 weeks’ gestation or delivery for suspected macrosomia. Moreover, delivery or induction for suspected macrosomia at term is likewise not indicated.

Elective Cesarean Delivery

Rouse and colleagues (1996, 1999) analyzed the potential effects of a policy of elective cesarean delivery for sonographically diagnosed fetal macrosomia compared with standard obstetrical management. They concluded that for women who are not diabetic, a policy of elective cesarean delivery was medically and economically unsound. The American College of Obstetricians and Gynecologists (2013b) does not recommend routine cesarean delivery in women without diabetes when the estimated fetal weight is < 5000 g. Conversely, in *diabetic* women with overgrown fetuses, such a policy of elective cesarean delivery seems tenable. Conway and Langer (1998) described a protocol of routine cesarean delivery for

sonographic estimates of 4250 g or greater in diabetic women. This management significantly reduced the shoulder dystocia rate from 2.4 to 1.1 percent.

Prevention of Shoulder Dystocia

With the delivery of macrosomic infants, shoulder dystocia and its attendant risks described in Chapter 27 (p. 541) are major concerns. That said, the American College of Obstetricians and Gynecologists (2012) notes that fewer than 10 percent of all shoulder dystocia cases result in a persistent brachial plexus injury, and 4 percent of these follow cesarean delivery.

It appears that planned cesarean delivery on the basis of suspected macrosomia to prevent brachial plexopathy is an unreasonable strategy in the *general population* (Chauhan, 2005). Ecker and coworkers (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive infants born at Brigham and Women's Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in neonates born to women without diabetes. Conversely, planned cesarean delivery may be a reasonable strategy for diabetic women with an estimated fetal weight > 4250 or > 4500 g.

In summary, when fetal overgrowth is suspected, the obstetrician naturally seeks to balance the risks to the fetus with maternal risks. Although interventions to prevent shoulder dystocia may someday prove beneficial, eliminating shoulder dystocia will likely remain an impossible goal. We agree with the American College of Obstetricians and Gynecologists that elective delivery for the fetus that is suspected to be overgrown is inadvisable, particularly before 39 weeks' gestation. Finally, we agree that elective cesarean delivery is not indicated when estimated fetal weight is < 5000 g among women without diabetes and < 4500 g among women with diabetes (American College of Obstetricians and Gynecologists, 2013b).

CHAPTER 45

Multifetal Pregnancy

MECHANISMS OF MULTIFETAL GESTATIONS	892
DIAGNOSIS OF MULTIPLE FETUSES	896
MATERNAL ADAPTATION TO MULTIFETAL PREGNANCY	898
PREGNANCY COMPLICATIONS	899
UNIQUE FETAL COMPLICATIONS	901
DISCORDANT GROWTH OF TWIN FETUSES	909
FETAL DEMISE	910
PRENATAL CARE AND ANTEPARTUM MANAGEMENT	912
PRETERM BIRTH	913
LABOR AND DELIVERY	915
TRIPLLET OR HIGHER-ORDER GESTATION	918
SELECTIVE REDUCTION OR TERMINATION	919

Multifetal pregnancies may result from two or more fertilization events, from a single fertilization followed by an “erroneous” splitting of the zygote, or from a combination of both. Such pregnancies are associated with increased risk for both mother and child, and this risk increases with the number of offspring. For example, 60 percent of twins, 90 percent of triplets, and virtually all of quadruplets are born preterm (Martin, 2012). From these observations, it is apparent that women were not intended to concurrently bear more than one offspring. And although they are often viewed as a novelty or miracle, multifetal pregnancies represent a potentially perilous journey for the mother and her unborn children.

Fueled largely by infertility therapy, both the rate and the number of twin and higher-order multifetal births have increased dramatically since 1980. Specifically, the twinning rate rose 76 percent from 18.9 to 32.1 per 1000 live births in 2009 (Martin, 2012). During the same time, the number of higher-order multifetal births increased more than 400 percent to a peak in 1998. Since then, however, evolving infertility management has resulted in decreased rates of higher-order multifetal births to its lowest level in 15 years. Specifically, the rate of triplets or more decreased by 10 percent from 153 per 100,000 births in 2009 to 138 per 100,000 births in 2010 (Martin, 2012).

The overall increase in prevalence of multifetal births is of concern because the corresponding increase in the rate of preterm birth compromises neonatal survival and increases the risk of lifelong disability. For example, in this country, about a fourth of very-low-birthweight neonates—those born weighing < 2500 g—are from multifetal gestations, and 15 percent of infants who die in the first year after birth are from multifetal pregnancies (Martin, 2012). In 2009, the infant mortality rate for multiple births was five times the rate for singletons (Mathews, 2013). A comparison of singleton and twin outcomes from infants delivered at Parkland Hospital is shown in [Table 45-1](#). These risks are magnified further with triplets or quadruplets. In addition to these adverse outcomes, the risks for congenital malformations are increased with multifetal gestation. Importantly, this increased risk is for *each* fetus and is not simply because there are more fetuses per pregnancy.

The mother may also experience higher obstetrical morbidity and mortality rates. These also increase with the number of fetuses (Mhyre, 2012; Wen, 2004). In a study of more than 44,000 multifetal pregnancies, Walker and colleagues (2004) reported that, compared with singletons, the risks for preeclampsia, postpartum hemorrhage, and maternal death were increased twofold or more. The risk for peripartum hysterectomy is also increased, and Francois and associates (2005) reported this to

TABLE 45-1. Selected Outcomes in Singleton and Twin Pregnancies Delivered at Parkland Hospital from 2002 through 2012

Outcome	Singletons (No.)	Twins (No.)
Pregnancies	78,879	850
Births ^a	78,879	1700
Stillbirths	406 (5.1)	24 (14.1)
Neonatal deaths	253 (3.2)	38 (22.4)
Perinatal deaths	659 (8.4)	62 (36.5)
Very low birthweight (< 1500 g)	895 (1.0)	196 (11.6)

^aBirth data are represented as number (per 1000).

be threefold for twins and 24-fold for triplets or quadruplets. Finally, these mothers are at increased risk for depression compared with women with a singleton pregnancy (Choi, 2009).

MECHANISMS OF MULTIFETAL GESTATIONS

Twin fetuses usually result from fertilization of two separate ova—*dizygotic* or *fraternal twins*. Less often, twins arise from a single fertilized ovum that divides—*monozygotic* or *identical twins*. Either or both processes may be involved in the formation of higher numbers. Quadruplets, for example, may arise from as few as one to as many as four ova.

■ Dizygotic versus Monozygotic Twinning

Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle. Moreover, from a genetic perspective, dizygotic twins are like any other pair of siblings. On the other hand, monozygotic or identical twins, although they have virtually the same genetic heritage, are usually not identical.

As discussed subsequently, the division of one fertilized zygote into two does not necessarily result in equal sharing of protoplasmic material. Monozygotic twins may actually be discordant for genetic mutations because of a postzygotic mutation, or may have the same genetic disease but with marked variability in expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Furthermore, the process of monozygotic twinning is in a sense a teratogenic event, and monozygotic twins have an increased incidence of often discordant malformations (Glinianaia, 2008). For example, in a study of 926 monozygotic twins, Pettit (2013) reported a 12-fold increase in the prevalence of congenital heart defects, but 68 percent of affected infants had a normal sibling. Accordingly, dizygotic or fraternal twins of the same sex may appear more nearly identical at birth than monozygotic twins.

Genesis of Monozygotic Twins

The developmental mechanisms underlying monozygotic twinning are poorly understood. Minor trauma to the blastocyst during assisted reproductive technology (ART) may lead to the increased incidence of monozygotic

twinning observed in pregnancies conceived in this manner (Wenstrom, 1993).

The outcome of the monozygotic twinning process depends on when division occurs. If zygotes divide within the first 72 hours after fertilization, two embryos, two amnions, and two chorions develop, and a diamnionic, dichorionic twin pregnancy evolves (Fig. 45-1). Two distinct placentas or a single, fused placenta may develop. If division occurs between the fourth and eighth day, a diamnionic, monochorionic twin pregnancy results. By approximately 8 days after fertilization, the chorion and the amnion have already differentiated, and division results in two embryos within a common amnionic sac, that is, a monoamniotic, monochorionic twin pregnancy. Conjoined twins result if twinning is initiated later.

It has long been accepted that monochorionicity incontrovertibly indicated monozygosity. Rarely, however, monochorionic twins may in fact be dizygotic (Hack, 2009). Mechanisms for this are speculative, but Ekelund and coworkers (2008) found in their review of 14 such cases that nearly all have been conceived after ART procedures.

Superfetation and Superfecundation

In *superfetation*, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation requires ovulation and fertilization during the course of an established pregnancy, which is theoretically possible until the uterine cavity is obliterated by fusion of the decidua capsularis to the decidua parietalis. Although known to occur in mares, superfetation is not known to occur spontaneously in humans. Lantieri and colleagues (2010) reported a case after ovarian hyperstimulation and intrauterine insemination in the presence of an undiagnosed tubal pregnancy. Most authorities believe that alleged cases of human superfetation result from markedly unequal growth and development of twin fetuses with the same gestational age.

Superfecundation refers to fertilization of two ova within the same menstrual cycle but not at the same coitus, nor necessarily by sperm from the same male. An instance of superfecundation or heteropaternality, documented by Harris (1982), is demonstrated in Figure 45-2. The mother was sexually assaulted on the 10th day of her menstrual cycle and had intercourse 1 week later with her husband. She was delivered of a black neonate whose blood type was A and a white neonate whose blood type was O. The blood type of the mother and her husband was O.

■ Frequency of Twinning

Dizygotic twinning is much more common than monozygous splitting of a single oocyte, and its incidence is influenced by race, heredity, maternal age, parity, and, especially, fertility treatment. By contrast, the frequency of monozygotic twin births is relatively constant worldwide—approximately one set per 250 births, and this incidence is generally independent of race, heredity, age, and parity. One exception is that zygotic splitting is increased following ART (Aston, 2008).

The “Vanishing Twin”

The incidence of twins in the first trimester is much greater than the incidence of twins at birth. Studies in which fetuses were

FIGURE 45-1 Mechanism of monozygotic twinning. Black boxing and blue arrows in columns A, B, and C indicate timing of division. **A.** At 0 to 4 days postfertilization, an early conceptus may divide into two. Division at this early stage creates two chorions and two amnions (dichorionic, diamniotic). Placentas may be separate or fused. **B.** Division between 4 and 8 days leads to formation of a blastocyst with two separate embryoblasts (inner cell masses). Each embryoblast will form its own amnion within a shared chorion (monochorionic, diamniotic). **C.** Between 8 and 12 days, the amnion and amniotic cavity form above the germinal disc. Embryonic division leads to two embryos with a shared amnion and shared chorion (monochorionic, monoamniotic). **D.** Differing theories explain conjoined twin development. One describes an incomplete splitting of one embryo into two. The other describes fusion of a portion of one embryo from a monozygotic pair onto the other.

evaluated with sonography in the first trimester have shown that one twin is lost or “vanishes” before the second trimester in up to 10 to 40 percent of all twin pregnancies (Brady, 2013). The incidence is higher in the setting of ART.

Monochorionic twins have a significantly greater risk of abortion than dichorionic twins (Sperling, 2006). In some cases, the entire pregnancy aborts. In many cases, however, only one fetus dies, and the remaining fetus delivers as a singleton. Undoubtedly, some threatened abortions have resulted in death and resorption of one embryo from an unrecognized twin ges-

tation. It has been estimated that 1 in 80 *births* are multifetal, whereas 1 in 8 *pregnancies* begin multifetal followed by spontaneous reduction of one or more embryos or fetuses (Corsello, 2010).

Dickey and associates (2002) described spontaneous reduction in 709 women with a multifetal pregnancy. Before 12 weeks, one or more embryos died in 36 percent of twin pregnancies, 53 percent of triplet pregnancies, and 65 percent of quadruplet pregnancies. Interestingly, pregnancy duration and birthweight were inversely related to the initial gestational sac number regardless

FIGURE 45-2 An example of dizygotic twin boys as the consequence of superfecundation.

of the final number of fetuses at delivery. This effect was most pronounced in twins who started as quadruplets. Chasen and coworkers (2006) reported that spontaneous reduction of an in vitro fertilization (IVF) twin pregnancy to a singleton pregnancy was associated with perinatal outcomes intermediate between IVF singleton pregnancies and IVF twin pregnancies that did not undergo spontaneous reduction.

In one analysis of 41 cases of spontaneous reduction, higher values of *pregnancy-associated plasma protein A* (PAPP-A) and free β -human chorionic gonadotropin (β -hCG) were identified (Chasen, 2006). Gjerris and colleagues (2009) compared 56 cases of “vanishing twin” to 897 singletons after ART and did not identify any differences in first-trimester serum markers as long as the reduction was identified before 9 weeks. If diagnosed after 9 weeks, the serum markers were higher and less precise than in singleton ART gestations. Therefore, the diagnosis of vanishing twin should be excluded to avoid confusion during maternal serum screening for Down syndrome or neural-tube defects (Chap. 14, p. 283).

Factors That Influence Twinning

Race. The frequency of multifetal births varies significantly among different races and ethnic groups (Table 45-2). Abel and Kruger (2012) analyzed more than 8 million births in

TABLE 45-2. Twinning Rates per 1000 Births by Zygosity			
Country	Monozygotic	Dizygotic	Total
Nigeria	5.0	49	54
United States			
Black	4.7	11.1	15.8
White	4.2	7.1	11.3
England and Wales	3.5	8.8	12.3
India (Calcutta)	3.3	8.1	11.4
Japan	3.0	1.3	4.3

FIGURE 45-3 Multifetal birth rates in the United States according to maternal age and race, 2010. (Data from Martin, 2012.)

the United States between 2004 and 2008. These investigators found the highest rate of twinning in African American women (3.5 percent) and lower rates in white (3.0 percent) women. Hispanic, Asian, and Native American women had comparatively lower rates than white women. In one rural community in Nigeria, Knox and Morley (1960) found that twinning occurred once in every 20 births! These marked differences in twinning frequency may be the consequence of racial variations in levels of follicle-stimulating hormone—FSH (Nylander, 1973).

Maternal Age. As depicted in Figure 45-3, maternal age is another important risk factor for multiple births. Dizygotic twinning frequency increases almost fourfold between the ages of 15 and 37 years (Painter, 2010). It is in this age range that maximal FSH stimulation increases the rate of multiple follicles developing (Beemsterboer, 2006). The rate of twinning also increases dramatically with advancing maternal age because the use of ART is more likely in older women (Ananth, 2012). Although paternal age has been linked to frequency of twinning, its affect is felt to be small (Abel, 2012).

Parity. Increasing parity has been shown to independently increase the incidence of twinning in all populations studied. Antsaklis and coworkers (2013) noted a progressive increase in multiparity in twinning during a 30-year period, but cautioned

that some of this increase is presumably due to ART. In a two-year study from Nigeria, where such technology is not commonly available, Olusanya (2012) calculated an eightfold increase in multiple gestations when parity was 4 or less and a 20-fold increase when parity was 5 or more compared with primiparas.

Heredity. As a determinant of twinning, the family history of the mother is more important than that of the father. In a study of 4000 genealogical records, White and Wyshak (1964) found that women who themselves were a dizygotic twin gave birth to twins at a rate of 1 set per 58 births. Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at a rate of 1 set per 116 pregnancies. Painter and associates (2010) performed genome-wide linkage analyses on more than 500 families of mothers of dizygotic twins and identified four potential linkage peaks. The highest peak was on the long arm of chromosome 6, with other suggestive peaks on chromosomes 7, 9, and 16. That said, the contribution of these variants to the overall incidence of twinning is likely small (Hoekstra, 2008).

Nutritional Factors. In animals, litter size increases in proportion to nutritional sufficiency. Evidence from various sources indicates that this occurs in humans as well. Nylander (1971) showed a definite increasing gradient in the twinning rate related to greater nutritional status as reflected by maternal size. Taller, heavier women had a twinning rate 25 to 30 percent greater than short, nutritionally deprived women. Evidence acquired during and after World War II showed that twinning correlated more with nutrition than body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959). Several investigators have reported a 40-percent increase in the prevalence of twinning among women who have taken supplementary folic acid (Ericson, 2001; Haggarty, 2006; Hasbargen, 2000). Conversely, in a systematic review, Muggli and Halliday (2007) were unable to demonstrate a significant association. Analysis of twinning rate in Texas after folic acid fortification of cereal-grain products also did not demonstrate an independent increase in twinning between 1996 and 1998 (Waller, 2003).

Pituitary Gonadotropin. The common factor linking race, age, weight, and fertility to multifetal gestation may be FSH levels (Benirschke, 1973). This theory is supported by the fact that increased fecundity and a higher rate of dizygotic twinning have been reported in women who conceive within 1 month after stopping oral contraceptives, but not during subsequent months (Rothman, 1977). This may be due to the sudden release of pituitary gonadotropin in amounts greater than usual during the first spontaneous cycle after stopping hormonal contraception. Indeed, the paradox of declining fertility but increasing twinning with advancing maternal age can be explained by an exaggerated pituitary release of FSH in response to decreased negative feedback from impending ovarian failure (Beemsterboer, 2006).

Infertility Therapy. Ovulation induction with FSH plus chorionic gonadotropin or clomiphene citrate remarkably

enhances the likelihood of multiple ovulations. A mainstay of current infertility therapy and common antecedent to IVF is ovarian stimulation followed by timed intrauterine insemination. In their review of this practice, McClamrock and coworkers (2012) reported rates of twin and higher-order multifetal pregnancies as high as 28.6 percent and 9.3 percent, respectively. Rates this high remain a major concern. There are currently two ongoing multicenter trials—Assessment of Multiple Gestations from Ovarian Stimulation (AMIGOS) and Pregnancy in Polycystic Ovary Syndrome II (PPCOSII)—that are designed to provide guidance on achieving maximum pregnancy rates while minimizing multifetal gestation rates (Diamond, 2011; Legro, 2012).

In general with IVF, the greater the number of embryos that are transferred, the greater the risk of twins and multiple fetuses. In 2005, 1 percent of infants born in the United States were conceived through ART, and these infants accounted for 17 percent of multifetal births (Wright, 2008). The American Society for Reproductive Medicine (2013) recently revised their age-related guidelines on numbers of cleavage-stage embryos or blastocysts to transfer in an effort to reduce the incidence of higher-order multifetal pregnancies. For example, women younger than 35 years with a favorable prognosis should have no more than two embryos transferred. These practices have effectively lowered rates (Kulkarni, 2013).

Sex Ratios with Multiple Fetuses

In humans, as the number of fetuses per pregnancy increases, the percentage of male conceptuses decreases. Strandkov and coworkers (1946) found the percentage of males in 31 million singleton births in the United States was 51.6 percent. For twins, it was 50.9 percent; for triplets, 49.5 percent; and for quadruplets, 46.5 percent. Swedish birth data spanning 135 years reveals the number of males per 100 female infants born was 106 among singletons, 103 among twins, and 99 among triplets (Fellman, 2010). Females predominate even more in twins from late twinning events. For example, 68 percent of thoracopagus conjoined twins are female (Mutchinick, 2011). Two explanations have been offered. First, beginning in utero and extending throughout the life cycle, mortality rates are lower in females. Second, female zygotes have a greater tendency to divide.

Determination of Zygosity

Twins of opposite sex are almost always dizygotic. In rare instances, due to somatic mutations or chromosome aberrations, the karyotype or phenotype of a monozygous twin gestation can be different. Most reported cases are related to postzygotic loss of the Y chromosome in one 46,XY twin. This results in a phenotypically female twin due to Turner syndrome (45,X). Zech and colleagues (2008) reported a rare case of a 47,XXY zygote that underwent postzygotic loss of the X chromosome in some cells and loss of the Y chromosome in other cells. The phenotype of the resultant twins was one male and one female. Karyotype analyses revealed both to be 46,XX/46,XY genetic mosaics.

TABLE 45-3. Overview of the Incidence of Twin Pregnancy Zygosity and Corresponding Twin-Specific Complications

Type of Twinning	Twins	Rates of Twin-Specific Complications in Percent			
		Fetal-Growth Restriction	Preterm Delivery ^a	Placental Vascular Anastomosis	Perinatal Mortality
Dizygous	80	25	40	0	10–12
Monozygous	20	40	50		15–18
Diamnionic/dichorionic	6–7	30	40	0	18–20
Diamnionic/monochorionic	13–14	50	60	100	30–40
Monoamnionic/monochorionic	< 1	40	60–70	80–90	58–60
Conjoined	0.002 to 0.008	—	70–80	100	70–90

^aDelivery before 37 weeks.

The risk for twin-specific complications varies in relation to zygosity as well as *chorionicity*—the number of chorions. As shown in [Table 45-3](#), the latter is the more important determinant. Specifically, there are increased rates of perinatal mortality and neurological injury in monochorionic diamnionic twins compared with dichorionic pairs (Hack, 2008; Lee, 2008). In their retrospective analysis of more than 2000 twins, McPherson and associates (2012) reported that the risk of fetal demise in one or both monochorionic twins was twice that in dichorionic multifetal gestations.

Sonographic Determination of Chorionicity

Chorionicity can sometimes be identified in the first trimester with sonography. Two separate placentas suggest dizygosity. In pregnancies with a single placental mass, it may be difficult to identify chorionicity. Identification of a thick dividing membrane—generally 2 mm or greater—supports a presumed diagnosis of dichorionicity. Also, the *twin peak sign* is seen by examining the point of origin of the dividing membrane on the placental surface. The peak appears as a triangular projection of placental tissue extending a short distance between the layers of the dividing membrane ([Fig. 45-4](#)).

In contrast, monochorionic pregnancies have a dividing membrane that is so thin it may not be seen until the second trimester. The membrane is generally less than 2-mm thick, and magnification reveals only two layers. The right-angle relationship between the membranes and placenta and no apparent extension of placenta between the dividing membranes is called the *T sign* ([Fig. 45-5](#)). Evaluation of the dividing membrane can establish chorionicity in more than 99 percent of pregnancies in the first trimester (Miller, 2012).

Placental Examination

A carefully performed visual examination of the placenta and membranes after delivery serves to establish zygosity and chorionicity promptly in approximately two thirds of cases. The following systematic examination is recommended. As the first neonate is delivered, one clamp is placed on a portion of its cord. Cord blood is generally not collected until after delivery of the other twin. As the second neonate is delivered, two clamps are placed on that cord. Three clamps are used to mark the cord of a third neonate, and so on as necessary. Until

the delivery of the last fetus, each cord segment must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then through an unclamped cord.

The placenta should be carefully delivered to preserve the attachment of the amnion and chorion. With one common amnionic sac, or with juxtaposed amnions not separated by chorion arising between the fetuses, the fetuses are monozygotic. If adjacent amnions are separated by chorion, then the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (see [Figs. 45-1](#) and [45-6](#)). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different blood types confirm dizygosity, although demonstrating the same blood type in each fetus does not confirm monozygosity. For definitive diagnosis, more complicated techniques such as DNA fingerprinting can be used, but these tests are generally not performed at birth unless there is a pressing medical indication.

DIAGNOSIS OF MULTIPLE FETUSES

Clinical Evaluation

During examination, accurate fundal height measurement, described in [Chapter 9](#) (p. 176), is essential. With multiple fetuses, uterine size is typically larger during the second trimester than expected. Rouse and associates (1993) reported fundal heights in 336 well-dated twin pregnancies. Between 20 and 30 weeks, fundal heights averaged approximately 5 cm greater than expected for singletons of the same fetal age.

In general, it is difficult to diagnose twins by palpation of fetal parts before the third trimester. Even late in pregnancy, it may be difficult to identify twins by abdominal palpation, especially if one twin overlies the other, if the woman is obese, or if there is hydramnios. Palpating two fetal heads, often in different uterine quadrants, strongly supports a twin diagnosis.

Late in the first trimester, fetal heart action may be detected with Doppler ultrasonic equipment. Thereafter, it becomes possible to identify two fetal heartbeats if their rates are clearly distinct from each other and from that of the mother. Careful examination with an aural fetal stethoscope can identify fetal heart sounds in twins as early as 18 to 20 weeks.

A

B

FIGURE 45-4 A. Sonographic image of the “twin-peak” sign, also termed the “lambda sign,” in a 24-week gestation. At the top of this sonogram, tissue from the anterior placenta is seen extending downward between the amnion layers. This sign confirms dichorionic twinning. **B.** Schematic diagram of the “twin-peak” sign. A triangular portion of placenta is seen insinuating between the amniochorion layers.

A

B

FIGURE 45-5 A. Sonographic image of the “T” sign in a mono-chorionic diamnionic gestation at 30 weeks. **B.** Schematic diagram of the “T” sign. Twins are separated only by a membrane created by the juxtaposed amnion of each twin. A “T” is formed at the point at which amnions meet the placenta.

Sonography

By careful sonographic examination, separate gestational sacs can be identified early in twin pregnancy (Fig. 45-7). Subsequently, each fetal head should be seen in two perpendicular planes so as not to mistake a cross section of the fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens should be seen in the same image plane, to avoid scanning the same fetus twice and interpreting it as twins. Sonographic examination should detect practically all sets of twins. Given the increased frequency of sonographic examinations during the first trimester, early detection of a twin pregnancy is common. Indeed, one argument in favor of routine first-trimester sonographic screening is earlier detection of multiple fetuses.

Higher-order multifetal gestations are more difficult to evaluate. Even in the first trimester, it can be difficult to identify the actual number of fetuses and their position. This determination is especially important if pregnancy reduction or selective termination is considered (p. 919).

FIGURE 45-6 Dichorionic diamnionic twin placenta. The membrane partition that separated twin fetuses is elevated and consists of chorion (c) between two amnions (a).

FIGURE 45-7 Sonograms of first-trimester twins. **A.** Dichorionic diamniotic twin pregnancy at 6 weeks' gestation. Note the thick dividing chorion (yellow arrow). One of the yolk sacs is indicated (blue arrow). **B.** Monochorionic diamniotic twin pregnancy at 8 weeks' gestation. Note the thin amnion encircling each embryo, resulting in a thin dividing membrane (blue arrow).

Other Diagnostic Aids

Radiography and Magnetic Resonance Imaging

Abdominal radiography can be used if fetal number in a higher-order multifetal gestation is uncertain. However, radiographs generally have limited utility and may lead to an incorrect diagnosis if there is hydramnios, obesity, fetal movement during the exposure, or inappropriate exposure time. Additionally, fetal skeletons before 18 weeks' gestation are insufficiently radiopaque and may be poorly seen.

Although not typically used to diagnose multifetal pregnancy, magnetic resonance (MR) imaging may help delineate complications in monochorionic twins (Hu, 2006). Bekiesinska-Figatowska and colleagues (2013) reviewed their experience with 17 complicated twin gestations evaluated by both sonographic and MR imaging. They concluded that MR imaging provides a more detailed assessment of pathology in twins and is particularly helpful in cases of conjoined twins.

Biochemical Tests

There is no biochemical test that reliably identifies multiple fetuses. Serum and urine levels of β -hCG and maternal serum alpha-fetoprotein (MSAFP) are generally higher with twins compared with singletons. However, levels may vary considerably and overlap with those of singletons.

MATERNAL ADAPTATION TO MULTIFETAL PREGNANCY

The various physiological burdens of pregnancy and the likelihood of serious maternal complications are typically greater with multiple fetuses than with a singleton. This should be considered, especially when counseling a woman whose health is compromised and in whom multifetal gestation is recognized early. Similar consideration is given to a woman who is not pregnant but is considering infertility treatment.

Beginning in the first trimester, and temporarily associated with higher serum β -hCG levels, women with multifetal

gestation often have nausea and vomiting in excess of women with a singleton pregnancy. In women with multiple fetuses, blood volume expansion is greater and averages 50 to 60 percent compared with 40 to 50 percent in those with a singleton (Pritchard, 1965). Although the red cell mass also increases, it does so proportionately less in twin pregnancies. Combined with increased iron and folate requirements, this predisposes to anemia. This augmented hypervolemia teleologically offsets blood loss with vaginal delivery of twins, which is twice that with a single fetus.

Women carrying twins also have a typical pattern of arterial blood pressure change. MacDonald-Wallis and coworkers (2012) analyzed serial blood pressures in more than 13,000 singleton and twin pregnancies. As early as 8 weeks' gestation, the diastolic blood pressure in women with twins was lower than that with singleton pregnancies but generally increased to a greater degree at term. In an earlier study, Campbell (1986) demonstrated that this increase was at least 15 mm Hg in 95 percent of women with twins compared with only 54 percent of women with a singleton.

Hypervolemia along with decreased vascular resistance has an impressive affect on cardiac function. Kametas and associates (2003) assessed function in 119 women with a twin pregnancy. In these women, cardiac output was increased another 20 percent above that in women with a singleton pregnancy. Kuleva and colleagues (2011) compared serial echocardiography results in 20 women with uncomplicated twin pregnancies with those of 10 women with singletons. Similarly, they also demonstrated a greater increase in cardiac output in those with twins. Both studies found the cardiac output rise was predominantly due to greater stroke volume and to a much lesser degree due to increased heart rate. Vascular resistance was significantly lower in twin gestations throughout pregnancy compared with singleton gestations (Kuleva, 2011).

Uterine growth in a multifetal gestation is substantively greater than in a singleton pregnancy. The uterus and its non-fetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds. Especially with monozygotic

twins, excessive amounts of amniotic fluid may rapidly accumulate. In these circumstances, maternal abdominal viscera and lungs can be appreciably compressed and displaced by the expanding uterus. As a result, the size and weight of the large uterus may preclude more than a sedentary existence for these women.

If hydrops develops, maternal renal function can become seriously impaired, most likely as the consequence of obstructive uropathy (Quigley, 1977). With severe hydrops, therapeutic amniocentesis may provide relief for the mother, may improve obstructive uropathy, and possibly may lower the preterm delivery risk that follows preterm labor or prematurely ruptured membranes (Chap. 11, p. 236). Unfortunately, hydrops is often characterized by acute onset remote from term and by rapid reaccumulation following amniocentesis.

PREGNANCY COMPLICATIONS

Spontaneous Abortion

Miscarriage is more likely with multiple fetuses. During a 16-year study, Joo and colleagues (2012) demonstrated that the spontaneous abortion rate per live birth in singleton pregnancies was 0.9 percent compared with 7.3 percent in multiple pregnancies. Furthermore, they found that monochorial placentation was more common in multiple gestations ending in miscarriage than in those resulting in a livebirth. Twin pregnancies achieved through ART are at increased risk for abortion compared with those conceived spontaneously (Szymusik, 2012).

Congenital Malformations

The incidence of congenital malformations is appreciably increased in multifetal gestations compared with singletons. Glinianaia and associates (2008) reported that the rate of congenital malformations was 406 per 10,000 twins versus 238 per 10,000 singletons. In this survey-based study, the malformation rate in monochorionic twins was almost twice that of dichorionic twin gestations. This increase has been attributed to the high incidence of structural defects in monozygotic twins. But from a 30-year European registry of multifetal births, Boyle and coworkers (2013) found a steady increase in structural anomalies from 1987 (2.16 percent) to 2007 (3.26 percent). During this time, the proportion of dizygotic twins increased by 30 percent, while the proportion of monozygotic twins remained stable. This higher risk of congenital malformations in dizygotic twins over time correlates with increased availability of ART. An increase in birth defects related to ART has been reported repeatedly (Talaaliker, 2012).

Low Birthweight

Multifetal gestations are more likely to be low birthweight than singleton pregnancies due to restricted fetal growth and preterm delivery. From 1988 to 2012 at Parkland Hospital, data were collected from 357,205 singleton neonates without malformations and from 3714 normal twins who were both liveborn. Birthweights in twin infants closely paralleled those of singletons until 28 to 30 weeks' gestation. Thereafter, twin

FIGURE 45-8 Birthweight percentiles (25th to 75th) for 357,205 singleton neonates compared with the 50th birthweight percentile for 3714 twins, Parkland Hospital 1988–2012. Infants with major malformations, pregnancies complicated by stillbirth, and twin gestations with > 25 percent discordance were excluded. (Data courtesy of Dr. Don McIntire.)

birthweights progressively lagged (Fig. 45-8). Beginning at 35 to 36 weeks, twin birthweights clearly diverge from those of singletons.

In general, the degree of growth restriction increases with fetal number. The caveat is that this assessment is based on growth curves established for singletons. Several authorities argue that fetal growth in twins is different from that of singleton pregnancies, and thus abnormal growth should be diagnosed only when fetal size is less than expected for *multifetal gestation*. Accordingly, twin and triplet growth curves have been developed (Kim, 2010; Odibo, 2013; Vora, 2006).

The degree of growth restriction in monozygotic twins is likely to be greater than that in dizygotic pairs (Fig. 45-9). With monochorionic embryos, allocation of blastomeres may not be equal, vascular anastomoses within the placenta may cause unequal distribution of nutrients and oxygen, and discordant structural anomalies resulting from the twinning event

FIGURE 45-9 Marked growth discordance in monozygotic twins. (Photograph contributed by Dr. Laura Greer.)

FIGURE 45-10 Davis quintuplets at 3 weeks following delivery. The first, second, and fourth newborns from the left each arose from separate ova, whereas the third and fifth neonates are from the same ovum.

itself may affect growth. For example, the quintuplets shown in [Figure 45-10](#) represent three dizygotic and two monozygotic fetuses. When delivered at 31 weeks, the three neonates from separate ova weighed 1420, 1530, and 1440 g, whereas the two derived from the same ovum weighed 990 and 860 g.

In the third trimester, the larger fetal mass leads to accelerated placental maturation and relative placental insufficiency. In dizygotic pregnancies, marked size discordancy usually results from unequal placentation, with one placental site receiving more perfusion than the other. Size differences may also reflect different genetic fetal-growth potentials. Discordancy can also result from fetal malformations, genetic syndromes, infection, or umbilical cord abnormalities such as velamentous insertion, marginal insertion, or vasa previa (Chap. 6, p. 122).

Hypertension

Hypertensive disorders due to pregnancy are more likely to develop with multiple fetuses. The exact incidence attributable to twin gestation is difficult to determine because twin pregnancies are more likely to deliver preterm before preeclampsia can develop and because women with twin pregnancies are often older and multiparous. The incidence of pregnancy-related hypertension in women with twins is 20 percent at Parkland Hospital. In their analysis of 513 twin pregnancies > 20 weeks' gestation, Fox and coworkers (2014) also identified 20 percent of parturients with either gestational hypertension or preeclampsia. Case-control analyses suggest that prepregnancy body mass index (BMI) ≥ 30 kg/m² and egg donation are additional independent risk factors for preeclampsia. Gonzalez and colleagues (2012) compared 257 women with twins and gestational diabetes with 277 nondiabetic women carrying twins. These researchers found a twofold increased risk of preeclampsia in women diagnosed with gestational diabetes. Finally, in the Matched Multiple Birth Dataset for the

National Center for Health Statistics, Luke and associates (2008) analyzed 316,696 twin, 12,193 triplet, and 778 quadruple pregnancies. These investigators found that the risk for pregnancy-associated hypertension was significantly increased for triplets and quadruplets (11 and 12 percent, respectively) compared with that for twins (8 percent).

These data suggest that fetal number and placental mass are involved in preeclampsia pathogenesis. Women with twin pregnancies have levels of antiangiogenic soluble fms-like tyrosine kinase-1 (sFlt-1) that are twice that of singletons. Levels are seemingly related to increased placental mass rather than primary placental pathology (Bdolah, 2008; Maynard, 2008). Rana and coworkers (2012) measured antiangiogenic sFlt-1 and proangiogenic placental growth factor (PlGF) in 79 women with twins referred for evaluation of preeclampsia. In the 58 women identified with either gestational hypertension or preeclampsia, there was

a stepwise increase in sFlt-1 concentrations, decrease in PlGF levels, and increase in sFlt-1/PlGF ratios compared with normotensive twin pregnancies. With multifetal gestation, hypertension not only develops more often but also tends to develop earlier and be more severe. In the analysis of angiogenic factors mentioned above, more than one half presented before 34 weeks, and in those who did, the sFlt-1/PlGF ratio rise was more striking (Rana, 2012). This relationship is discussed in Chapter 40 (p. 735).

Preterm Birth

The duration of gestation decreases with increasing fetal number ([Fig. 45-11](#)). According to Martin and colleagues (2012), more than five of every 10 twins and nine of 10 triplets born in the United States in 2010 were delivered preterm. Delivery before term is a major reason for increased neonatal morbidity and mortality rates in multifetal pregnancy. Prematurity is increased sixfold and tenfold in twins and triplets, respectively (Giuffre, 2012). In their review, Chauhan and associates (2010) reported that, similar to singleton pregnancies, approximately 60 percent of preterm births in twins are indicated, about a third result from spontaneous labor, and 10 percent follow prematurely ruptured membranes. In their analysis of almost 300,000 live births in Ohio, Pakrashi and DeFranco (2013) found that the proportion of preterm birth associated with premature membrane rupture increased with gestational plurality from 13 percent with singletons to 20 percent with triplets or more.

The preterm birth rate among multifetal gestations has increased during the past two decades. In an analysis of nearly 350,000 twin births, Kogan and coworkers (2000) showed that during the 16-year period ending in 1997, the term birth rate among twins declined by 22 percent. Joseph and colleagues (2001) attributed this decline to an increased rate of indicated preterm deliveries. This trend is not necessarily negative, as it was associated with decreased perinatal morbidity and mortality

FIGURE 45-11 Cumulative percent of singleton, twin, and triplet or higher-order multifetal births according to gestational age at delivery in the United States during 1990. (From Luke, 1994, with permission.)

rates among twins that reached 34 weeks. Although the causes of preterm delivery in twins and singletons may be different, neonatal outcome is generally the same at similar gestational ages (Gardner, 1995; Kilpatrick, 1996; Ray, 2009). Importantly, outcomes for preterm twins who are markedly discordant may not be comparable with those for singletons because whatever caused the discordance may have long-lasting effects.

■ Prolonged Pregnancy

More than 40 years ago, Bennett and Dunn (1969) suggested that a twin pregnancy of 40 weeks or more should be considered postterm. Twin stillborn neonates delivered at 40 weeks or beyond commonly had features similar to those of postmature singletons (Chap. 43, p. 864). From an analysis of almost 300,000 twin births, Kahn and coworkers (2003) calculated that at and beyond 39 weeks, the risk of subsequent stillbirth was greater than the risk of neonatal mortality. At Parkland Hospital, twin gestations have empirically been considered to be prolonged at 40 weeks.

■ Long-Term Infant Development

Historically, twins have been considered cognitively delayed compared with singletons (Record, 1970; Ronalds, 2005). However, in cohort studies evaluating normal-birthweight term infants, cognitive outcomes between twins and singletons are similar (Lorenz, 2012). Christensen and associates (2006) found similar national standardized test scores in ninth grade in 3411 twins and 7796 singletons born between 1986 and 1988. In contrast, among normal-birthweight infants, the cerebral palsy risk is higher among twins and higher-order multiples.

For example, the cerebral palsy rate has been reported to be 2.3 per 1000 in singletons, 12.6 per 1000 in twins, and 44.8 per 1000 in triplets (Giuffrè, 2012). Much of this excess risk is thought to be related to an increased risk of fetal-growth restriction, congenital anomalies, twin-twin transfusion syndrome, and fetal demise of a cotwin (Lorenz, 2012).

UNIQUE FETAL COMPLICATIONS

Several unique and fascinating complications arise in multifetal pregnancies. These have been best described in twins but can be found in higher-order multifetal gestations. Most fetal complications due to the twinning process itself are seen with monozygotic twins. Their pathogenesis is best understood after reviewing the possibilities shown in Figure 45-1.

■ Monoamniotic Twins

Only about 1 percent of all monozygotic twins will share an amniotic sac (Hall, 2003). Said another way, approximately 1 in 20 monochorionic twins are monoamniotic (Lewi, 2013). This configuration is associated with a high fetal death rate from cord entanglement, congenital anomalies, preterm birth, or twin-twin-transfusion syndrome, which is described subsequently. In a comprehensive review, Allen and associates (2001) reported that monoamniotic twins diagnosed antenatally and alive at 20 weeks have approximately a 10-percent risk of subsequent fetal demise. In a Dutch report of 98 monoamniotic twin pregnancies, the perinatal mortality rate was 17 percent (Hack, 2009). Umbilical cord entanglement, a frequent cause of death, is estimated to complicate at least half of cases (Fig. 45-12). Diamniotic twins can become monoamniotic if the dividing membrane ruptures and therefore have similar associated morbidity and mortality rates.

FIGURE 45-12 Monozygotic twins in a single amniotic sac. The smaller fetus apparently died first, and the second subsequently succumbed when umbilical cords entwined.

Unfortunately, there are no management methods that guarantee good outcomes for either or both twins. This is because of the unpredictability of fetal death from cord entanglement and the lack of an effective means of monitoring for it. Quinn and colleagues (2011) retrospectively evaluated the feasibility of inpatient continuous fetal heart monitoring in 17 sets of monoamniotic twins. After review of more than 10,000 hours of fetal tracing, these investigators concluded that this was possible in only 50 percent of cases. Importantly, an abnormal fetal heart rate tracing prompted delivery in only six cases. Morbid cord entanglement appears to occur early, and monoamniotic pregnancies that have successfully reached 30 to 32 weeks are at reduced risk. In the Dutch series described above, the incidence of intrauterine demise dropped from 15 percent after 20 weeks to 4 percent when gestational age exceeded 32 weeks (Hack, 2009).

Although umbilical cords frequently entangle, factors that lead to pathological umbilical vessel constriction are unknown. Color-flow Doppler sonography can be used to diagnose entanglement (Fig. 45-13). However, once identified, evidence to guide management is observational, retrospective, and subject to biased reporting. One proposed management scheme is based on a study by Heyborne and coworkers (2005), who reported no stillbirths in 43 twin pregnancies of women admitted at 26 to 27 weeks' gestation for daily fetal surveillance. Conversely, there were 13 stillbirths in 44 women who were managed as outpatients and admitted only for an obstetrical indication. Because of this report, women with monoamniotic twins are recommended to undergo 1 hour of daily fetal heart rate monitoring, either as outpatients or as inpatients, beginning at 26 to 28 weeks. With initial testing, a course of betamethasone is given to promote pulmonary maturation (Chap. 42, p. 850). If fetal testing remains reassuring, cesarean delivery is performed at 34 weeks and after a second course of betamethasone. This management scheme is used at Parkland Hospital and resulted in the successful 34-week delivery of the twins depicted in Figure 45-13.

■ Aberrant Twinning Mechanisms

Several aberrations in the twinning process result in a spectrum of fetal malformations. These are traditionally ascribed to incomplete splitting of an embryo into two separate twins. However, it is possible that they may result from early secondary fusion of two separate embryos. These separated embryos are either symmetrical or asymmetrical, and the spectrum of anomalies is shown in Figure 45-14.

Conjoined Twins

In the United States, united or conjoined twins have been referred to as *Siamese twins*—after Chang and Eng Bunker of Siam (Thailand), who were displayed worldwide by P. T. Barnum. Joining of the twins may begin at either pole and may produce characteristic forms depending on which body parts are joined or shared (Fig. 45-15). Of these, thoracopagus is the most common (Mutchinick, 2011). The frequency of conjoined twins is not well established. At Kandang Kerbau Hospital in Singapore, Tan and coworkers (1971) identified

FIGURE 45-13 Monochorionic monoamniotic cord entanglement. **A.** Despite marked knotting of the cords, vigorous twins were delivered by cesarean. **B.** Preoperative sonogram of this pregnancy shows entwined cords. **C.** This finding is accentuated with application of color Doppler. (Photographs contributed by Dr. Julie Lo.)

seven cases of conjoined twins among more than 400,000 deliveries—an incidence of 1 in 60,000.

As reviewed by McHugh and associates (2006), conjoined twins can frequently be identified using sonography at midpregnancy. This provides an opportunity for parents to decide whether to continue the pregnancy. As shown in

FIGURE 45-14 Possible outcomes of monozygotic twinning. The asymmetrical category contains twinning types in which one twin complement is substantially smaller and incompletely formed.

Figure 45-16, identification of cases during the first trimester is also possible. A targeted examination, including a careful evaluation of the connection and the organs involved, is necessary before counseling can be provided. As shown in Figure 45-17, MR imaging can play an important adjunctive role in clarifying shared organs. Compared with sonography, MR imaging may provide superior views, especially in later pregnancy when amniotic fluid is diminished and fetal crowding is increased (Hibbeln, 2012).

Surgical separation of an almost completely joined twin pair may be successful if essential organs are not shared (Spitz, 2003; Tannuri, 2013). Consultation with a pediatric surgeon often assists parental decision making. Conjoined twins may have discordant structural anomalies that further complicate decisions about whether to continue the pregnancy.

Viable conjoined twins should be delivered by cesarean. For the purpose of pregnancy termination, however, vaginal delivery is possible because the union is most often pliable (Fig. 45-18). Still, dystocia is common, and if the fetuses are mature, vaginal delivery may be traumatic to the uterus or cervix.

External Parasitic Twins

This is a grossly defective fetus or merely fetal parts, attached externally to a relatively normal twin. A parasitic twin usually consists of externally attached supernumerary limbs, often with some viscera. Classically, however, a functional heart or brain is absent. Attachment mirrors those sites described earlier for conjoined twins (see Fig. 45-14). Parasites are believed to result from demise of the defective twin, with its surviving tissues attached to and vascularized by its normal twin (Spencer,

FIGURE 45-15 Types of conjoined twins. (Redrawn from Spencer, 2000.)

FIGURE 45-16 Sonogram of a conjoined twin pregnancy at 13 weeks' gestation. These thoracoomphalopagus twins have two heads but a shared chest and abdomen.

2001). In a worldwide collaborative epidemiological study, parasitic twins were found to account for 3.9 percent of all conjoined twins and to occur more frequently in male fetuses (Mutchinick, 2011).

Fetus-in-Fetu

Early in development, one embryo may be enfolded within its twin. Normal development of this rare parasitic twin usually arrests in the first trimester. As a result, normal spatial arrangement of and presence of many organs is lost. Classically, vertebral or axial bones are found in these fetiform masses, whereas heart and brain are lacking. These masses are typically supported by their host by a few large parasitic vessels (Spencer, 2000). Malignant degeneration is rare (Kaufman, 2007).

FIGURE 45-17 Magnetic resonance imaging of conjoined twins. This T2-weighted HASTE sagittal image demonstrates fusion from the level of the xiphoid process to just below the level of the umbilicus, that is, omphalopagus twins. Below the fused liver (L), there is a midline cystic mass (arrow) within the tissue connecting the twins. An omphalomesenteric cyst was favored given the location within the shared tissue. Monochorionic Twins and Vascular Anastomoses

Another group of fascinating fetal syndromes can arise when monozygotic twinning results in two amniotic sacs and a common surrounding chorion. This leads to anatomical sharing of the two fetal circulations through anastomoses of placental arteries and veins. All monochorionic placentas likely share some anastomotic connections. However, there are marked variations in the number, size, and direction of these seemingly haphazard connections (Fig. 45-19). In their analyses of more than 200 monochorionic placentas, Zhao and colleagues (2013) found the median number of anastomoses to be 8 with an interquartile range of 4 to 14. With rare exceptions, anastomoses between twins are unique to monochorionic twin placentas.

Artery-to-artery anastomoses are most common and are identified on the chorionic surface of the placenta in up to 75 percent of monochorionic twin placentas. Vein-to-vein and artery-to-vein communications are each found in approximately half. One vessel may have several connections, sometimes to both arteries and veins. In contrast to these superficial vascular connections on the surface of the chorion, deep artery-to-vein communications can extend through the capillary bed of a given villus (Fig. 45-20). These deep arteriovenous anastomoses create a common villous compartment or third circulation that has been identified in approximately half of monochorionic twin placentas.

Whether these anastomoses are dangerous to either twin depends on the degree to which they are hemodynamically balanced. In those with significant pressure or flow gradients, a shunt will develop between fetuses. This chronic fetofetal transfusion may result in several clinical syndromes that include *twin-twin transfusion syndrome (TTTS)*, *twin anemia polycythemia sequence (TAPS)*, and *acardiac twinning*.

Twin-Twin Transfusion Syndrome (TTTS)

The prevalence of this condition is approximately 1 to 3 per 10,000 births (Simpson, 2013). In this syndrome, blood is

FIGURE 45-19 Shared placenta from pregnancy complicated by twin-twin transfusion syndrome. The following color code was applied for injection. Left twin: yellow = artery, blue = vein; right twin: red = artery, green = vein. **A.** Part of the arterial network of the right twin is filled with yellow dye, due to the presence of a small artery-to-artery anastomosis (arrow). **B.** Close-up of the lower portion of the placenta displays the yellow dye-filled anastomosis. (From De Paepe, 2005, with permission.)

transfused from a donor twin to its recipient sibling such that the donor may eventually become anemic and its growth may be restricted. In contrast, the recipient becomes polycythemic and may develop circulatory overload manifest as hydrops.

The donor twin is pale, and its recipient sibling is plethoric (**Fig. 45-21**). Similarly, one portion of the placenta often appears pale compared with the remainder.

The recipient neonate may have circulatory overload from heart failure and severe hypervolemia and hyperviscosity. Occlusive thrombosis is another concern. Finally, polycythemia in the recipient twin may lead to severe hyperbilirubinemia and kernicterus (Chap. 33, p. 644).

FIGURE 45-20 Anastomoses between twins may be artery-to-vein (AV), artery-to-artery (AA), or vein-to-vein (VV). Schematic representation of an AV anastomosis in twin-twin transfusion syndrome that forms a “common villous district” or “third circulation” deep within the villous tissue. Blood from a donor twin may be transferred to a recipient twin through this shared circulation. This transfer leads to a growth-restricted discordant donor twin with markedly reduced amniotic fluid, causing it to be “stuck.”

FIGURE 45-21 Twin-twin transfusion syndrome at 23 weeks. **A.** Pale donor twin (690 g) also had oligohydramnios. **B.** The plethoric recipient twin (730 g) had hydramnios. (From Mahone, 1993, with permission.)

Pathophysiology. Any of the different types of vascular anastomoses discussed before may be found with monochorionic placentas. Classically, chronic TTTS results from unidirectional flow through arteriovenous anastomoses. Deoxygenated blood from a *donor* placental artery is pumped into a cotyledon shared by the recipient (see Fig. 45-20). Once oxygen exchange is completed in the chorionic villus, the oxygenated blood leaves the cotyledon via a placental vein of the *recipient* twin. Unless compensated—typically through arterioarterial anastomoses—this unidirectional flow leads to an imbalance in blood volumes (Lewi, 2013).

Clinically important twin-twin transfusion syndrome frequently is chronic and results from significant vascular volume differences between the twins. Even so, the pathogenesis is more complex than a net transfer of red blood cells from one twin to another. Indeed, in most monochorionic twin pregnancies complicated by the syndrome, there is no difference in hemoglobin concentrations between the donor and recipient twin (Lewi, 2013).

The syndrome typically presents in midpregnancy when the donor fetus becomes oliguric from decreased renal perfusion (Simpson, 2013). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production. Virtual absence of amniotic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term *stuck twin* or *polyhydramnios-oligohydramnios-syndrome*—“*poly-oli*.” This amniotic fluid imbalance is associated with growth restriction, contractures, and pulmonary hypoplasia in the donor twin, and premature rupture of the membranes and heart failure in the recipient.

Fetal Brain Damage. Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications

associated with placental vascular anastomoses in multifetal gestation. The exact pathogenesis of neurological damage is not fully understood but is likely caused by ischemic necrosis leading to cavitory brain lesions (Fig. 45-22). In the donor twin, ischemia results from hypotension, anemia, or both. In the recipient, ischemia develops from blood pressure instability and episodes of severe hypotension (Lopriore, 2011). Cerebral lesions may also be due to postnatal injury associated with preterm delivery. Quarello and associates (2007) reviewed data from 315 liveborn fetuses from pregnancies with twin-twin-transfusion syndrome and reported cerebral abnormalities in 8 percent.

If one twin of an affected pregnancy dies, cerebral pathology in the survivor probably results from acute hypotension. A less likely cause is emboli of thrombotic material originating from the dead fetus. Fusi and coworkers (1990, 1991) observed that with the death of one twin, acute twin-twin anastomotic transfusion from the high-pressure vessels of the living twin to the low-resistance vessels of the dead twin leads rapidly to hypovolemia and ischemic antenatal brain damage in the survivor. In their systematic review of 343 twin pregnancies complicated by single fetal demise, Hillman and colleagues (2011) calculated a 26-percent risk of neurodevelopmental morbidity in monochorionic twins compared with 2 percent in dichorionic twins. They also found that this morbidity was related to gestational age at the death of the cotwin. If the death occurred between 28 and 33 weeks' gestation, monochorionic twins had an almost eightfold risk of neurodevelopmental morbidity compared with dichorionic twins of the same gestational age. With fetal death after 34 weeks, the likelihood dramatically decreased—odds ratio 1.48.

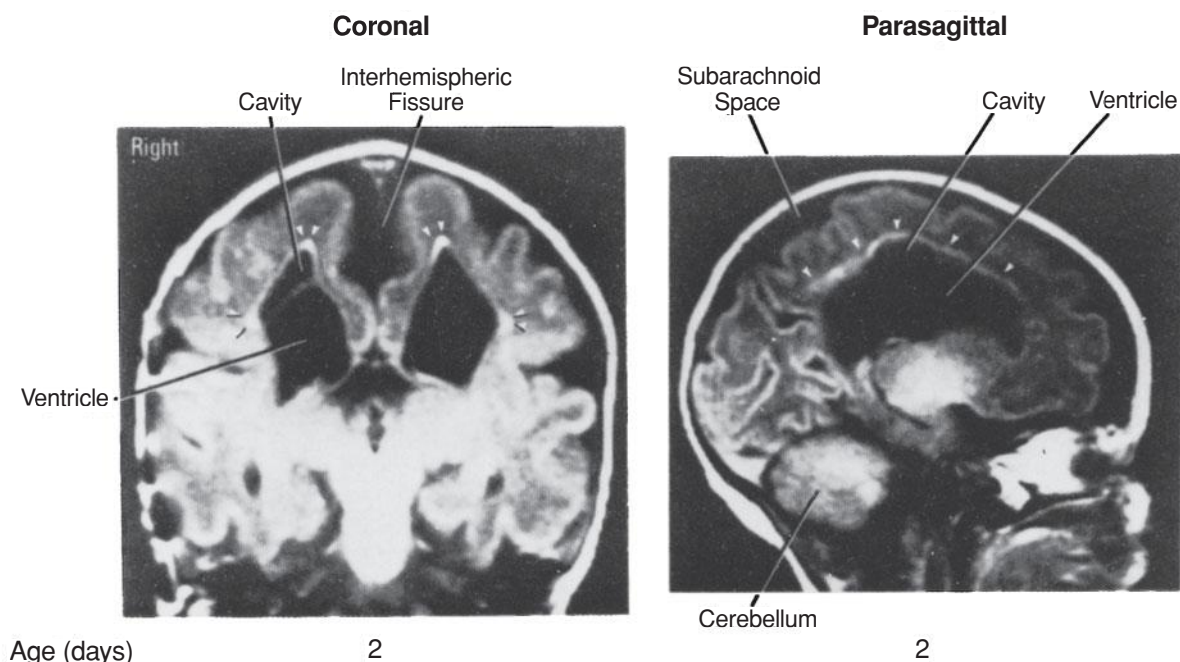

FIGURE 45-22 Cranial magnetic resonance imaging study of a diamniotic-monochorionic twin performed on day 2 of life. The subarachnoid space and lateral ventricles are markedly enlarged. There are large cavitory lesions in the white matter adjacent to the ventricles. The bright signals (*arrowheads*) in the periphery of the cavitory lesions most probably correspond to gliosis. (From Bejar, 1990, with permission.)

The acuity of hypotension following the death of one twin with twin-twin-transfusion syndrome makes successful intervention for the survivor nearly impossible. Even with delivery immediately after a cotwin demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible brain damage (Langer, 1997; Wada, 1998).

Diagnosis. There have been dramatic changes in the criteria used to diagnose and classify varying severities of twin-twin transfusion syndrome. Previously, weight discordancy and hemoglobin differences in monochorionic twins were calculated. However, it was soon appreciated that in many cases these were late-onset findings. According to the Society for Maternal-Fetal Medicine (2013), TTTS is diagnosed based on two criteria: (1) presence of a monochorionic diamniotic pregnancy, and (2) hydramnios defined if the largest vertical pocket is > 8 cm in one twin and oligohydramnios defined if the largest vertical pocket is < 2 cm in the other twin. Only 15 percent of pregnancies complicated by lesser degrees of fluid imbalance progress to TTTS (Huber, 2006).

Once identified, TTTS is typically staged by the Quintero (1999) staging system:

- Stage I—discordant amniotic fluid volumes as described above, but urine is still visible sonographically within the bladder of the donor twin.
- Stage II—criteria of stage I, but urine is not visible within the donor bladder.
- Stage III—criteria of stage II and abnormal Doppler studies of the umbilical artery, ductus venosus, or umbilical vein.
- Stage IV—ascites or frank hydrops in either twin.
- Stage V—demise of either fetus.

In addition to these criteria, there is evidence that cardiac function of the recipient twin correlates with fetal outcome (Crombleholme, 2007). Although fetal echocardiographic findings are not part of the staging system above, many centers routinely perform fetal echocardiography for TTTS. It has been theorized that early diagnosis of cardiomyopathy in the recipient twin may identify pregnancies that would benefit from early intervention. One system for evaluating cardiac function—the *myocardial performance index (MPI)* or *Tei index*—is a Doppler index of ventricular function calculated for each ventricle (Michelfelder, 2007). Although scoring systems that include assessment of cardiac function have been developed, their usefulness in prediction of outcomes remains controversial (Simpson, 2013).

At Parkland Memorial Hospital, evaluation before and during treatment includes anatomical and neurological fetal assessment using echocardiography, MPI calculation, Doppler velocimetry, and MR imaging; genetic counseling and amniocentesis; and placental mapping.

Management and Prognosis. The prognosis for multifetal gestations complicated by TTTS is related to Quintero stage and gestational age at presentation. More than three fourths of stage I cases remain stable or regress without intervention. Conversely, outcomes in those identified at stage III or higher are much worse, and the perinatal loss rate is 70 to 100 percent

without intervention (Simpson, 2013). Several therapies are currently used for TTTS, including amnioreduction, laser ablation of vascular anastomoses, selective feticide, and septostomy (intentional creation of a communication in the dividing amniotic membrane). Comparative data from randomized trials for some of these techniques are discussed below.

The Eurofetus trial included 142 women with severe TTTS diagnosed before 26 weeks. Participants were randomly assigned to laser ablation of vascular anastomoses or to serial amnioreduction (Senat, 2004). These investigators reported an increased survival rate to age 6 months for at least one twin with laser ablation compared with serial amnioreduction—76 versus 51 percent, respectively. Moreover, analyses of randomized studies confirm better neonatal outcomes with laser therapy compared with selective amnioreduction (Roberts, 2008; Rossi, 2008, 2009). In contrast, Crombleholme and associates (2007), in a randomized trial of 42 women, found equivalent rates of 30-day survival of one or both twins treated with either amnioreduction or selective fetoscopic laser ablation—75 versus 65 percent, respectively. Furthermore, evaluation of twins from the Eurofetus trial through 6 years of age did not demonstrate any additional survival benefit beyond 6 months or improved neurological outcomes in those treated with laser (Salomon, 2010).

At this time, laser ablation of anastomoses is preferred for severe TTTS (stages II-IV), although optimal therapy for stage I disease is controversial. After laser therapy, close ongoing surveillance is necessary. Robyr and colleagues (2006) reported that a fourth of 101 pregnancies treated with laser required additional invasive therapy because of either recurrent TTTS, or middle cerebral artery Doppler evidence of anemia or polycythemia. Recently, in a comparison of selective laser ablation of individual anastomoses versus ablation of the entire surface of chorionic plate along the vascular equator, Baschat and coworkers (2013) found that equatorial photocoagulation reduced the likelihood of recurrence.

Moise and associates (2005) compared amnioreduction and septostomy in a multicentered randomized trial of 73 women. Repeated procedures were performed for symptoms or if the greatest vertical pocket of amniotic fluid met the original inclusion criteria of 8 to 12 cm, depending on gestational age. Perinatal outcomes were the same in each group, with at least one survivor in 80 percent of pregnancies. The average number of additional procedures was two in each group. Much of this is moot, however, because intentional septostomy has largely been abandoned as treatment (Simpson, 2013).

Selective reduction has generally been considered if severe amniotic fluid and growth disturbances develop before 20 weeks. In such cases, both fetuses typically will die without intervention. Selection of which twin is to be terminated is based on evidence of damage to either fetus and comparison of their prognoses. Any substance injected into one twin may affect the other twin because of shared circulations. Therefore, feticidal techniques include methods to occlude the circulation of the chosen fetal umbilical vein or by umbilical cord occlusion using radiofrequency ablation, fetoscopic ligation, or coagulation with laser, monopolar, or bipolar cauterization (Challis, 1999; Chang, 2009; Donner, 1997). Even after these

procedures, however, the risks to the remaining fetus are still appreciable (Rossi, 2009).

Twin Anemia Polycythemia Sequence (TAPS)

This form of chronic fetofetal transfusion is characterized by significant hemoglobin differences between donor and recipient twins *without* the discrepancies in amniotic fluid volumes typical of twin-twin-transfusion syndrome (Slaghekke, 2010). It is diagnosed antenatally by middle cerebral artery (MCA) peak systolic velocity (PSV) > 1.5 multiples of the median (MoM) in the donor and < 1.0 MoM in the recipient twin (Simpson, 2013). The spontaneous form reportedly complicates 3 to 5 percent of monochorionic pregnancies, and it occurs in up to 13 percent of pregnancies after laser photocoagulation. *Spontaneous* TAPS usually occurs after 26 weeks and *iatrogenic* TAPS develops within 5 weeks of a procedure (Lewi, 2013). Although a staging system has been proposed by Slaghekke and colleagues (2010), further studies are necessary to better understand the natural history of TAPS and its management.

Twin-Reversed Arterial Perfusion (TRAP) Sequence

Also known as an *acardiac twin*, this is a rare—1 in 35,000 births—but serious complication of monochorionic multifetal gestation. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure and a recipient twin that lacks a heart (*acardius*) and other structures. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The “used” arterial blood (colored blue) that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body. Failure of head growth is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous*, which is shown in Figure 45-24 (Faye-Petersen, 2006). Because of this vascular connection, the normal donor twin must not only support its own circulation but also pump its blood through the underdeveloped acardiac recipient. This may lead to cardiomegaly and high-output heart failure in the normal twin (Fox, 2007).

Lewi and coworkers (2010) reviewed 26 cases of TRAP sequence identified in the first trimester. In one third, the pump twin died before planned intervention at 16 to 18 weeks. In more than half of all the cases, there was spontaneous cessation of flow to the acardiac twin, and such flow arrest was associated with subsequent death or neurological injury in 85 percent of the normal twins. Quintero and associates (1994, 2006) have reviewed methods of in utero treatment of acardiac twinning in which the goal is interruption of aberrant vascular communication between the twins. Of these methods, Lee (2007), Lewi (2010), Livingston (2007), and their colleagues found an approximate 90-percent survival rate following second-trimester radiofrequency ablation. This method cauterizes umbilical vessels in the malformed recipient

FIGURE 45-23 Twin reversed-arterial-perfusion sequence. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure, and a recipient twin that lacks a heart. It has been hypothesized that the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The “used” arterial blood (colored blue) that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body.

FIGURE 45-24 Photograph of an acardiac twin weighing 475 grams. The underdeveloped head is indicated by the black arrow, and its details are shown in the inset. A yellow clamp is seen on its umbilical cord. Its viable donor cotwin was delivered vaginally at 36 weeks and weighed 2325 grams. (Photograph contributed by Dr. Michael D. Hnat.)

twin to terminate blood flow from the donor. In a review of 118 complicated monochorionic twin gestations that underwent bipolar cord coagulation, Lanna and associates (2012) reported a fetal loss rate in those treated before 19 weeks of 45 percent compared with 3 percent in those treated after 19 weeks. Prompted by the high mortality rate of TRAP sequence in the first trimester, small case series of early intervention have been reported (O'Donoghue, 2008; Scheier, 2012). Importantly, efficacy and safety of intervention before fusion of the amnion and chorion has not been demonstrated convincingly (Lewi, 2013).

Complete Hydatidiform Mole with Coexisting Normal Fetus

Also termed a twin molar pregnancy, this is due to a complete diploid molar pregnancy comprising one conceptus, whereas the cotwin is a normal fetus. Reported prevalence rates range from 1 in 22,000 to 1 in 100,000 pregnancies (Dolapcioglu, 2009). It must be differentiated from a partial molar pregnancy in which an anomalous singleton fetus—usually triploid—is accompanied by molar tissue (Chap. 20, p. 398).

Optimal management is not known for this twin gestation. Diagnosis is usually made in the first half of pregnancy, and termination at that time would remove the mole but also the normal fetus. However, pregnancy progression exposes the woman to the later postpartum dangers of persistent trophoblastic disease that requires chemotherapy and may be fatal. Despite this, pregnancy continuation is increasingly being recommended in cases with a karyotypically normal and nonanomalous twin, no early preeclampsia, and declining hCG levels (Sebire, 2002).

If observation and pregnancy progression is chosen, preterm delivery is frequently required because of persistent and heavy bleeding or severe preeclampsia. Dolapcioglu and coworkers (2009) reviewed 159 reported cases and reported a live birth in 35 percent. Preeclampsia and preterm birth each developed in a third. Niemann and colleagues (2007) reported that persistent trophoblastic disease rates following such a twin gestation were not increased compared with those after a singleton complete mole.

DISCORDANT GROWTH OF TWIN FETUSES

Size inequality of twin fetuses, which can be a sign of pathological growth restriction in one fetus, is calculated using the larger twin as the index. Generally, as the weight difference within a twin pair increases, the perinatal mortality rate increases proportionately. Because the single placenta is not always equally shared in monochorionic twins, these twins have greater rates of discordant growth outside of TTTS than dichorionic twins. It develops in approximately 15 percent of twin gestations (Lewi, 2013; Miller, 2012). As discussed further in Chapter 44 (p. 879), restricted growth of one twin fetus usually develops late in the second and early third trimester. Earlier discordancy indicates higher risk for fetal demise in the smaller twin. Specifically, when discordant growth is identified before 20 weeks, fetal death occurs in about 20 percent (Lewi, 2013). Importantly, differences in crown-rump length (CRL) are associated with fetal structural and chromosomal anomalies but are not reliable predictors for birthweight discordance (Miller, 2012).

Etiopathogenesis

The cause of birthweight inequality in twin fetuses is often unclear, but the etiology in monochorionic twins likely differs from that in dichorionic twins. Discordancy in monochorionic twins is usually attributed to placental vascular anastomoses that cause hemodynamic imbalance between the twins. Reduced pressure and perfusion of the donor twin can cause diminished placental and fetal growth. Even so, unequal placental sharing is probably the most important determinant of discordant growth in monochorionic twins (Lewi, 2013). Occasionally, monochorionic twins are discordant in size because they are discordant for structural anomalies.

Discordancy in dichorionic twins may result from various factors. Dizygotic fetuses may have different genetic growth potential, especially if they are of opposite genders. Alternatively, because the placentas are separate and require more implantation space, one placenta might have a suboptimal implantation site. Bagchi and associates (2006) observed that the incidence of severe discordancy is twice as great in triplets as it is in twins. This finding lends credence to the view that in utero crowding is a factor in fetal-growth restriction. Placental pathology may play a role as well. Kent and coworkers (2012) evaluated placental abnormalities in 668 twin gestations. They observed a strong relationship between histological placental abnormalities and birthweight discordancy with associated growth restriction in dichorionic, but not monochorionic, twin pregnancies.

Diagnosis

Size discordancy between twins can be determined sonographically in several ways. One common method uses sonographic fetal biometry to compute an estimated weight for each twin (Chap. 10, p. 198). The weight of the smaller twin is then compared with that of the larger twin. Thus, percent discordancy = weight of larger twin minus weight of smaller twin, divided by weight of larger twin. Alternatively, considering that growth restriction is the primary concern and that abdominal circumference (AC) reflects fetal nutrition, some use the sonographic AC value of each twin. With these methods, some specify discordance if the AC measurements differ more than 20 mm or if the estimated fetal weight difference is 20 percent or more.

That said, several different weight disparities between twins have been used to define discordancy. Accumulated data suggest that weight discordancy greater than 25 to 30 percent most accurately predicts an adverse perinatal outcome. Hollier and coworkers (1999) retrospectively evaluated 1370 twin pairs delivered at Parkland Hospital and stratified twin weight discordancy in 5-percent increments within a range of 15 to 40 percent. They found that the incidence of respiratory distress, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis increased directly with the degree of weight discordancy. These conditions increased substantially if discordancy was greater than 25 percent. The relative risk of fetal death increased significantly to 5.6 if there was more than 30-percent discordancy. It increased to 18.9 if there was greater than 40-percent discordancy.

Management

Sonographic monitoring of growth within a twin pair and calculating discordancy has become a mainstay in management. Other sonographic findings, such as oligohydramnios, may be helpful in gauging fetal risk. Monochorionic twins are generally monitored more frequently. This is because their risk of death is higher—3.6 percent versus 1.1 percent—and the risk of neurological damage in the surviving twin is substantial compared with those risks in dichorionic twins (Hillman, 2011; Lee, 2008). Thorson and colleagues (2011) retrospectively analyzed 108 monochorionic twin pregnancies and found that a sonographic surveillance interval of greater than 2 weeks was associated with detection of higher-stage twin-twin transfusion syndrome. These findings have led some to recommend serial sonographic surveillance every 2 weeks in monochorionic twins (Simpson, 2013; Society for Maternal-Fetal Medicine, 2013). However, there have been no randomized trials of the optimal frequency of sonographic surveillance in monochorionic twin pregnancies. At Parkland Hospital, monochorionic twins undergo sonographic evaluation to assess interval growth every 4 weeks. Dichorionic twins are evaluated every 6 weeks. Depending on the degree of discordancy and the gestational age, fetal surveillance may be indicated, especially if one or both fetuses exhibit restricted growth. Nonstress testing, biophysical profile scores, and umbilical artery Doppler assessment have all been recommended in the management of twins, but none have been evaluated in appropriately sized prospective trials (Miller, 2012).

The American College of Obstetricians and Gynecologists (2010) recommends that antepartum testing be performed in multifetal gestations for the same indications as in singleton fetuses (Chap 17, p. 345). At Parkland Hospital, all women with twin discordance of 25 percent or greater undergo daily monitoring as an inpatient. There are limited data to establish the optimal timing of delivery of twins. Delivery is usually not prompted by size discordancy alone, except occasionally at advanced gestational ages. The Royal College of Obstetricians and Gynecologists (2008) advocates delivery by 37 weeks' gestation in monochorionic twins and by 38 weeks in dichorionic twins.

FETAL DEMISE

At any time during multifetal pregnancy, one or more fetuses may die, either simultaneously or sequentially. The causes and incidence of fetal death are related to zygosity, chorionicity, and growth concordance.

Death of One Fetus

In some pregnancies, one fetus dies remote from term, but pregnancy continues with one or more live fetuses. When this occurs early in pregnancy, it may manifest as a *vanishing twin* discussed on page 892. Fetal death in a slightly more advanced gestation may go undetected until delivery of a normal-appearing live infant along with a dead fetus that is barely identifiable. It may be compressed appreciably—*fetus compressus*, or it may be flattened remarkably through desiccation—*fetus papyraceus* (Fig. 45-25).

FIGURE 45-25 This fetus papyraceus is a tan ovoid mass compressed against the fetal membranes. Anatomical parts can be identified as marked. Demise of this twin had been noted during sonographic examination performed at 17 weeks' gestation. Its viable cotwin delivered at 40 weeks. (Photograph contributed by Dr. Michael V. Zaretsky.)

In a review of 9822 Japanese twin pregnancies, Morikawa and associates (2012) reported that 2.5 percent of monochorionic diamniotic twins greater than 22 weeks' gestation had a death of one or both twins compared with 1.2 percent of dichorionic twins. As shown in Figure 45-26, the risk of stillbirth is related to gestational age in all twins, but is much higher for monochorionic twin pregnancies before 32 weeks. In this same review, women with monochorionic diamniotic twins who lost one twin were 16 times more likely to experience death of the cotwin than women with dichorionic

FIGURE 45-26 Prospective risk of stillbirth among women who reached a given gestational week (per 1000 women). (From Morikawa, 2012, with permission.)

twins who lost one twin (Morikawa, 2012). Similarly, in their analysis of 1094 twin pregnancies, Mahony and associates (2011) identified a threefold increased risk of death of one or both fetuses in monochorionic twins compared with dichorionic pairs. Last, in their systematic review and metaanalyses, Hillman and colleagues (2011) concluded that after one twin dies, the odds of cotwin demise was five times higher in monochorionic twins compared with dichorionic twins experiencing the same fate. Analyses of 701 triplets identified mortality rates to be 2.1 percent, 3.2 percent, and 5.3 percent in trichorionic triamniotic, dichorionic triamniotic, and monochorionic triamniotic triplets, respectively (Kawaguchi, 2013).

Other factors that affect the prognosis for the surviving twin include gestational age at the time of the demise and duration between the demise and delivery of the surviving twin. With demise of the *vanishing twin* discussed earlier, after the first trimester, the risk of death is not increased for the survivor. However, when one fetus dies in the second trimester or later, the effect of gestational age at the time of death and the mortality risk to the cotwin is less clear. In the analysis by Hillman and colleagues (2011), cotwin demise rates were unaffected regardless of whether the first death occurred at 13 to 27 weeks or at 28 to 34 weeks. In cases with the death of one twin after the first trimester, however, the odds of spontaneous and iatrogenic preterm delivery of the remaining living twin were increased (Hillman, 2011). Preterm birth was five times more likely in monochorionic twin gestations complicated by demise of one twin between 28 and 33 weeks' gestation. If the fetus died after 34 weeks, preterm delivery rates were similar.

The neurological prognosis for a surviving cotwin depends almost exclusively on chorionicity. In their comprehensive review, Ong and coworkers (2006) found an 18-percent rate of neurological abnormality in twins with monochorionic placentation compared with only 1 percent in those with dichorionic placentation. In another review, in twin pregnancies complicated by a single fetal demise before 34 weeks, a fivefold increased risk of neurodevelopmental morbidity was identified in monochorionic twins compared with dichorionic twins. If the one fetus died after 34 weeks, the likelihood of neurological deficits was essentially the same between monochorionic and dichorionic twin pregnancies (Hillman, 2011).

Later in gestation, the death of one of multiple fetuses could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported. This is probably because the surviving twin is usually delivered within a few weeks of the demise (Eddib, 2006). That said, we have observed transient, spontaneously corrected consumptive coagulopathy in multifetal gestations in which one fetus died and was retained in utero along with its surviving twin. The plasma fibrinogen concentration initially decreased but then increased spontaneously, and the level of serum fibrinogen-fibrin degradation products increased initially but then returned to normal levels. At delivery, the portions of the placenta that supplied the living fetus appeared normal. In contrast, the part that had once provided for the dead fetus

was the site of massive fibrin deposition. This is further discussed and illustrated in Chapter 41 (p. 811).

Management

Decisions should be based on gestational age, the cause of death, and the risk to the surviving fetus. As mentioned previously, if the loss occurs early in the first trimester, a vanishing twin is considered harmless to the survivor. If the loss occurs after the first trimester, the risk of death or damage to the survivor is largely limited to monochorionic twin gestations. Morbidity in the monochorionic twin survivor is almost always due to vascular anastomoses, which often cause the demise of one twin followed by sudden hypotension in the other. If one fetus of a monochorionic twin gestation dies after the first trimester but before viability, pregnancy termination can be considered (Blickstein, 2013). Occasionally, death of one but not all fetuses results from a maternal complication such as diabetic ketoacidosis or severe preeclampsia with abruption. Pregnancy management is based on the diagnosis and the status of both the mother and surviving fetus. If the death of one dichorionic twin is due to a discordant congenital anomaly, its death should not affect its surviving twin.

Single fetal death during late second and early third trimester presents the greatest risk to the surviving twin. Although the risks of subsequent death or neurological damage to the survivor are comparatively increased for monochorionic twins at this gestational age, the risk of preterm birth is equally increased in mono- and dichorionic twins (Ong, 2006). Delivery generally occurs within 3 weeks of diagnosis of fetal demise, thus antenatal corticosteroids for survivor lung maturity should be considered (Blickstein, 2013). Regardless, unless there is a hostile intrauterine environment, the goal should be to prolong pregnancy.

Timing of elective delivery after conservative management of a late second or early third trimester single fetal death is a matter of debate. Dichorionic twins can probably be safely delivered at term. Monochorionic twin gestations are more difficult to manage and are often delivered between 34 and 37 weeks' gestation (Blickstein, 2013). In cases of single fetal death at term, especially when the etiology is unclear, most opt for delivery instead of expectant management.

Impending Death of One Fetus

Abnormal antepartum test results of fetal health in one twin fetus, but not the other, pose a particular dilemma. Delivery may be the best option for the compromised fetus yet may result in death from immaturity of the cotwin. If fetal lung maturity is confirmed, salvage of both the healthy fetus and its jeopardized sibling is possible. Unfortunately, ideal management if twins are immature is problematic but should be based on the chances of intact survival for both fetuses. Often the compromised fetus is severely growth restricted or anomalous. Thus, performing amniocentesis for fetal karyotyping in women of advanced maternal age carrying twin pregnancies is advantageous, even for those who would continue their pregnancies regardless of the diagnosis. Aneuploidy identification in one fetus allows rational decisions regarding interventions.

PRENATAL CARE AND ANTEPARTUM MANAGEMENT

Primary goals of prenatal management of multifetal pregnancy are to provide close observation of the mother and her fetuses to prevent or interdict complications as they develop. A major imperative is to prevent preterm delivery of markedly immature neonates. At Parkland Hospital, women with multifetal gestations are seen every 2 weeks beginning at 22 weeks' gestation, and a digital cervical examination is performed at each visit. Identification of other unique complications discussed above may also lead to interventions including early delivery. We routinely perform sonographic studies to assess fetal growth and amniotic fluid every 4 weeks in monochorionic twins or 6 weeks in dichorionic pairs.

Diet

Along with more frequent prenatal visits, it must be ensured that the maternal diet provides additional requirements for calories, protein, minerals, vitamins, and essential fatty acids. Achievement of BMI-specific weight gain goals, supplementation with macro- and micronutrients to meet the increased needs associated with a twin gestation, and carbohydrate-controlled diets have been recommended (Goodnight, 2009). The Institute of Medicine guidelines for twin pregnancy recommend a 37- to 54-lb weight gain for women with a normal BMI. In their extensive review of the topic, Goodnight and Newman (2009) recommend supplementation of micronutrients such as calcium, magnesium, zinc, and vitamins C, D, and E based on upper intake levels from the Food and Nutrition Board of the Institute of Medicine. The daily recommended increased caloric intake for women with twins is 40 to 45 kcal/kg/d, composed of 20 percent protein, 40 percent carbohydrate, and 40 percent fat divided into three meals and three snacks daily.

Surveillance of Fetal Growth and Health

Because a cornerstone of fetal assessment in twin pregnancy is identification of abnormal fetal growth or discordancy, serial sonographic examinations are usually performed throughout the third trimester. Assessment of amniotic fluid volume is also important. Associated oligohydramnios may indicate uteroplacental pathology and should prompt further evaluation of fetal well-being. That said, quantifying amniotic fluid volume in multifetal gestation is sometimes difficult. Some measure the deepest vertical pocket in each sac or assess the fluid subjectively. Measurement of the amniotic fluid index (AFI) may also be helpful. Using data from 488 diamniotic twins with birthweight between the 10th and 90th percentiles, Hill and associates (2000) described a protocol for measuring the AFI in twin gestations. Each amniotic sac was divided into quadrants that extended along a vertical, horizontal, or oblique axis. The deepest vertical pocket free of umbilical cord in each quadrant was measured. They found a slightly lower median value in twins than singletons. The AFI was highest at 26 to 28 weeks' gestation and declined until delivery. Magann and coworkers (2000) compared subjective assessment and several objective

methods of assessing amniotic fluid in 23 sets of twins. They found all methods to be equally poor in predicting abnormal volumes in diamniotic twins. At Parkland Hospital, the single deepest vertical pocket is measured in each sac. A measurement < 2 cm is considered oligohydramnios and a measurement ≥ 8 cm is considered hydramnios (Hernandez, 2012).

Tests of Fetal Well-Being

As described throughout Chapter 17, there are several methods of assessing fetal health in singleton pregnancies. The nonstress test or biophysical profile is commonly used in management of twin or higher-order multifetal gestations. Because of the complex complications associated with multifetal gestations and the potential technical difficulties in differentiating fetuses during antepartum testing, the usefulness of these methods appears limited. According to DeVoe (2008), the few exclusive studies of nonstress testing in twins suggest that the method performs the same as in singleton pregnancies. Elliott and Finberg (1995) used the biophysical profile as the primary method for monitoring higher-order multifetal gestations. They reported that four of 24 monitored pregnancies had a poor outcome despite reassuring biophysical profile scores. Although biophysical testing is commonly performed in multifetal gestations, there are insufficient data to determine its efficacy (DeVoe, 2008).

In an early study of 272 twin sets, Giles and colleagues (1990) reported that availability of umbilical artery Doppler velocimetry led to a reduced perinatal mortality rate. In a later randomized trial of 526 twin pregnancies by the same group, the addition of umbilical artery Doppler velocimetry to management compared with fetal testing based on fetal-growth parameters alone resulted in no perinatal outcome improvement (Giles, 2003). Hack and associates (2008) investigated the utility of umbilical artery Doppler velocimetry in 67 uncomplicated monochorionic twin gestations. They found similar mortality rates in those with abnormal pulsatility indices of the umbilical artery compared with those with normal indices. Differences in neonatal morbidity were explained by gestational age at delivery.

All testing schemes have high false-positive rates in singletons, and data suggest that testing in multifetal gestations performs no better. In cases of abnormal testing in one twin and normal results in another, iatrogenic preterm delivery remains a major concern.

Pulmonary Maturation

According to Robinson and coworkers (2012), beyond a strategy of planned delivery of uncomplicated monochorionic twins at 38 weeks, a secondary strategy is amniocentesis to verify pulmonary maturity before delivery between 36 and 38 weeks. In cases of complicated twin gestations, amniocentesis may be performed earlier. As measured by determination of the lecithin-sphingomyelin ratio, pulmonary maturation is usually synchronous in twins (Leveno, 1984). Moreover, although this ratio usually does not exceed 2.0 until 36 weeks in singleton pregnancies, it often exceeds this value by approximately 32 weeks in multifetal pregnancies. McElrath and colleagues (2000) reported similar increased values of surfactant in twins

after 31 weeks' gestation. In a comparison of respiratory morbidity in 100 twins and 241 singleton newborns delivered by cesarean before labor, Ghi and associates (2013) found less neonatal respiratory morbidity in twins, especially those delivered ≤ 37 weeks' gestation. In some cases, however, pulmonary function may be markedly different, and the smallest, most stressed twin fetus is typically more mature.

PRETERM BIRTH

Preterm labor is common in multifetal pregnancies and may complicate up to 50 percent of twin, 75 percent of triplet, and 90 percent of quadruplet pregnancies (Elliott, 2007). The proportion of preterm births in multifetal gestations, however, varies widely. For example, the preterm birth rate is 42 percent in Ireland but is 68 percent in Austria (Giuffre, 2012). These differences likely reflect different clinical approaches to management. Several techniques have been applied in attempts to prolong these pregnancies. Methods include bed rest—especially through hospitalization, prophylactic administration of β -mimetic drugs or progestins, prophylactic cervical cerclage, and pessary placement.

Prediction of Preterm Birth

A major goal of multifetal pregnancy prenatal care is accurate prediction of women likely to experience preterm delivery, with prediction followed by prevention. This has been an elusive goal, but some advances have been made. Goldenberg and coworkers (1996) prospectively screened 147 twin pregnancies for more than 50 potential preterm birth risk factors. These investigators found that cervical length and fetal fibronectin concentration in the cervical canal were predictive of preterm birth (Chap. 42, p. 843). At 24 weeks, a cervical length ≤ 25 mm was the best predictor of birth before 32 weeks. At 28 weeks, an elevated fetal fibronectin level was the best predictor. Similarly, To and associates (2006) sonographically measured cervical length in 1163 twin pregnancies at 22 to 24 weeks. Rates of preterm delivery before 32 weeks were 66 percent in those with cervical lengths of 10 mm; 24 percent for lengths of 20 mm; 12 percent for 25 mm; and only 1 percent for 40 mm. McMahon and colleagues (2002) found that women with multifetal gestations at 24 weeks who had a closed internal os on digital cervical examination, a normal cervical length by sonographic examination, and a negative fetal fibronectin test result had a *low* risk to deliver before 32 weeks. Interestingly, a closed internal os by digital examination was as predictive of early delivery as the combination of normal sonographically measured cervical length and negative fetal fibronectin test results.

In a systematic review and metaanalysis of transvaginal cervical length for the prediction of preterm birth, Conde-Agudelo and coworkers (2010) concluded that cervical length between 20 and 24 weeks was a good predictor of spontaneous preterm birth in asymptomatic women with twin pregnancies. These authors found that a cervical length ≤ 20 mm was most accurate for predicting birth < 34 weeks, with a specificity of 97 percent and positive likelihood ratio of 9.0.

Prevention of Preterm Birth

Several schemes have been evaluated to prevent preterm labor and delivery. In recent years, some have been shown to decrease the risk of preterm delivery in small subgroups of singleton pregnancies. Unfortunately, most have been disappointingly ineffective.

Bed Rest

Most evidence suggests that routine hospitalization is not beneficial in prolonging multifetal pregnancy. In a metaanalysis of seven trials of hospitalization with bed rest, Crowther and Han (2010) concluded that the practice did not reduce the risk of preterm birth or perinatal mortality. Also at Parkland Hospital, elective hospitalization was compared with outpatient management, and no advantages were found (Andrews, 1991). Importantly, however, almost half of the women required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health care visits and sonographic examinations, and structured maternal education regarding preterm delivery risks have been advocated to reduce preterm birth rates in women with multiple fetuses. Unfortunately, there is little evidence that these measures substantially change outcome.

Prophylactic Tocolysis

Tocolytic therapy in multifetal pregnancies has not been extensively studied. In a Cochrane review of five randomized trials of prophylactic oral β -mimetic therapy that included 374 twin pregnancies, Yamasmit and coworkers (2012) concluded that treatment did not reduce the rate of twins delivering before 37 or before 34 weeks. Especially in light of the recent Food and Drug Administration warning against the use of oral terbutaline, prophylactic use of β -mimetics in multifetal gestations seems especially unwarranted.

Intramuscular Progesterone Therapy

Although somewhat effective in reducing recurrent preterm birth in women with a singleton pregnancy, weekly injections of 17α -hydroxyprogesterone caproate (17-OHPC) are not effective for multifetal gestations (Caritis, 2009; Rouse, 2007). These results were corroborated in a more recent randomized trial in 240 twin pregnancies (Combs, 2011). Moreover, women carrying twins and identified with a cervical length < 36 mm (25th percentile) did not benefit despite their increased risk for preterm birth (Durnwald, 2010). Senat and colleagues (2013) randomly assigned 165 asymptomatic women with twins and a cervical length < 25 mm to 17-OHPC and also found no reduction in delivery before 37 weeks.

Caritis and associates (2012), in an evaluation of plasma drug concentrations in a Maternal-Fetal Medicine Units (MFMU) Network trial, reported that higher concentrations of 17-OHPC were associated with earlier gestational age at delivery. They concluded that 17-OHPC may adversely lower the gestational age at delivery in women with twin gestations. When taken together, administration of intramuscular 17-OHPC to women with twin pregnancies, even to those with a shortened cervix, does not lower the preterm birth risk.

Vaginal Progesterone Therapy

Micronized progesterone administered vaginally to women with twins is of uncertain benefit. Cetingoz and coworkers (2011) gave 100 mg of micronized progesterone intravaginally daily from 24 to 34 weeks. These authors reported that this practice reduced rates of delivery before 37 weeks from 79 to 51 percent in 67 women with twins. In contrast, several studies have failed to demonstrate any preterm birth rate reduction in women receiving various formulations of vaginal progesterone. Norman and colleagues (2009) randomly assigned 494 women with twins to 10 weeks of daily 90-mg intravaginal progesterone and failed to show reduced rates of delivery before 34 weeks. In the multicenter Prevention of Preterm Delivery in Twin Gestations (PREDICT) trial, Rode and associates (2011) randomly assigned 677 women with twins to receive prophylactic, 200-mg progesterone pessaries or placebo pessaries. These investigators also failed to demonstrate a reduction in delivery rates before 34 weeks. In a subgroup analysis of this trial that included only women with a short cervix or a history of prior preterm birth, Klein and associates (2011) also did not demonstrate a benefit. At Parkland Hospital, management of women with multifetal gestations does not typically include progesterone in any formulation.

Cervical Cerclage

Prophylactic cerclage has not been shown to improve perinatal outcome in women with multifetal pregnancies. Studies have included women who were not specially selected and those who were selected because of a shortened cervix that was identified sonographically (Dor, 1982; Elimian, 1999; Newman, 2002; Rebarber, 2005). In the latter group, cerclage may actually worsen outcomes (Berghella, 2005).

Pessary

A vaginal pessary that encircles and theoretically compresses the cervix, alters the inclination of the cervical canal, and relieves direct pressure on the internal cervical os has been proposed as an alternative to cerclage. The most popular is the silicone Arabin pessary. In a study of pessary use in women with a short cervix between 18 and 22 weeks, a subgroup analysis of 23 women with twins showed a significant reduction in the delivery rate before 32 weeks compared with the rate in 23 control pregnancies (Arabin, 2003). Liem and coworkers (2013) recently reported on the open-label Pessaries in Multiple Pregnancy as a Prevention of Preterm Birth (ProTWIN) trial completed at 40 centers throughout the Netherlands. These researchers randomized 813 unselected women with twins to receive either the Arabin pessary between 12 and 20 weeks or no treatment. The pessary failed to reduce preterm birth overall but did decrease delivery rates before 32 weeks in a subset of women with a cervical length < 38 mm—29 versus 14 percent. At this time, before such treatment can be recommended, beneficial effects of pessary use in women with a short cervix need to be confirmed.

Treatment of Preterm Labor

Although many advocate their use, therapy with tocolytic agents to forestall preterm labor in multifetal pregnancy has not resulted in measurably improved neonatal outcomes (Chauhan, 2010; Gyetvai, 1999). They are similarly ineffective in singleton pregnancy as discussed in further detail in Chapter 42 (p. 851). Another caveat is that tocolytic therapy in women with a multifetal pregnancy entails higher risk than in singleton pregnancy. This is in part because of the augmented pregnancy-induced hypervolemia and its increased cardiac demands and susceptibility to iatrogenic pulmonary edema. Gabriel and colleagues (1994) compared outcomes of 26 twin and six triplet pregnancies with those of 51 singletons—all treated with a β -mimetic drug for preterm labor. Women with a multifetal gestation had significantly more cardiovascular complications—43 versus 4 percent—including three with pulmonary edema. In a recent retrospective analysis, Derbent and coworkers (2011) evaluated nifedipine tocolysis in 58 singleton and 32 twin pregnancies. These authors reported higher incidences of side effects such as maternal tachycardia in women with twins—19 versus 9 percent.

Glucocorticoids for Lung Maturation

Administration of corticosteroids to stimulate fetal lung maturation has not been well studied in multifetal gestation. However, these drugs logically should be as beneficial for multiples as they are for singletons (Roberts, 2006). Battista and colleagues (2008) compared the efficacy of betamethasone therapy in 60 preterm twin pregnancies to 60 preterm singleton pregnancies. These researchers found no differences in neonatal morbidity, including respiratory distress. Moreover, Gyamfi and associates (2010) evaluated betamethasone concentrations in maternal and umbilical cord blood in 30 singleton and 15 twin pregnancies receiving weekly antenatal corticosteroids. They found no differences in levels between twins and singletons. These treatments are discussed in Chapter 42 (p. 850). At this time, guidelines for the use of these agents are not different from those for singleton gestations (American College of Obstetricians and Gynecologists, 2010).

Preterm Premature Membrane Rupture

The frequency of preterm premature rupture of membranes (PPROM) increases with increasing plurality. In a population-based retrospective cohort study of more than 290,000 live births in Ohio, Pakrashi and coworkers (2013) reported the proportion of preterm birth complicated by premature rupture was 13.2 percent in singletons. This rate was compared with 17, 20, 20, and 100 percent in twins, triplets, quadruplets, and higher-order multiples, respectively. Multifetal gestations with PPRM are managed expectantly much like singleton pregnancies (Chap. 42, p. 846). Ehsanipoor and colleagues (2012) compared outcomes of 41 twin and 82 singleton pregnancies, both with ruptured membranes between 24 and 32 weeks. They found the median latency was overall shorter for twins—3.6 days compared with 6.2 days for singletons. This difference was significant in pregnancies after 30 weeks—1.7 days and

6.9 days. Importantly, latency beyond 7 days approximated 40 percent in both groups.

■ Delayed Delivery of Second Twin

Infrequently, after preterm birth of the presenting fetus, it may be advantageous for undelivered fetus(es) to remain in utero. Trivedi and Gillett (1998) reviewed the English literature and described 45 case reports of asynchronous birth in multifetal gestation. Although likely biased, those pregnancies with a surviving retained twin or triplet continued for an average of 49 days. No advantage was gained by management with tocolytics, prophylactic antimicrobials, or cerclage. In their 10-year experience, Roman and associates (2010) reported a median latency of 16 days in 13 twin and five triplet pregnancies with delivery of the first fetus between 20 and 25 weeks. Survival of the firstborn infant was 16 percent. Although 54 percent of the retained fetuses survived, only 37 percent of survivors did so without major morbidity. Livingston and coworkers (2004) described 14 pregnancies in which an active attempt was made to delay delivery of 19 fetuses after delivery of the first neonate. Only one fetus survived without major sequelae, and one mother developed sepsis syndrome with shock. Arabin and van Eyck (2009) reported better outcomes in a few of the 93 twin and 34 triplet pregnancies that qualified for delayed delivery in their center during a 17-year period.

If asynchronous birth is attempted, there must be careful evaluation for infection, abruption, and congenital anomalies. The mother must be thoroughly counseled, particularly regarding the potential for serious, life-threatening infection. The range of gestational age in which the benefits outweigh the risks for delayed delivery is likely narrow. Avoidance of delivery from 23 to 26 weeks would seem most beneficial. In our experience, good candidates for delayed delivery are rare.

LABOR AND DELIVERY

There is a litany of complications that may be encountered during labor and delivery of multiple fetuses. In addition to preterm labor and delivery as already discussed, there are increased rates of uterine contractile dysfunction, abnormal fetal presentation, umbilical cord prolapse, placenta previa, placental abruption, emergent operative delivery, and postpartum hemorrhage from uterine atony. All of these must be anticipated and thus certain precautions and special arrangements are prudent. These should include:

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous external electronic monitoring is preferable. If membranes are ruptured and the cervix dilated, the presenting fetus is monitored internally.
2. An intravenous infusion system capable of delivering fluid rapidly is established. In the absence of hemorrhage, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 125 mL/hr.
3. Blood for transfusion is readily available if needed.

4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present.
5. A sonography machine is readily available to evaluate the presentation and position of the fetuses during labor and to image the remaining fetus(es) after delivery of the first.
6. An anesthesia team is immediately available in the event that emergent cesarean delivery is necessary or that intrauterine manipulation is required for vaginal delivery.
7. For each fetus, at least one attendant who is skilled in resuscitation and care of newborns and who has been appropriately informed of the case should be immediately available.
8. The delivery area should provide adequate space for the nursing, obstetrical, anesthesia, and pediatric team members to work effectively. Equipment must be on site to provide emergent anesthesia, operative intervention, and maternal and neonatal resuscitation.

■ Evaluation upon Admission

Fetal Presentation

In addition to the standard preparations for the conduct of labor and delivery discussed in Chapter 22, there are special considerations for women with a multifetal pregnancy. First, the positions and presentations of fetuses are best confirmed sonographically (American College of Obstetricians and Gynecologists, 2011). Although any possible combination of positions may be encountered, those most common at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse. At Parkland Hospital between 2008 and 2013, 71 percent of twin pregnancies had cephalic presentation of the first fetus at the time of admission to labor and delivery. Importantly, with perhaps the exception of cephalic-cephalic presentations, these are all unstable before and during labor and delivery. Accordingly, compound, face, brow, and footling breech presentations are relatively common, and even more so if fetuses are small, amniotic fluid is excessive, or maternal parity is high. Cord prolapse is also frequent in these circumstances.

After this initial evaluation, if active labor is confirmed, then a decision is made to attempt vaginal delivery or to proceed with cesarean delivery. The latter is chosen in many cases because of fetal presentations. Cephalic presentation of the first fetus in a laboring woman with twins may be considered for expectant management. Of the 547 women who presented like this at Parkland Hospital during 5 years, 32 percent delivered spontaneously. Nevertheless, the overall cesarean delivery rate in twin pregnancies during those years was 77 percent. Notably, 5 percent of cesareans performed were for emergent delivery of the second twin following vaginal delivery of the first twin. The desire to avoid this obstetrical dilemma has contributed to the increasing cesarean delivery rate in twin pregnancies across the United States (Antsaklis, 2013; Lee, 2011).

Labor Induction or Stimulation

According to a comparison of 891 twins with more than 100,000 singleton pregnancies included in the *Consortium of Safe Labor*, Leftwich and colleagues (2013) concluded that

both nulliparas and multiparas with twins had slower progression of active labor. Women with twins required between 1 and 3 additional hours to complete first-stage labor. This was despite equivalent rates of labor induction or augmentation. Provided women with twins meet all criteria for oxytocin administration, it may be used as described in Chapter 26 (p. 529). Wolfe and associates (2013) evaluated the success of labor induction in 40 sets of twins compared with 80 singletons and found that protocols for oxytocin alone or in combination with cervical ripening can safely be used in twin gestations. Taylor and coworkers (2012) reported that 100 women with twins undergoing labor induction had similar labor lengths and cesarean delivery rates compared with those of 100 matched women with singleton pregnancies. Still, in an analysis of twin births in the United States between 1995 and 2008, Lee and colleagues (2011) reported that induction rates of twin pregnancies has decreased from a maximum of 13.8 percent in 1999 to 9.9 percent in 2008.

■ Analgesia and Anesthesia

During labor and delivery of multiple fetuses, decisions regarding analgesia and anesthesia may be complicated by problems imposed by preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and postpartum uterine atony and hemorrhage.

Labor epidural analgesia is ideal because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required. There are special considerations for women with severe preeclampsia or with hemorrhage as discussed in their respective chapters. Because of these eventualities, most recommend that continuous epidural analgesia be performed by anesthesia personnel with special expertise in obstetrics.

If general anesthesia becomes necessary for intrauterine manipulation, then uterine relaxation can be accomplished rapidly with one of the halogenated inhalation agents discussed in Chapter 25 (p. 519). Some clinicians use intravenous or sublingual nitroglycerin to achieve uterine relaxation yet avoid the aspiration and hypoxia risks associated with general anesthetics.

■ Delivery Route

Regardless of fetal presentation during labor, there must be a readiness to deal with any change of fetal position during delivery and especially following delivery of the first twin. If the first fetus is nonvertex, cesarean delivery is typically performed, whereas cephalic-cephalic twins are commonly considered for vaginal delivery (Peaceman, 2009; Rossi, 2011). Importantly, when comparing neonatal outcomes among all these options, second twins at term as a group have worse composite neonatal outcomes than those of their cotwin regardless of delivery method (Smith, 2007; Thorngren-Jerneck, 2001).

Cephalic-Cephalic Presentation

If the first twin presents cephalic, delivery can usually be accomplished spontaneously or with forceps. According to D'Alton (2010), there is general consensus that a trial of labor

is reasonable in women with cephalic-cephalic twins. Hogle and associates (2003) performed an extensive literature review and concluded that planned cesarean delivery does not improve neonatal outcome when both twins are cephalic. The recent randomized trial by Barrett and coworkers (2013) affirms this conclusion. Muleba and colleagues (2005) identified increased rates of respiratory distress in the second twin of preterm pairs regardless of delivery mode or corticosteroid use.

Cephalic-Noncephalic Presentation

The optimal delivery route for cephalic–noncephalic twin pairs remains controversial (D'Alton, 2010). Patient selection is crucial, and options include cesarean delivery of both twins, or less commonly, vaginal delivery with intrapartum external cephalic version of the second twin. Longer intertwin delivery time has been shown in some studies to be associated with poorer second twin outcome (Edris, 2006; Stein, 2008). Thus, breech extraction may be preferable to version. Least desirable, vaginal delivery of the first but cesarean delivery of the second twin may be required due to intrapartum complications such as umbilical cord prolapse, placental abruption, contracting cervix, and fetal distress. Most, but not all, studies show the worst composite fetal outcomes for this scenario (Alexander, 2008; Rossi, 2011; Wen, 2004).

Several reports attest to the safety of vaginal delivery of second noncephalic twins whose birthweight is > 1500 g. Recently, Fox and associates (2014) reported outcomes of 287 diamniotic twin pregnancies between 2005 and 2009. Cesarean delivery was routinely performed for all women with a noncephalic presenting twin fetus, a noncephalic second twin weighing < 1500 g, or a second twin estimated to be 20 percent larger than the presenting twin. All others without contraindications to labor were offered a vaginal delivery and were treated using a strict protocol of second-stage labor management. This included vaginal delivery of a second cephalic twin, breech extraction of a second noncephalic twin, and internal podalic version of an unengaged cephalic second twin followed by breech extraction. Of the 130 who planned a vaginal delivery, only 15 percent underwent cesarean delivery. There was no difference in the rate of 5-minute Apgar score < 7 or of umbilical arterial pH < 7.20 in second twins. The data are less informative concerning vaginal delivery of a second twin whose estimated fetal weight is < 1500 g. That said, however, comparable or even better fetal outcomes with vaginal delivery have been reported with these smaller infants compared with those who weigh > 1500 g (Caukwell, 2002; Davidson, 1992; Rydhström, 1990).

Other investigators advocate cesarean delivery for both members of a cephalic–noncephalic twin pair (Armson, 2006; Hoffmann, 2012). Yang and coworkers (2005a,b) studied 15,185 cephalic–noncephalic twin pairs. The risk of asphyxia-related neonatal deaths and morbidity was increased in the group in which both twins were delivered vaginally compared with the group in which both twins underwent cesarean delivery.

Randomized Trial of Planned Cesarean versus Vaginal Delivery. To add insight into the clinical complexities discussed above, a randomized trial was designed by the Twin Birth Study Collaborative Group from Canada. The study

TABLE 45-4. Maternal and Perinatal Outcomes of Women with a Twin Pregnancy Randomized to Planned Cesarean versus Vaginal Delivery

Outcome	Planned Cesarean Delivery	Planned Vaginal Delivery	p value
Maternal (No.)	1393	1393	
Cesarean delivery	89.9%	39.6%	
Before labor	53.8%	14.1%	
Serious morbidity	7.3%	8.5%	0.29
Death (No.)	1	1	
Hemorrhage	6.0%	7.8%	
Blood Transfusion	4.7%	5.4%	
Thromboembolism	0.4%	0.1%	
Perinatal (No.)	2783	2782	
Primary composite outcome	2.2%	1.9%	0.49
Perinatal mortality	9 per 1000	6 per 1000	
Serious morbidity	1.3%	1.3%	
Possible encephalopathy ^a	0.5%	0.4%	
Intubation	1.0%	0.6%	

^aIncludes coma; stupor; hyperalert, drowsy or lethargic; or ≥ 2 seizures.

Data from Barrett, 2013.

results described by Barrett and colleagues (2013) included 2804 women carrying a presumed diamniotic twin pregnancy with the first fetus presenting cephalic. Women were randomly assigned between 32 and 38 weeks to planned cesarean or vaginal delivery. The time from randomization to delivery—12.4 versus 13.3 days, the mean gestational age at delivery—36.7 versus 36.8 weeks, and use of regional analgesia—92 versus 87 percent was similar in both groups. Salient maternal and perinatal outcomes are shown in Table 45-4. No significant differences in outcomes were noted between the two groups of women. Although there were no increased risks to mother or fetuses with planned vaginal delivery in these circumstances, we agree with Greene (2013) that this trial will moderately affect the cesarean delivery rate of women with twins.

Breech Presentation of First Twin

Problems with the first twin presenting as a breech are similar to those encountered with a singleton breech fetus. Thus, major problems may develop if:

1. The fetus is unusually large, and the aftercoming head is larger than the birth canal.
2. The fetal body is small, and delivery of the extremities and trunk through an inadequately effaced and dilated cervix causes the relatively larger head to become trapped above the cervix. This is more likely when there is disproportion between the fetal buttocks or trunk and the head. This may

be seen with preterm or growth-restricted fetuses or with a macrocephalic fetus due to hydrocephaly.

3. The umbilical cord prolapses.

If these problems are anticipated or identified, cesarean delivery is often preferred with a viable-size fetus. But even without these problems, many obstetricians perform cesarean delivery if the first twin presents as breech. This is despite data that support the safety of vaginal delivery. Specifically, Blickstein and associates (2000) reported experiences from 13 European centers with 613 twin pairs and the first twin presenting breech. Vaginal delivery was attempted in 373 of these cases and was successful in 64 percent. Cesarean delivery of the second twin was done in 2.4 percent. There was no difference in the rate of 5-minute Apgar score < 7 or of mortality in breech-presenting first twins who weighed at least 1500 g. Details of techniques for delivery of a breech presentation are described in Chapter 28 (p. 563).

Locked Twins. For twin fetuses to become locked together during delivery, the first must present as breech and the second as cephalic. As the breech of the first twin descends through the birth canal, the chin locks between the neck and chin of the second cephalic-presenting cotwin. This phenomenon is rare, and Cohen and coworkers (1965) described it only once in 817 twin gestations. Cesarean delivery should be considered when the potential for locking is identified.

Vaginal Delivery of the Second Twin

Following delivery of the first twin, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly and carefully ascertained by combined abdominal, vaginal, and at times, intrauterine examination. Sonography may be a valuable aid. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude cord prolapse. Labor is allowed to resume. If contractions do not begin within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

In the past, the safest interval between delivery of the first and second twins was frequently cited as less than 30 minutes. Rayburn and colleagues (1984), and others, have shown that if continuous fetal monitoring is used, a good outcome is achieved even if this interval is longer. Several investigators have demonstrated a direct correlation between worsening umbilical cord blood gas values and increasing time between delivery of first and second twins (Leung, 2002; Stein, 2008). Gourheux and associates (2007) retrospectively reviewed delivery intervals in 239 twin gestations in France and determined that mean umbilical arterial pH was significantly lower after the interval exceeded 15 minutes. Thus, vigilant monitoring for nonreassuring fetal heart rate or bleeding is required. Hemorrhage may indicate clinically significant placental abruption.

If the occiput or breech presents immediately over the pelvic inlet, but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina, while a second hand on the uterine fundus exerts moderate pressure

caudally. Alternatively, with abdominal manipulation, an assistant can guide the presenting part into the pelvis. Sonography can aid guidance and allow heart rate monitoring. Intrapartum external version of a noncephalic second twin has also been described.

A presenting shoulder may be gently converted into a cephalic presentation. If the occiput or breech is not over the pelvic inlet and cannot be so positioned by gentle pressure or if appreciable uterine bleeding develops, delivery of the second twin can be problematic.

To obtain a favorable outcome, it is essential to have an obstetrician skilled in intrauterine fetal manipulation and anesthesia personnel skilled in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin (American College of Obstetricians and Gynecologists, 2010). To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay must be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version or if anesthesia that will provide effective uterine relaxation is not immediately available.

Internal Podalic Version

With this maneuver, a fetus is turned to a breech presentation using the hand placed into the uterus (Fig. 45-27). The obstetrician grasps the fetal feet to then effect delivery by breech extraction. As mentioned earlier, Fox and colleagues (2010) described a strict protocol for management of the delivery of the second twin, which included internal podalic version. They reported that none of the 110 women who delivered the first twin vaginally underwent a cesarean delivery for the second twin. Chauhan and coworkers (1995) compared outcomes of 23 second twins delivered by podalic version and breech extraction with those of 21 who underwent external cephalic version. Breech extraction was considered superior to external version because less fetal distress developed. The technique of breech extraction is described in Chapter 28 (p. 567).

FIGURE 45-27 Internal podalic version. Upward pressure on the head by an abdominal hand is applied as downward traction is exerted on the feet.

Vaginal Birth after Cesarean Delivery

Any attempt to deliver twins vaginally in a woman who has previously undergone one or more cesarean deliveries should be carefully considered. As discussed in Chapter 31 (p. 614), some studies support the safety of attempting a vaginal birth after cesarean delivery (VBAC) for selected women with twins (Cahill, 2005; Ford, 2006; Varner, 2005). According to the American College of Obstetricians and Gynecologists (2013b), there currently is no evidence of an increased risk of uterine rupture, and women with twins and one previous cesarean delivery with a low transverse incision may be considered candidates for trial of labor. At Parkland Hospital, such women are generally offered repeat cesarean delivery.

Cesarean Delivery for Multifetal Gestation

There are several unusual intraoperative problems that can arise during cesarean delivery of twins or higher-order multiples. Supine hypotension is common, and thus these women should be positioned in a left lateral tilt to deflect uterine weight off the aorta (Chap. 4, p. 60). A low-transverse hysterotomy is preferable if the incision can be made large enough to allow atraumatic delivery of both fetuses. Piper forceps can be used if the second twin is presenting breech (Fig. 28-13, p. 568). In some cases, a vertical hysterotomy beginning as low as possible in the lower uterine segment may be advantageous. For example, if a fetus is transverse with its back down and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision laterally or to make a “T” incision vertically.

Cesarean Delivery of the Second Twin

It is not uncommon for cesarean delivery to become necessary for delivery of a second twin after the first has been delivered vaginally. As described earlier, this occurred in 32 of 770 women with twins at Parkland Hospital between 2008 and 2013. In these cases, prompt cesarean delivery is required and is frequently emergently indicated. Indications most often cited are a second fetus that is much larger than the first and is presenting breech or transverse. In other cases, the cervix promptly contracts and thickens after delivery of the first twin. This may be followed by a nonreassuring fetal status or by a cervix that fails to completely dilate again despite adequate uterine contractions.

TRIPLET OR HIGHER-ORDER GESTATION

Fetal heart rate monitoring during labor with triplet pregnancies is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two fetuses are each being monitored separately. With vaginal delivery, the first neonate is usually born with little or no manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of fetuses is an increased

incidence of cord prolapse. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

For all these reasons, many clinicians believe that pregnancies complicated by three or more fetuses are best delivered by cesarean. Vaginal delivery is reserved for those circumstances in which survival is not expected because fetuses are markedly immature or maternal complications make cesarean delivery hazardous to the mother. Others believe that vaginal delivery is safe under certain circumstances. For example, Alamia and colleagues (1998) evaluated a protocol for vaginal delivery of triplet pregnancies in which the presenting fetus was cephalic. A total of 23 sets of triplets were analyzed, and a third of these were delivered vaginally. Neonatal outcomes were the same in the vaginal and cesarean delivery groups, with no morbidity and 100-percent fetal survival. Grobman and associates (1998) and Alran and coworkers (2004) reported vaginal delivery completion rates of 88 and 84 percent, respectively, in women carrying triplets who underwent a trial of labor. Neonatal outcomes did not differ from those of a matched group of triplet pregnancies delivered by elective cesarean. Conversely, Vintzeleos and colleagues (2005) reviewed more than 7000 triplet pregnancies and found that vaginal delivery was associated with an increased perinatal mortality rate. Importantly, the overall cesarean delivery rate among triplets was 95 percent. At Parkland Hospital, triplet gestations are routinely delivered by cesarean.

SELECTIVE REDUCTION OR TERMINATION

In some cases of higher-order multifetal gestation, reduction of the fetal number to two or three improves survival of the remaining fetuses. *Selective reduction* implies early pregnancy intervention, whereas *selective termination* is performed later.

Selective Reduction

Reduction of a selected fetus or fetuses in a multichorionic multifetal gestation may be chosen as a therapeutic intervention to enhance survival of the remaining fetuses (American College of Obstetricians and Gynecologists, 2013a). There are no randomized controlled trials on the effects of such reduction. However, a metaanalysis of nonrandomized prospective studies indicates that pregnancy reduction to twins compared with expectant management is associated with lower rates of maternal complications, preterm birth, and neonatal death (Dodd, 2004, 2012). Pregnancy reduction can be performed transcervically, transvaginally, or transabdominally, but the transabdominal route is usually easiest.

Transabdominal fetal reductions are typically performed between 10 and 13 weeks. This gestational age is chosen because most spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low. The smallest fetuses and any anomalous fetuses are chosen for reduction. Potassium chloride is then injected under sonographic guidance into the heart or thorax of each selected fetus. Care is used to not enter

or traverse the sacs of fetuses selected for retention. In most cases, pregnancies are reduced to twins to increase the chances of delivering at least one viable fetus.

Evans and associates (2005) reported continued improvement in fetal outcomes with this procedure. They analyzed more than 1000 pregnancies managed in 11 centers from 1995 to 1998. The pregnancy loss rate varied from a low of 4.5 percent for triplets who were reduced to twins. The loss rate increased with each addition to the starting number of fetuses and peaked at 15 percent for six or more fetuses (Evans, 2001). Operator skill and experience are believed responsible for the low and declining rates of pregnancy loss.

Selective Termination

With the identification of multiple fetuses discordant for structural or genetic abnormalities, three options are available: abortion of all fetuses, selective termination of the abnormal fetus, or pregnancy continuation. Because anomalies are typically not discovered until the second trimester, selective termination is performed later in gestation than selective reduction and entails greater risk. This procedure is therefore usually not performed unless the anomaly is severe but not lethal. Thus, a triplet pregnancy in which one fetus has Down syndrome might be a candidate for selective termination, whereas a twin pregnancy in which one fetus has trisomy 18 might not. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one. For example, pathological hydramnios in a twin with esophageal atresia could lead to preterm birth of its sibling.

Prerequisites to selective termination include a precise diagnosis for the anomalous fetus and absolute certainty of fetal location. Thus, if genetic amniocentesis is performed on a multifetal gestation, a map of the uterus with locations of all the fetuses clearly labeled should be made at the time of the diagnostic procedure. Unless a special procedure such as umbilical cord interruption is used, selective termination should be performed only in multichorionic multifetal gestations to avoid damaging the surviving fetuses (Lewi, 2006). Roman and coworkers (2010) compared 40 cases of bipolar umbilical cord coagulation with 20 cases of radiofrequency ablation for treatment of complicated monochorionic multifetal gestations at midpregnancy. They found similar survival rates of 87 and 88 percent, and a median gestational age > 36 weeks at delivery in both. Prefumo and colleagues (2013) reported their preliminary experience with microwave ablation of the umbilical cord for selective termination in two monochorionic twin pregnancies. One pregnancy aborted within 7 days, and the other resulted in a term singleton delivered at 39 weeks' gestation.

Evans and coworkers (1999) have provided the most comprehensive results to date on second-trimester selective termination for fetal abnormalities. A total of 402 cases were analyzed from eight centers worldwide. Included were 345 twin, 39 triplet, and 18 quadruplet pregnancies. Selective termination using potassium chloride resulted in delivery of a viable neonate or neonates in more than 90 percent of cases, with a mean age of 35.7 weeks at delivery. The entire pregnancy was lost in 7.1 percent of pregnancies reduced to singletons and in 13 percent of those reduced

to twins. The gestational age at the time of the procedure did not appear to affect the pregnancy loss rate. Several losses occurred because the pregnancy was actually monochorionic, and potassium chloride also killed the normal fetus through placental vascular anastomoses.

Ethics

The ethical issues associated with these techniques are almost limitless. There is a beneficence-based justification for offering selective termination in cases in which continuation of the pregnancy poses a threat to the life of coexistent fetuses. The final decision to continue the pregnancy without intervention, to terminate the entire pregnancy, or to elect selective termination is solely the patient's (Chervenak, 2013). The interested reader is referred to the excellent reviews by Evans and coworkers (1996, 2004) and Simpson and Carson (1996).

Informed Consent

Before selective termination or reduction, a discussion should include the morbidity and mortality rates expected if the pregnancy is continued; the morbidity and mortality rates expected with surviving twins or triplets; and the risks of the procedure itself.

With couples seeking infertility treatment, the issue of selective reduction should ideally be discussed *before* conception. Grobman and associates (2001) reported that these couples were generally unaware of the risks associated with multifetal gestation, and they were less desirous of having a multifetal gestation once apprised of the risks.

Specific risks that are common to selective termination or reduction include:

1. Abortion of the remaining fetuses
2. Abortion of the wrong (normal) fetus(es)
3. Retention of genetic or structurally abnormal fetuses after a reduction in number
4. Damage without death to a fetus
5. Preterm labor
6. Discordant or growth-restricted fetuses
7. Maternal infection, hemorrhage, or possible disseminated intravascular coagulopathy because of retained products of conception.

The procedure should be performed by an operator skilled and experienced in sonographically guided procedures.

Psychological Reaction

Women and their spouses who elect to undergo selective termination or reduction find this decision highly stressful. Schreiner-Engel and colleagues (1995) retrospectively studied the emotional reactions of 100 women following selective reduction. Although 70 percent of the women mourned for their dead fetus(es), most grieved only for 1 month. Persistent depressive symptoms were mild, although moderately severe sadness and guilt continued for many of them. Fortunately, most were reconciled to the termination of some fetuses to

preserve the lives of a remaining few. Indeed, 93 percent of the women would have made the same decision again.

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY 936

Never penalize a woman because she is pregnant. Pregnant women are susceptible to any of the medical and surgical disorders that can affect childbearing-aged women. Some of these, especially those that are chronic, more often precede pregnancy. But, they as well as others can acutely complicate an otherwise normal pregnancy. It is difficult to accurately quantify nonobstetrical disorders that complicate pregnancy, however, some estimates can be made. For example, one managed-care population had an overall antenatal hospitalization rate of 10.1 per 100 deliveries (Gazmararian, 2002). Of these, approximately a third were for nonobstetrical conditions that included renal, pulmonary, and infectious diseases. In another study from the 2002 Nationwide Inpatient Sample, the injury hospitalization rate was found to be 4.1 women per 1000 deliveries (Kuo, 2007). Approximately 1 in every 635 pregnant women will undergo a nonobstetrical surgical procedure (Corneille, 2010; Kizer, 2011).

Many of these nonobstetrical disorders are within the purview of the obstetrician. Some, however, will warrant consultation,

and still others require a multidisciplinary team. The latter may include maternal-fetal medicine specialists, internists and medical subspecialists, surgeons, anesthesiologists, and numerous other disciplines (American College of Obstetricians and Gynecologists, 2013). In these latter situations, obstetricians should have a working knowledge of the wide range of medical disorders common to childbearing-aged women. At the same time, nonobstetricians who help care for these women and their unborn fetuses should be familiar with pregnancy-induced physiological changes and special fetal considerations. Many of these normal pregnancy perturbations have clinically significant effects on various diseases and cause seemingly aberrant changes in routine laboratory values.

It should be axiomatic that a woman should never be penalized because she is pregnant. To ensure this, a number of questions should be addressed:

- What management plan would be recommended if the woman was not pregnant?
- If the proposed management is different because the woman is pregnant, can this be justified?
- What are the risks versus benefits to the mother and her fetus, and are they counter to each other?
- Can an individualized management plan be devised that balances the benefits versus risks of any alterations?

Such an approach should allow individualization of care for women with most medical and surgical disorders complicating pregnancy. Moreover, it may be especially helpful for consideration by nonobstetrical consultants.

MATERNAL PHYSIOLOGY AND LABORATORY VALUES

Pregnancy induces physiological changes in virtually all organ systems. Some are profound and may amplify or obfuscate evaluation of coexisting conditions. Coincidentally, results

of numerous laboratory tests are altered, and some values would, in the nonpregnant woman, be considered abnormal. Conversely, some may appear to be within a normal range but are decidedly abnormal for the pregnant woman. The wide range of pregnancy effects on normal physiology and laboratory values are discussed in the chapters that follow as well as throughout Chapter 4 and the Appendix.

MEDICATIONS DURING PREGNANCY

It is indeed fortunate that most medications necessary to treat the most frequently encountered illnesses complicating pregnancy can be given with relative safety. That said, there are notable exceptions, which are considered in Chapter 12.

SURGICAL PROCEDURES DURING PREGNANCY

The risk of an adverse pregnancy outcome is not appreciably increased in most women who undergo an uncomplicated surgical procedure. With complications, however, risks likely will be increased. For example, perforative appendicitis with feculent peritonitis has significant maternal and perinatal morbidity and mortality rates even if surgical and anesthetic techniques are flawless. Conversely, procedure-related complications may adversely affect outcomes. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents at the time of tracheal intubation or extubation. Still, compared with nonpregnant women undergoing similar procedures, pregnant women do not appear to have excessive complications (Silvestri, 2011).

Effect of Surgery and Anesthesia on Pregnancy Outcome

The most extensive data regarding anesthetic and surgical risks to pregnancy are from the Swedish Birth Registry as described by Mazze and Källén (1989). The effects on pregnancy outcomes of 5405 nonobstetrical surgical procedures performed in 720,000 pregnant women from 1973 to 1981 were analyzed. General anesthesia was used for approximately half of these procedures and commonly involved nitrous oxide supplemented by another inhalation agent or intravenous medications. These procedures were performed in 41 percent of women in the first trimester, 35 percent in the second, and 24 percent in the third. The distribution by the type of procedure is shown in Figure 46-1. Overall, 25 percent were abdominal operations and 20 percent were gynecological or urological procedures. Laparoscopy was the most frequently performed operation, and appendectomy was the most common second-trimester procedure.

Perinatal Outcomes

Excessive perinatal morbidity associated with nonobstetrical surgery is attributable in many cases to the disease itself rather than to adverse effects of surgery and anesthesia. The Swedish Birth Registry again provides valuable data as shown in Table 46-1 (Mazze, 1989). The incidence of neonates with congenital malformations or those stillborn was not

FIGURE 46-1 Proportions of surgical procedures by trimester in 3615 women. (Data from Mazze, 1989.)

significantly different from that of nonexposed control newborns. There were, however, significantly increased incidences of low birthweight, preterm birth, and neonatal death in infants born to women who had undergone surgery. Increased neonatal deaths were largely due to preterm birth. These investigators concluded that these adverse outcomes likely were due to a synergistic effect of the illness in concert with the surgical procedures. In another study, there was an increased preterm delivery rate in 235 women undergoing adnexal mass surgery (Hong, 2006).

In a follow-up study of the Swedish database, Källén and Mazze (1990) scrutinized 572 operations performed at 4 to 5 weeks' gestation and reported a nonsignificant relationship with increased neural-tube defect rates. In a similar study from a Hungarian database, Czeizel and colleagues (1998) found no evidence that anesthetic agents were teratogenic. In a review, Kuczkowski (2006) concluded that there is no robust evidence that anesthetic agents are harmful to the fetus.

TABLE 46-1. Birth Outcomes in 5405 Pregnant Women Undergoing Nonobstetrical Surgery

Outcome	Rate	p value ^a
Major malformation	1.9%	NS
Stillbirth	7 per 1000	NS
Neonatal death by 7 days	10.5 per 1000	< 0.05
Preterm < 37 wk	7.5%	< 0.05
Birthweight < 1500 g	1.2%	< 0.05
Birthweight < 2500 g	6.6%	< 0.05

^aCompared with 720,000 pregnancies in women without surgery.

NS = not significant.

Data from Mazze, 1989.

LAPAROSCOPIC SURGERY DURING PREGNANCY

Laparoscopy has become the most common first-trimester procedure used for diagnosis and management of several surgical disorders (Kuczkowski, 2007). In addition to management of ectopic pregnancy (Chap. 19, p. 385), it is used preferentially during most of pregnancy for exploration and treatment of adnexal masses (Chap. 63, p. 1226), for appendectomy (Chap. 54, p. 1079), and for cholecystectomy (Chap. 55, p. 1096). In 2011, the Guidelines Committee of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) updated its recommendations concerning laparoscopy use in pregnant women. Some of these guidelines are listed in Table 46-2.

Information regarding surgical approach selection in pregnant women comes from the American College of Surgeons database (Silvestri, 2011). During the 5-year period ending in 2009, almost 1300 pregnant women who had undergone either appendectomy or cholecystectomy were studied. Open appendectomy was performed in 36 percent of 857 pregnant women compared with only 17 percent of those not pregnant. Of those undergoing cholecystectomy, an open procedure was used in 10 percent of 436 pregnant women compared with 5 percent of nonpregnant women.

There are no randomized trials comparing laparoscopic with open surgery, however, most reviews report equally satisfactory outcomes (Bunyavejchevin, 2013; Fatum, 2001; Lachman, 1999). The most frequently performed procedures were cholecystectomy, adnexal surgery, and appendectomy. Laparoscopic adnexal mass surgery in pregnancy is preferred, and its relative safety is attested to by several investigators (Biscette, 2011; Hoover, 2011; Koo, 2011, 2012). At first, 26 to 28 weeks became the upper gestational-age limit recommended, but as experience has continued to accrue, many now describe laparoscopic surgery performed in the third trimester (Donkervoort,

2011; Kizer, 2011). In one report of 59 pregnant women undergoing laparoscopic cholecystectomy or appendectomy, a third were > 26 weeks pregnant (Rollins, 2004). There were no serious adverse sequelae to these procedures. There are now reports of laparoscopic splenectomy, adrenalectomy, and nephrectomy done in pregnant women (Aubrey-Bassier, 2012; Gernsheimer, 2007; Kosaka, 2006; Miller, 2012; Stroup, 2007).

Hemodynamic Effects

Abdominal insufflation for laparoscopy causes hemodynamic changes that are similar in pregnant and nonpregnant women, and these are summarized in Table 46-3. Reedy and associates (1995) studied baboons at the human equivalent of 22 to 26 weeks' gestation. There were no substantive physiological changes with 10 mm Hg insufflation pressures, but 20 mm Hg caused significant maternal cardiovascular and respiratory changes after 20 minutes. These included increased respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery and capillary wedge pressures.

In women, cardiorespiratory changes are generally not severe if insufflation pressures are kept below 20 mm Hg. With noninvasive hemodynamic monitoring in women at midpregnancy, the cardiac index decreased 26 percent by 5 minutes of insufflation and 21 percent by 15 minutes (Steinbrook, 2001). Despite this, mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly.

Perinatal Outcomes

Because precise effects of laparoscopy in the human fetus are unknown, animal studies are informative. In early studies of pregnant ewes, various investigators reported that uteroplacental blood flow decreased when intraperitoneal insufflation pressure exceeded 15 mm Hg (Barnard, 1995; Hunter, 1995). This was the result of decreased perfusion pressure and increased placental vessel resistance (see Table 46-3). The previously cited baboon studies by Reedy and coworkers (1995) produced similar findings. Since then, other studies in sheep have corroborated these observations (O'Rourke, 2006; Reynolds, 2003).

Pregnancy outcomes in women are limited to observations. Reedy and colleagues (1997) used the updated Swedish Birth Registry database to analyze a 20-year period and more than 2 million deliveries. There were 2181 laparoscopic procedures, most of which were performed during the first trimester. Perinatal outcomes for these women were compared with those of all women in the database as well as those undergoing open surgical procedures. These investigators confirmed the earlier findings of an increased risk of low birthweight, preterm delivery, and fetal-growth restriction in pregnancies of women in both operative groups compared with controls. There were no differences, however, when outcomes of women undergoing laparoscopy versus laparotomy were compared. Similar findings were reported from an observational study of 262 women undergoing surgery for an adnexal mass (Koo, 2012).

Technique

Preparation for laparoscopy differs little from that used for laparotomy. Bowel cleansing empties the large intestine and may aid

TABLE 46-2. Some Guidelines for the Performance of Laparoscopic Surgery in Pregnancy

Indications —same as for nonpregnant women
Adnexal mass excision
Investigation of acute abdominal processes
Appendectomy, cholecystectomy, nephrectomy, adrenalectomy, splenectomy
Timing —all trimesters
Technique
Position: left lateral recumbent
Entry: open technique, careful Veress needle, or optical trocar; fundal height may alter insertion site selection
Trocars: direct visualization for placement; fundal height may alter insertion site selection
CO ₂ insufflation pressures: 10–15 mm Hg
Monitoring: capnography intraoperatively, FHR assessment pre- and postoperatively
Perioperative pneumatic compression devices and early postoperative ambulation

CO₂ = carbon dioxide; FHR = fetal heart rate.
Summarized from Pearl, 2011.

TABLE 46-3. Physiological Effects of CO₂ Insufflation of the Peritoneal Cavity

System	Effects ^a	Mechanisms	Possible Maternal-Fetal Effects
Respiratory	Pco ₂ increases, pH decreases	CO ₂ absorption	Hypercarbia, acidosis
Cardiovascular	Increased—heart rate; systemic vascular resistance; pulmonary, central venous, and mean arterial pressures	Hypercarbia and increased intraabdominal pressure	Uteroplacental hypoperfusion—possible fetal hypoxia, acidosis, and hypoperfusion ^b
	Decreased—cardiac output	Decreased venous return	
Blood flow	Decreased splanchnic flow with hypoperfusion of liver, kidneys, and gastrointestinal organs	Increased intraabdominal pressure	As above
	Decreased venous return from lower extremities	Increased intraabdominal pressure	As above
	Increased cerebral blood flow	Hypercarbia possibly from shunting due to splanchnic tamponade	Increased CSF pressure ^b

^aEffects intensified when insufflation pressure > 20 mm Hg in baboons (Reedy, 1995).

^bData primarily from animal studies.

CO₂ = carbon dioxide; CSF = cerebrospinal fluid; Pco₂ = partial pressure of CO₂.

Data from O'Rourke, 2006; Reynolds, 2003.

visualization. Nasogastric or orogastric decompression reduces the risk of stomach trocar puncture and aspiration. Aortocaval compression is avoided by a left-lateral tilt. Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or *manual* uterine displacement. Vaginally placed instruments that enter the cervix or uterus for uterine manipulation should not be used during pregnancy.

Most reports describe the use of general anesthesia after tracheal intubation with monitoring of end-tidal carbon dioxide—EtCO₂ (Hong, 2006; Ribic-Pucelj, 2007). With controlled ventilation, EtCO₂ is maintained at 30 to 35 mm Hg.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid uterine puncture or laceration. Many recommend *open entry* techniques to avoid perforations of the uterus, pelvic vessels, and adnexa (Kizer, 2011; Koo, 2012). The abdomen is incised at or above the umbilicus, and the peritoneal cavity entered under direct visualization. At this point, the cannula is then connected to the insufflation system, and a 12-mm Hg pneumoperitoneum is created. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp. Insertion of secondary trocars into the abdomen is most safely performed under direct laparoscopic visual observation through the primary port. Single-port surgery has also been described (Dursun, 2013).

In more advanced pregnancies, direct entry through a left upper quadrant port in the midclavicular line, 2 cm beneath the costal margin, has been described (Donkervoort, 2011; Stepp, 2004). Known as Palmer point, this entry site is used in gynecological laparoscopy because visceroparietal adhesions uncommonly form here (Vilos, 2007).

Gasless Laparoscopy

This is a less commonly used alternative approach that uses a rod with intraabdominal fan-blade-shaped retractors. When opened, these allow the abdominal wall to be lifted upward. It avoids the typical laparoscopic cardiovascular changes because the pneumoperitoneum is created by retraction rather than insufflation (Phupong, 2007).

Complications

Risks inherent to any abdominal endoscopy are possibly increased slightly during pregnancy. The obvious unique complication is perforation of the pregnant uterus with either a trocar or Veress needle (Azevedo, 2009; Kizer, 2011). That said, reported complications are infrequent (Fatum, 2001; Joumblat, 2012; Koo, 2012). After a Cochrane database review, it was determined that randomized trials would be necessary to deduce comparative benefits and risks of laparoscopy versus laparotomy during pregnancy (Bunyavejchevin, 2013). Pragmatically, this seems unfeasible, and common sense should dictate the approach used.

IMAGING TECHNIQUES

Imaging modalities that are used as adjuncts for diagnosis and therapy during pregnancy include sonography, radiography, and magnetic resonance (MR) imaging. Of these, radiography is the most problematic. Inevitably, some radiographic procedures are performed before recognition of early pregnancy, usually because of trauma or serious illness. Fortunately, most diagnostic radiographic procedures are associated with minimal fetal risks. As with drugs and medications, however, these procedures may lead to litigation if there is an adverse pregnancy outcome. And x-ray exposure may lead to a needless therapeutic abortion because of patient or physician anxiety.

Beginning 2007, the American College of Radiology (ACR) has addressed the growing concern of radiation dose in all fields of medicine. Some of the goals were to limit exposure through radiation safety practices and promote lifelong accumulated records of exposures in any given patient (Amis, 2007). Task Force recommendations included additional considerations for special radiosensitive populations, such as children and pregnant and potentially pregnant women. The Task Force also suggested that the College should encourage radiologists to record all ionizing radiation times and exposures, compare them with benchmarks, and evaluate outliers as part of ongoing quality assurance programs. At the present time at Parkland Hospital, special recommendations are made for the pregnant woman. Radiation exposure values and duration are recorded in high-exposure areas such as computed tomography (CT) and fluoroscopy. Moreover, quality assurance mechanisms are in place to monitor these parameters.

An excellent review of ionizing radiation exposure during pregnancy was performed following the recent Fukushima nuclear plant disaster in Japan (Groen, 2012). This review reinforced considerations during pregnancy that are discussed subsequently.

■ Ionizing Radiation

The term *radiation* is poorly understood. Literally, it refers to energy transmission and thus is often applied not only to x-rays, but also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are ionizing radiation forms. The other four energy forms have rather long wavelengths and low energy (Brent, 1999b, 2009).

The biological effects of x-rays are caused by an electrochemical reaction that can damage tissue. According to Brent (1999a, 2009), x- and gamma-radiation at high doses can create two types of biological effects and reproductive risks in the fetus:

- 1. *Deterministic effects*—these may cause congenital malformations, fetal-growth restriction, mental retardation, and abortion. Although controversial, this so-called NOAEL—No Observed Adverse Effect Level—suggests that there is a threshold dose (0.05 gray or 5 rad) below which there is no risk. It also suggests that the threshold for gross fetal malformations is more likely to be 0.2 gray (20 rad).
- 2. *Stochastic effects*—these are randomly determined probabilities, which may cause genetic diseases and carcinogenesis. In this case, cancer risk is increased, and hypothetically, at even very low doses.

In this sense, ionizing radiation refers to waves or particles—photons—of significant energy that can change the structure of molecules such as those in DNA, or that can create free radicals or ions capable of causing tissue damage (Hall, 1991; National Research Council, 1990). Methods of measuring the effects of x-rays are summarized in Table 46-4. The standard terms used are *exposure* (in air), *dose* (to tissue), and *relative effective dose* (to tissue). In the range of energies for diagnostic x-rays, the dose is now expressed in grays (Gy), and the relative effective dose is now expressed in sieverts (Sv). These can be used interchangeably. For consistency, all doses discussed

TABLE 46-4. Some Measures of Ionizing Radiation

Exposure	Number of ions produced by x-rays per kg of air Unit: roentgen (R)
Dose	Amount of energy deposited per kg of tissue Modern unit: gray (Gy) (1 Gy = 100 rad) Traditional unit: rad
Relative effective dose	Amount of energy deposited per kg of tissue normalized for biological effectiveness Modern unit: sievert (Sv) (1 Sv = 100 rem) Traditional unit: rem

subsequently are expressed in contemporaneously used units of gray (1 Gy = 100 rad) or sievert (1 Sv = 100 rem). To convert, 1 Sv = 100 rem = 100 rad.

■ X-Ray Dosimetry

When calculating the ionizing radiation dose, such as that from x-rays, several factors to be considered include: (1) type of study, (2) type and age of equipment, (3) distance of target organ from radiation source, (4) thickness of the body part penetrated, and (5) method or technique used for the study (Wagner, 1997).

Estimates of dose to the uterus and embryo for various frequently used radiographic examinations are summarized in Table 46-5. Studies of maternal body parts farthest from the uterus, such as the head, result in a very small dose of radiation scatter to the embryo or fetus. The size of the woman, radiographic technique, and equipment performance are variable factors. Thus, data in the table serve only as guidelines. When the radiation dose for a specific individual is required, a medical physicist should be consulted. Brent (2009) recommends consulting the Health Physics Society website (www.hps.org) to view some examples of questions and answers posed by patients exposed to radiation.

■ Deterministic Effects of Ionizing Radiation

One potential harmful effect of radiation exposure is deterministic, which may result in abortion, growth restriction, congenital malformations, microcephaly, or mental retardation. These deterministic effects are threshold effects, and the level below which they are induced is the NOAEL (Brent, 2009).

The harmful deterministic effects of ionizing radiation have been extensively studied for cell damage with resultant embryogenesis dysfunction. These have been assessed in animal models, as well as in Japanese atomic bomb survivors and the Oxford Survey of Childhood Cancers (Sorahan, 1995). Additional sources have confirmed previous observations and provided more information (Groen, 2012). One is the 2003 International Commission on Radiological Protection publication, which describes biological fetal effects from prenatal irradiation. Another is the Biological Effects of Ionizing Radiation—BEIR VII Phase 2 report of the National Research

Council (2006), which discusses health risks from exposure to low levels of ionizing radiation.

Animal Studies

In the mouse model, the lethality risk is highest during the preimplantation period—up to 10 days postconception. This is likely due to blastomere destruction caused by chromosomal damage (Hall, 1991). The NOAEL for lethality is 0.15 to 0.2 Gy. Genomic instability can be induced in some mouse models at levels of 0.5 Gy (50 rad), which greatly exceeds levels with diagnostic studies (International Commission on Radiological Protection, 2003).

During organogenesis, high-dose radiation—1 gray or 100 rad—is more likely to cause malformations and growth restriction and less likely to have lethal effects in the mouse. Acute low-dose ionizing radiation appears to have no deleterious effects (Howell, 2013). Studies of brain development suggest that there are effects on neuronal development and a window of cortical sensitivity in early and midfetal periods. During this, the threshold ranges from 0.1 to 0.3 Gy or 10 to 30 rad (International Commission on Radiological Protection, 2003).

Human Data

Data on adverse human effects of high-dose ionizing radiation have most often been derived from atomic bomb survivors from Hiroshima and Nagasaki (Greskovich, 2000; Otake, 1987). The International Commission on Radiological Protection (2003) confirmed initial studies showing that the increased risk of severe mental retardation was greatest between 8 and 15 weeks (Fig. 46-2). There may be a lower-threshold dose of 0.3 Gy—30 rad—a range similar to the window of cortical sensitivity in the mouse model discussed above. The mean decrease in intelligence quotient (IQ) scores was 25 points per Gy or 100 rad. There appears to be linear dose response, but it is not clear whether there is a threshold dose. Most estimates

err on the conservative side by assuming a linear nonthreshold hypothesis. From their review, Strzelczyk and coworkers (2007) conclude that limitations of epidemiological studies at low-level exposures, along with new radiobiological findings, challenge the hypothesis that any amount of radiation causes

FIGURE 46-2 Follow-up of subjects from Hiroshima and Nagasaki after the atomic bomb explosion in 1945. Subsequent severe mental retardation caused by exposure to ionizing in utero radiation at two gestational age epochs to 1 Gy, that is, 100 rad. Mean values and 90-percent confidence levels are estimated from dosimetry calculated by two methods—T65DR and D586—used by the Radiation Effects Research Foundation of the Japanese Ministry of Health and National Academy of Sciences of the United States. (Data from Otake, 1987, with permission.)

adverse effects. In one such study describing fetuses exposed to low radiation doses, Choi and colleagues (2012) did not find an increased risk for congenital anomalies.

Finally, there is no documented increased risk of mental retardation in humans less than 8 weeks' or greater than 25 weeks' gestation, even with doses exceeding 0.5 Gy or 50 rad (Committee on Biological Effects, BEIR V, 1990; International Commission on Radiological Protection, 2003).

There are reports that have described high-dose radiation used to treat women for malignancy, menorrhagia, and uterine myomas. Dekaban (1968) described 22 infants with microcephaly, mental retardation, or both following exposure in the first half of pregnancy to an estimated 2.5 Gy or 250 rad. Malformations in other organs were not found unless they were accompanied by microcephaly, eye abnormalities, or growth restriction (Brent, 1999b).

The implications of these findings seem straightforward. From 8 to 15 weeks, the embryo is most susceptible to radiation-induced mental retardation. It has not been resolved whether this is a threshold or nonthreshold linear function of dose. The Committee on Biological Effects (1990) estimates the risk of severe mental retardation to be as low as 4 percent for 0.1 Gy (10 rad) and as high as 60 percent for 1.5 Gy (150 rad). But recall that these doses are 2 to 100 times higher than those considered maximal from diagnostic radiation. Importantly, cumulative doses from multiple procedures may reach the harmful range, especially at 8 to 15 weeks. At 16 to 25 weeks, the risk is less. And again, there is no proven risk before 8 weeks or after 25 weeks.

Embryo-fetal risks from low-dose diagnostic radiation appear to be minimal. Current evidence suggests that there are no increased risks for malformations, growth restriction, or abortion from a radiation dose of less than 0.05 Gy (5 rad). Indeed, Brent (2009) concluded that gross congenital malformations would not be increased with exposure to less than 0.2 Gy (20 rad). Because diagnostic x-rays seldom exceed 0.1 Gy (10 rad), Strzelczyk and associates (2007) concluded that these procedures are unlikely to cause deterministic effects. As emphasized by Groen and coworkers (2012), 0.1 Gy is the radiation equivalent to that from more than 1000 chest x-rays!

■ Stochastic Effects of Ionizing Radiation

This refers to random, presumably unpredictable oncogenic or mutagenic effects of radiation exposure. They concern associations between fetal diagnostic radiation exposure and increased risk of childhood cancers or genetic diseases. According to Doll and Wakeford (1997), as well as the National Research Council (2006) BEIR VII Phase 2 report, excess cancers can result from in utero exposure to doses as low as 0.01 Sv or 1 rad. Stated another way by Hurwitz and colleagues (2006), the estimated risk of childhood cancer following fetal exposure to 0.03 Gy or 3 rad doubles the background risk of 1 in 600 to that of 2 in 600.

In one report, in utero radiation exposure was determined for 10 solid cancers in adults from age 17 to 45 years. There was a dose-response relationship as previously noted at the 0.1 Sv or 10 rem threshold. Intriguingly, nine of 10 cancers were found

in females (National Research Council, 2006). These likely are associated with a complex series of interactions between DNA and ionizing radiation. They also make it more problematic to predict cancer risk from low-dose radiation of less than 0.1 Sv or 10 rem. Importantly, below doses of 0.1 to 0.2 Sv, there is no convincing evidence of a carcinogenic effect (Brent, 2009; Preston, 2008; Strzelczyk, 2007).

■ Therapeutic Radiation

In an earlier report, the Radiation Therapy Committee Task Group of the American Association of Physics in Medicine found that approximately 4000 pregnant women annually undergo cancer therapy in the United States (Stovall, 1995). Their recommendations, however, stand to date. The Task Group emphasizes careful individualization of radiotherapy for the pregnant woman (Chap. 63, p. 1220). For example, in some cases, shielding of the fetus and other safeguards can be employed (Fenig, 2001; Nuyttens, 2002). In other instances, the fetus will be exposed to dangerous radiation doses, and a carefully designed plan must be improvised (Prado, 2000). One example is the model to estimate the fetal dose with maternal brain radiotherapy, and another is the model to calculate the fetal dose with tangential breast irradiation (Mazonakis, 1999, 2003). The impact of radiotherapy on future fertility and pregnancy outcomes was reviewed by Wo and Viswanathan (2009) and others, and this is discussed in detail in Chapter 63 (p. 1220).

■ Diagnostic Radiation

To estimate fetal risk, approximate x-ray dosimetry must be known. According to the American College of Radiology no single diagnostic procedure results in a radiation dose significant enough to threaten embryo-fetal well-being (Hall, 1991).

Radiographs

Dosimetry for standard radiographs is presented in Table 46-5. In pregnancy, the AP-view chest radiograph is the most commonly used study, and fetal exposure is exceptionally small—0.0007 Gy or 0.07 mrad. With one abdominal radiograph, because the embryo or fetus is directly in the x-ray beam, the dose is higher—0.001 Gy or 100 mrad. The standard intravenous pyelogram may exceed 0.005 Gy or 500 mrad because of several films. The one-shot pyelogram described in Chapter 53 (p. 1056) is useful when urolithiasis or other causes of obstruction are suspected but unproven by sonography. Most “trauma series,” such as radiographs of an extremity, skull, or rib series, deliver low doses because of the fetal distance from the target area.

Fetal indications for radiographic studies are limited. In some countries, x-ray pelvimetry is done for a breech presentation (Chap. 28, p. 562).

Fluoroscopy and Angiography

Dosimetry calculations are much more difficult with these procedures because of variations in the number of radiographs obtained, total fluoroscopy time, and fluoroscopy

TABLE 46-6. Estimated X-Ray Doses to the Uterus/Embryo from Common Fluoroscopic Procedures

Procedure	Dose to Uterus (mGy)	Fluoroscopic Exposure in Seconds (SD)
Cerebral angiography ^a	< 0.1	—

PTCA = percutaneous transluminal coronary angioplasty; SD = standard deviation.

time in which the fetus is in the radiation field. As shown in [Table 46-6](#), the range is variable. The Food and Drug Administration limits the exposure rate for conventional fluoroscopy such as barium studies, however, special-purpose systems such as angiography units have the potential for much higher exposure.

Endoscopy is the preferred method of gastrointestinal tract evaluation in pregnancy (Chap. 54, p. 1069). Occasionally, an upper gastrointestinal series or barium enema may be performed before a pregnancy is recognized. Most would likely be done during preimplantation or early organogenesis.

Angiography and vascular embolization may occasionally be necessary for serious maternal disorders, especially renal disease, and for trauma (Wortman, 2013). As before, the greater the distance from the embryo or fetus, the less the exposure and risk.

Computed Tomography

This is usually performed by obtaining a spiral of 360-degree images that are postprocessed in multiple planes. Of these, the axial image remains the most commonly obtained. Multidetector CT (MDCT) images are now standard for common clinical indications. The most recent detectors have 16 or 64 channels, and MDCT protocols may result in increased dosimetry compared with traditional CT imaging. A number of imaging parameters have an effect on exposure (Brenner, 2007). These include pitch, kilovoltage, tube current, collimation, number of slices, tube rotation, and total acquisition time. If a study is performed with and without contrast, the dose is doubled because twice as many images are obtained. Fetal exposure is also dependent on factors such as maternal size as well as fetal size and position. And as with

TABLE 46-7. Estimated Radiation Dosimetry with 16-Channel Multidetector Computed-Tomographic (MDCT) Imaging Protocols

Protocol	Dosimetry (mGy)	
	Preimplantation	3 Months' Gestation
Pulmonary embolism	0.20–0.47	0.61–0.66
Renal stone	8–12	4–7
Appendix	15–17	20–40

Data from Hurwitz, 2006.

plain radiography, the closer the target area is to the fetus, the greater the delivered dose.

Cranial CT scanning is the most commonly requested study in pregnant women. It is used in women with neurological disorders as discussed in Chapter 60 (p. 1187) and with eclampsia as noted in Chapter 40 (p. 744). Nonenhanced CT scanning is commonly used to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces. Because of the distance from the fetus, radiation dosage is negligible (Goldberg-Stein, 2012).

Abdominal procedures are more problematic. Hurwitz and associates (2006) employed a 16-MDCT to calculate fetal exposure at 0 and 3 months' gestation using a phantom model ([Table 46-7](#)). Calculations were made for three commonly requested procedures in pregnant women. The pulmonary embolism protocol has the same dosimetry exposure as the ventilation-perfusion (V/Q) lung scan discussed below. Because of the pitch used, the appendicitis protocol has the highest radiation exposure, however, it is very useful clinically ([Fig. 46-3](#)). Using a similar protocol in 67 women with suspected appendicitis, Lazarus and coworkers (2007) reported sensitivity of 92 percent, specificity of 99 percent, and a negative-predictive value of 99 percent. Here dosimetry was markedly decreased compared with standard appendiceal imaging because of a different pitch. For suspected urolithiasis, the MDCT-scan

**FIGURE 46-3** Computed-tomographic protocol for appendix shows an enlarged, enhancing—and thus inflamed—appendix (arrow) next to the 25-week pregnancy. (Image contributed by Dr. Jeffrey H. Pruitt.)

FIGURE 46-4 Computed-tomographic protocol imaging for urolithiasis disclosed a renal stone in the distal ureter (*arrow*) at its junction with the bladder. (Image contributed by Dr. Jeffrey H. Pruitt.)

protocol shown in [Figure 46-4](#) is used if sonography is non-diagnostic. Using a similar protocol, White and colleagues (2007) identified urolithiasis in 13 of 20 women at an average of 26.5 weeks. Finally, and as discussed in Chapter 47 (p. 954), abdominal tomography should be performed if indicated in the pregnant woman with severe trauma.

Most experience with chest CT-scanning is with suspected pulmonary embolism. The most recent recommendations for its use in pregnancy from the Prospective Investigation of Pulmonary Embolism Diagnosis—PIOPED—II investigators were summarized by Stein and associates (2007). They found that pulmonary scintigraphy—the V/Q scan—was recommended for pregnant women by 70 percent of radiologists and chest CT angiography by 30 percent. And scintigraphy is still recommended by the American Thoracic Society in pregnant women with a normal chest x-ray (Leung, 2012). But most agree that MDCT angiography has improved accuracy because of increasingly faster acquisition times. Others have reported a higher use rate for CT angiography and emphasize that dosimetry is similar to that with V/Q scintigraphy (Brenner, 2007; Hurwitz, 2006; Matthews, 2006). At Parkland and UT Southwestern University Hospitals, we prefer MDCT scanning initially for suspected pulmonary embolism (Chap. 52, p. 1042).

CT pelvimetry is used by some before attempting breech vaginal delivery (Chap. 28, p. 562). The fetal dose approaches 0.015 Gy or 1.5 rad, but use of a low-exposure technique may reduce this to 0.0025 Gy or 0.25 rad.

Nuclear Medicine Studies

These studies are performed by “tagging” a radioactive element to a carrier that can be injected, inhaled, or swallowed. For example, the radioisotope technetium-99m may be tagged to red blood cells, sulfur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. The amount of placental transfer is obviously important, but so is renal clearance because of fetal proximity to the maternal bladder. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the becquerel (Bq). Dosimetry is usually expressed in millicuries (mCi). As shown in [Table 46-4](#), the

effective tissue dose is expressed in sievert units (Sv) with conversion as discussed: 1 Sv = 100 rem = 100 rad.

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in [Table 46-8](#). The radionuclide dose should be kept as low as possible (Adelstein, 1999). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effect of iodine-131 on the fetal thyroid (Wagner, 1997). The International Commission on Radiological Protection (2001) has compiled dose coefficients for radionuclides. Stather and coworkers (2002) detailed the biokinetic and dosimetric models used by the Commission to estimate fetal radiation doses from maternal radionuclide exposure.

As discussed above, MDCT-angiography is being used preferentially for suspected pulmonary embolism during pregnancy. Until recently, the imaging modality was the ventilation-perfusion lung scan in this setting. It is used if CT angiography is nondiagnostic (Chap. 52, p. 1043). Perfusion is measured with injected ^{99m}Tc -macroaggregated albumin, and ventilation is measured with inhaled xenon-127 or xenon-133. Fetal exposure with either is negligible (Chan, 2002; Mountford, 1997).

Thyroid scanning with iodine-123 or iodine-131 seldom is indicated in pregnancy. With trace doses used, however, fetal risk is minimal. Importantly, therapeutic radioiodine in doses to treat Graves disease or thyroid cancer may cause fetal thyroid ablation and cretinism.

The sentinel lymphoscintigram, which uses ^{99m}Tc -sulfur colloid to detect the axillary lymph node most likely to have metastases from breast cancer, is a commonly used preoperative study in nonpregnant women (Newman, 2007; Spanheimer, 2009; Wang, 2007). As shown in [Table 46-8](#), the calculated dose is approximately 0.014 mSv or 1.4 mrad, which should not preclude its use during pregnancy.

SONOGRAPHY

Of all of the major advances in obstetrics, the development of sonography for study of the fetus and mother certainly is one of the greater achievements. The technique has become virtually indispensable in everyday practice. The wide range of clinical uses of sonography in pregnancy is further discussed in Chapter 10 and in most other sections of this book.

MAGNETIC RESONANCE IMAGING

Magnetic resonance technology does not use ionizing radiation, and its application is cited throughout this book. Advantages include high soft-tissue contrast, ability to characterize tissue, and acquisition of images in any plane—particularly axial, sagittal, and coronal. An entire section in Chapter 10 (p. 222) is devoted to mechanisms that generate MR images.

Safety

The most recent update of the Blue Ribbon Panel on MR safety of the American College of Radiology was summarized

TABLE 46-8. Radiopharmaceuticals Used in Nuclear Medicine Studies

Study	Estimated Activity Administered per Examination (mCi) ^a	Weeks' Gestation ^b	Dose to Uterus/Embryo (mSv) ^c
Brain	20 mCi ^{99m} Tc DTPA	< 12 12	8.8 7 ^c
Hepatobiliary	5 mCi ^{99m} Tc sulfur colloid 5 mCi ^{99m} Tc HIDA	12	0.45 1.5
Bone	20 mCi ^{99m} Tc phosphate	< 12	4.6
Pulmonary			
Perfusion	3 mCi ^{99m} Tc-macroaggregated albumin	Any	0.45–0.57 (combined)
Ventilation	10 mCi ¹³³ Xe gas		
Renal	20 mCi ^{99m} Tc DTPA	< 12	8.8
Abscess or tumor	3 mCi ⁶⁷ Ga citrate	< 12	7.5
Cardiovascular	20 mCi ^{99m} Tc-labeled red blood cells 3 mCi ²¹⁰ Tl chloride	< 12 12 24 36	5 11 6.4 5.2 3
Thyroid	5 mCi ^{99m} TcO ₄ 0.3 mCi ¹²³ I (whole body) ^d 0.1 mCi ¹³¹ I	< 8 1.5–6	2.4 0.10
	Whole body	2–6	0.15
	Whole body	7–9	0.88
	Whole body	12–13	1.6
	Whole body	20	3
	Thyroid-fetal	11	720
	Thyroid-fetal	12–13	1300
	Thyroid-fetal	20	5900
Sentinel lymphoscintigram	5 mCi ^{99m} Tc sulfur colloid (1–3 mCi)		5

^amCi = millicuries. To convert to mrad, multiply by 100.

^bExposures are generally greater prior to 12 weeks compared with increasing gestational ages.

^cSome measurements account for placental transfer.

^dThe uptake and exposure of ¹³¹I increases with gestational age.

DTPA = diethylenetriaminepentaacetic acid; Ga = gallium; HIDA = hepatobiliary iminodiacetic acid; I = iodine; mCi = millicurie; mSv = millisievert; Tc = technetium; TcO₄ = pertechnetate; Tl = thallium.

Data from Adelstein, 1999; Schwartz, 2003; Stather, 2002; Wagner, 1997; Zanzonico, 2000.

by Kanal and colleagues (2007). The panel concluded that there are no reported harmful human effects from MR imaging. Chew and associates (2001) found no differences in blastocyst formation exposure of early murine embryos to MR imaging with 1.5 T strength. Vadeyar and coworkers (2000) noted no demonstrable fetal heart rate pattern changes during MR imaging in women. Chung (2002) has reviewed these safety issues.

Contraindications to MR imaging include internal cardiac pacemakers, neurostimulators, implanted defibrillators and infusion pumps, cochlear implants, shrapnel or other metal in biologically sensitive areas, some intracranial aneurysm clips, and any metallic foreign body in the eye. Of more than 51,000

nonpregnant patients scheduled for MR imaging, Dewey and colleagues (2007) found that only 0.4 percent had an absolute contraindication to the procedure.

Contrast Agents

Several elemental gadolinium chelates are used to create paramagnetic contrast. Some are gadopentetate, gadodiamide, gadoteridol, and gadoterate. These cross the placenta and are found in amniotic fluid. In doses approximately 10 times the human dose, gadopentetate caused slight developmental delay in rabbit fetuses. There is little experience with gadolinium in humans

(Wang, 2012). In one study, De Santis and associates (2007) described 26 women given a gadolinium derivative in the first trimester without adverse fetal effects. Currently, according to Briggs and coworkers (2011), as well as the Panel, these contrast agents are not recommended unless there are overwhelming benefits.

Maternal Indications

In some cases, MR imaging may be complementary to CT, and in others, MR imaging is preferable. Maternal central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MR imaging. As discussed in Chapter 40 (p. 743), MR imaging has provided valuable insights into the pathophysiology of eclampsia and to calculate cerebrovascular blood flow in preeclampsia (Twickler, 2007; Zeeman, 2003, 2004a,b, 2009). It is invaluable in the diagnosis of neurological emergencies (Edlow, 2013). MR imaging is a superb technique to evaluate the maternal abdomen and retroperitoneal space. It is chosen by many to determine the degree and extent of placenta accreta and its variants in women who have had a prior cesarean delivery (Chap. 41, p. 806). It has been employed for detection and localization of adrenal tumors, renal lesions, gastrointestinal lesions, and pelvic masses in pregnancy. It has particular value in evaluating neoplasms of the chest, abdomen, and pelvis in pregnancy (Boyd, 2012; Oto, 2007; Tica, 2013). MR urography has been used successfully for renal urolithiasis (Mullins, 2012). MR imaging may be selected to confirm pelvic and vena caval thrombosis—a common source of pulmonary embolism in pregnant women (Fig. 46-5). As discussed in Chapter 37 (p. 688), CT and MR imaging is useful for evaluation of puerperal infections, but MR imaging provides better visualization of the bladder flap area following cesarean delivery (Brown, 1999; Twickler, 1997). MR imaging now includes evaluation of right lower quadrant pain in

pregnancy, specifically appendicitis (Baron, 2012; Dewhurst, 2013; Pedrosa, 2007, 2009). Investigators have also found other disorders of the gastrointestinal tract to be easily diagnosed with MR imaging (Chap. 54, p. 1069).

Fetal Indications

Fetal MR imaging provides a complement to sonography (De Wilde, 2005; Laifer-Narin, 2007; Sandrasegaran, 2006). According to Zaretsky and colleagues (2003a), MR imaging can be used to image almost all elements of the standard fetal anatomical survey. The most frequent fetal indications for MR imaging are evaluation of complex abnormalities of the brain, chest, and genitourinary system. Bauer (2009), Reichel (2003), Twickler (2002), Weisz (2009), and their associates have validated its use for fetal central nervous system anomalies and biometry (Fig. 46-6). Caire and coworkers (2003) reported its merits for fetal genitourinary anomalies. Hawkins and colleagues (2008) described MR imaging in 21 fetuses with renal anomalies and oligohydramnios. Zaretsky and associates (2003b) noted that fetal-weight estimation was more accurate using MR imaging than with sonography. Fast-acquisition sequencing has solved problems with fetal movement to improve imaging. The technique is termed *HASTE*—Half-Fourier Acquisition Single slow Turbo spin Echo, or *SSFSE*—Single Shot Fast Spin Echo. A more extensive discussion of fetal indications and findings of MR imaging are discussed in Chapter 10 and throughout this book.

GUIDELINES FOR DIAGNOSTIC IMAGING DURING PREGNANCY

The American College of Obstetricians and Gynecologists (2009) has reviewed the effects of radiographic, sonographic, and magnetic-resonance exposure during pregnancy. Its suggested guidelines are shown in Table 46-9.

FIGURE 46-5 Magnetic-resonance images of a pelvic vein thrombosis in a 15-week pregnant woman who presented with left leg pain but no symptoms of a pulmonary embolus. **A.** Reconstructed magnetic resonance venogram demonstrates partial chronic occlusion of the left common iliac vein (*large arrow*) and thrombosis and complete occlusion of the left internal iliac vein (*small arrows*). **B.** From the axial images, there is normal flow in the right (*arrow*) and no flow in the left internal iliac vein (*curved arrow*). (Image contributed by Dr. R. Douglas Sims.)

TABLE 46-9. Guidelines for Diagnostic Imaging During Pregnancy

1. Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rads has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic x-ray procedures from being performed on a pregnant woman. During pregnancy, other imaging procedures not associated with ionizing radiation, e.g., ultrasonography, and MRI, should be considered instead of x-rays when appropriate.
3. Ultrasonography and MRI are not associated with known adverse fetal effects.
4. Consultation with an expert in dosimetry calculation may be helpful in calculating estimated fetal dose when multiple diagnostic x-rays are performed on a pregnant patient.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.
6. Radiopaque and paramagnetic contrast agents are unlikely to cause harm and may be of diagnostic benefit, but these agents should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Summarized from the American College of Obstetricians and Gynecologists, 2009.

FIGURE 46-6 Magnetic-resonance images of the brain of a 35-week fetus. **A.** Axial images show the normal frontal horns, cavum septum pellucidum, and cerebellum. **B.** Sagittal images demonstrate the normal corpus callosum, brainstem, and vermis.

TRAUMA 950

THERMAL INJURY 955

CARDIOPULMONARY RESUSCITATION 956

An endless number of medical, surgical, and obstetrical complications may be encountered in pregnancy or the puerperium. Those that are more complex and life threatening can be particularly challenging, especially when a multidisciplinary team is necessary for optimal care. It is axiomatic that obstetricians and other members of the health-care team have a working knowledge of the unique considerations for pregnant women. Some of those discussed in Chapter 46 include pregnancy-induced physiological changes, alterations in normal laboratory values, and finally and importantly, consideration for the second patient—the fetus. Because these severely ill women are usually young and in good health, their prognosis is generally better than that of many other patients admitted to intensive care units.

OBSTETRICAL INTENSIVE CARE

In the United States each year, 1 to 3 percent of pregnant women require critical care services, and the risk of death during such admission ranges from 2 to 11 percent (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Those with pregnancy-associated complications—especially hemorrhage and hypertension—have

the greatest need for intensive care (Baskett, 2009; Kuklina, 2009; Madan, 2008). That said, many antepartum admissions are for nonobstetrical reasons, and in our experiences from Parkland Hospital, these include diabetes, pneumonia or asthma, heart disease, chronic hypertension, pyelonephritis, or thyrotoxicosis (Zeeman, 2006). In addition to antenatal treatment, intrapartum and postpartum critical care for hypertensive disorders, hemorrhage, sepsis, or cardiopulmonary complications may be required for many. In instances of life-threatening hemorrhage, surgical procedures may be necessary, and close proximity to a delivery-operating room is paramount. For women who are undelivered, fetal well-being is also better served by this close proximity.

Organization of Critical Care

The concept and development of critical care for all aspects of medicine and surgery began in the 1960s. The National Institutes of Health held a Consensus Conference (1983) and the Society of Critical Care Medicine (1988, 1999) subsequently established guidelines for intensive care units (ICUs). Especially pertinent to obstetrics, costly ICUs prompted evolution of a step-down *intermediate care unit*. These units were designed for patients who did not require intensive care, but who needed a higher level of care than that provided on a general ward. The American College of Critical Care Medicine and the Society of Critical Care Medicine (1998) published guidelines for these units (Table 47-1).

Obstetrical Critical Care

Although the evolution of critical care for obstetrical patients has generally followed developments described above, there are no specific guidelines. Most hospitals employ a blend of these concepts, and in general, units can be divided into three types.

- 1. Medical or Surgical ICU—in most hospitals, severely ill women are transferred to a unit operated by medical and

TABLE 47-1. Guidelines for Conditions That Could Qualify for Intermediate Care

Cardiac: evaluation for possible infarction, stable infarction, stable arrhythmias, mild-to-moderate congestive heart failure, hypertensive urgency without end-organ damage
Pulmonary: stable patients for weaning and chronic ventilation, patients with potential for respiratory failure who are otherwise stable
Neurological: stable central nervous system, neuromuscular, or neurosurgical conditions that require close monitoring
Drug overdose: hemodynamically stable
Gastrointestinal: stable bleeding, liver failure with stable vital signs
Endocrine: diabetic ketoacidosis, thyrotoxicosis that requires frequent monitoring
Surgical: postoperative from major procedures or complications that require close monitoring
Miscellaneous: early sepsis, patients who require closely titrated intravenous fluids, pregnant women with severe preeclampsia or other medical problems

From Nasraway, 1998.

surgical “intensivists.” Admissions or transfers to these units are situation-specific and based on the acuity of care needed and on the ability of the facility to provide it. For example, in most institutions, pregnant women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are transferred to an ICU. Another example is the neurological ICU (Sheth, 2012). A review of more than 25 tertiary-care referral institutions indicated that approximately 0.5 percent of obstetrical patients are transferred to these types of ICUs (Zeeman, 2006).

2. Obstetrical Intermediate Care Unit—sometimes referred to as a High-Dependency Care Unit (HDU)—an example of this system is the one at Parkland Hospital. Located within the labor and delivery unit, it has designated rooms and experienced personnel. The two-tiered system incorporates the guidelines for intermediate and intensive care. Care is provided by maternal-fetal medicine specialists and nurses with experience in critical care obstetrics. As needed, this team is expanded to include other obstetricians and anesthesiologists, gynecological oncologists, pulmonologists, cardiologists, surgeons, and other medical and surgical subspecialists. Many tertiary-care centers have developed similar intermediate care units and use selected triage to ICUs. Guidelines for such transfers must follow the federal Emergency Medical Treatment and Labor Act (EMTALA) guidelines. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), the minimal monitoring required for a critically ill patient during

transport includes continuous pulse oximetry, electrocardiography, and regular assessment of vital signs. All critically ill patients must have secure venous access before transfer. Those who are mechanically ventilated must have their endotracheal tube position confirmed and secured before transfer. Left uterine displacement and supplemental oxygen should be applied routinely during transport of antepartum patients. The utility of continuous fetal heart rate or tocodynamic monitoring is unproven, therefore, its use should be individualized.

3. Obstetrical Intensive Care Unit—these units are full-care ICUs as described above, but are operated by obstetrical and anesthesia personnel in the labor and delivery unit. Very few units have these capabilities (Zeeman, 2003, 2006).

For smaller hospitals, transfer to a medical or surgical ICU may be preferable, and sometimes transfer to another hospital is necessary. As discussed, indications for admission to these various types of critical care units are highly variable. Shown in Table 47-2 are some examples. The American College of Obstetricians and Gynecologists (2011a) has summarized critical obstetrical care implementation depending on hospital size and technical facilities. Somewhat related, the concept has been explored of a *medical emergency team—MET*—for rapid response to emergent obstetrical situations (Gosman, 2008).

Pulmonary Artery Catheter

Data obtained during pregnancy with the pulmonary artery catheter (PAC) have contributed immensely to the understanding of normal pregnancy hemodynamics and pathophysiology of common obstetrical conditions. These include preeclampsia-eclampsia, acute respiratory distress syndrome

(ARDS), and amnionic-fluid embolism (Clark, 1988, 1995, 1997; Cunningham, 1986, 1987; Hankins, 1984, 1985). Because of these studies, most have concluded that such monitoring is seldom necessary (American College of Obstetricians and Gynecologists, 2013; Dennis, 2012).

In nonobstetrical patients, randomized trials of nearly 5000 subjects have shown no benefits with pulmonary artery catheter monitoring (Harvey, 2005; Richard, 2003; Sandham, 2003). A randomized trial by the National Heart, Lung, and Blood Institute (2006b) assessed catheter-guided therapy in 1000 patients with ARDS. Invasive monitoring did not improve outcomes and had more complications. According to a recent Cochrane Database review, there have been no randomized trials using this for preeclampsia management (Li, 2012). Overall mechanisms, benefits, and risks were reviewed by Vincent (2011).

■ Hemodynamic Changes in Pregnancy

Formulas for deriving some hemodynamic parameters are shown in Table 47-3. These measurements can be corrected for body size by dividing by body surface area (BSA) to obtain *index values*. Normal values for nonpregnant adults are used but with the caveat that these may not necessarily reflect changes induced by more “passive” uteroplacental perfusion (Van Hook, 1997).

In a landmark investigation, Clark and colleagues (1989) used pulmonary artery catheterization to obtain cardiovascular measurements in healthy pregnant women and again in these same women when nonpregnant. These values are shown in Chapter 4 (Table 4-4, p. 60) and are also plotted on a *ventricular function curve* (Fig. 4-9, p. 59). Because increased blood volume and cardiac output are compensated by decreased vascular resistance and increased pulse rate, ventricular performance remains within the normal range at term. A working knowledge of these changes is paramount to understanding the pathophysiology of pregnancy complications discussed later in this chapter and throughout the book.

TABLE 47-3. Formulas for Deriving Various Cardiopulmonary Parameters

Mean arterial pressure (MAP) (mm Hg) = [SBP + 2 (DBP)] ÷ 3
Cardiac output (CO) (L/min) = heart rate × stroke volume
Stroke volume (SV) (mL/beat) = CO/HR
Stroke index (SI) (mL/beat/m ²) = stroke volume/BSA
Cardiac index (CI) (L/min/m ²) = CO/BSA
Systemic vascular resistance (SVR) (dynes × sec × cm ⁻⁵) = [(MAP – CVP)/CO] × 80
Pulmonary vascular resistance (PVR) (dynes × sec × cm ⁻⁵) = [(MPAP – PCWP)/CO] × 80

BSA = body surface area (m²); CO = cardiac output (L/min); CVP = central venous pressure (mm Hg); DBP = diastolic blood pressure; HR = heart rate (beats/min); MAP = mean systemic arterial pressure (mm Hg); MPAP = mean pulmonary artery pressure (mm Hg); PCWP = pulmonary capillary wedge pressure (mm Hg); SBP = systolic blood pressure.

ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages 1 in 500 to 1000 deliveries at tertiary referral centers. The two general causes are: (1) *cardiogenic*—hydrostatic edema caused by high pulmonary capillary hydraulic pressures and (2) *noncardiogenic*—permeability edema caused by capillary endothelial and alveolar epithelial damage. In pregnancy, noncardiogenic pulmonary edema is more common. Taken in toto, studies in pregnant women indicate that more than half who develop pulmonary edema have some degree of sepsis syndrome in conjunction with tocolysis, severe preeclampsia, or obstetrical hemorrhage combined with vigorous fluid therapy (Thornton, 2011). To categorize these differences, Dennis and Solnordal (2012) proposed a classification to include those women who are normotensive or hypotensive versus those with hypertension.

Although cardiogenic pulmonary edema is less frequent, common precipitating causes include resuscitation for hemorrhage and vigorous treatment of preterm labor. The causes in 51 women with pulmonary edema were cardiac failure, tocolytic therapy, iatrogenic fluid overload, or preeclampsia, approximately a fourth each (Sciscione, 2003). In another study, more than half of cases were associated with preeclampsia, and there was equal distribution of the other three causes (Hough, 2007). Although used less commonly today, tocolytic therapy with β-mimetic drugs at one time was the cause of up to 40 percent of pulmonary edema cases (DiFederico, 1998; Jenkins, 2003).

■ Noncardiogenic Increased Permeability Edema

Endothelial activation is the common denominator that is associated with preeclampsia, sepsis syndrome, and acute hemorrhage—or frequently combinations thereof—and they are the most common predisposing factors to pulmonary edema (Table 47-4). As discussed, these clinical scenarios are often

TABLE 47-4. Some Causes and Associated Factors for Pulmonary Edema in Pregnancy

Noncardiogenic permeability edema —endothelial activation with capillary-alveolar leakage: <ul style="list-style-type: none">Preeclampsia syndromeAcute hemorrhageSepsis syndromeTocolytic therapy—β-mimetics, MgSO4Aspiration pneumonitisVigorous intravenous fluid therapy
Cardiogenic pulmonary edema —myocardial failure with hydrostatic edema from excessive pulmonary capillary pressure: <ul style="list-style-type: none">Hypertensive cardiomyopathyObesity—adipositas cordisLeft-sided valvular diseaseVigorous intravenous fluid therapy

associated with corticosteroids given to hasten fetal lung maturation along with vigorous fluid replacement and tocolytic therapy (Thornton, 2011). Although parenteral β -agonists are undisputedly linked to pulmonary edema, indictment of magnesium sulfate is less convincing. In one study in which pulmonary edema developed in 8 percent of nearly 800 women given magnesium sulfate for preterm labor, half of these were also given terbutaline (Samol, 2005). In our extensive experiences at Parkland Hospital with the use of magnesium sulfate for neuroprophylaxis for severe preeclampsia, we remain dubious that magnesium per se causes pulmonary edema. Similar conclusions were reached following a review by Martin and Foley (2006).

■ Cardiogenic Hydrostatic Edema

Ventricular failure causing pulmonary edema in pregnancy is usually associated with some form of gestational hypertension. Although it can be due to congenital or acquired anatomical defects, diastolic dysfunction is frequently from chronic hypertension, obesity, or both (Jessup, 2003; Kenchaiah, 2002). In these women, acute systolic hypertension exacerbates diastolic dysfunction and causes pulmonary edema (Dennis, 2012; Gandhi, 2001). Of note, concentric and eccentric hypertrophy is two- to threefold more common in black women compared with white women (Drazner, 2005).

Despite an underlying cardiomyopathy, heart failure is commonly precipitated by preeclampsia, hypertension, hemorrhage and anemia, and puerperal sepsis (Cunningham, 1986; Sibai, 1987). In many of these, when echocardiography is done later, systolic function is normal as measured by ejection fraction, but evidence for diastolic dysfunction can often be found (Aurigemma, 2004). The use of *brain natriuretic peptide* (BNP) has not been evaluated extensively in pregnancy (Chap. 4, p. 61 and Appendix, p. 1291). This neurohormone is secreted from ventricle myocytes and fibroblasts with distention seen in heart failure. In nonpregnant patients, values < 100 pg/mL have an excellent negative-predictive value, and levels > 500 pg/mL have an excellent positive-predictive value. It is problematic that levels frequently are 100 to 500 pg/mL, and thus nondiagnostic (Ware, 2005). Values for N-terminal BNP and atrial natriuretic peptide (ANP) are both elevated with preeclampsia (Tihonen, 2007).

■ Management

Acute pulmonary edema requires emergency management. Furosemide is given in 20- to 40-mg intravenous doses along with therapy to control dangerous hypertension. Further treatment depends on whether a woman is ante- or postpartum and whether the fetus is alive or not. A live fetus prohibits the use of cardioactive drugs that might lower peripheral resistance and in turn severely diminish uteroplacental circulation. The cause of cardiogenic failure is determined by echocardiography, which will help direct further therapy. Acute pulmonary edema is not, per se, an indication for emergency cesarean delivery. Indeed, in most cases, these women are better served by vaginal delivery.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury that causes a form of severe permeability pulmonary edema and respiratory failure is termed acute respiratory distress syndrome (ARDS). This is a pathophysiological continuum from mild pulmonary insufficiency to dependence on high inspired oxygen concentrations and mechanical ventilation. Because there are no uniform criteria for its diagnosis, the incidence is variably reported. One review computed it to be 1 in 3000 to 6000 deliveries, and this comports with our experiences at Parkland Hospital (Catanzarite, 2001). In its most extreme form requiring ventilatory support, there is an associated mortality rate of 45 percent. This rate can be as high as 90 percent if caused or complicated by sepsis (Phua, 2009). Although they are younger and usually healthier than the overall population, pregnant women still have mortality rates of 25 to 40 percent (Catanzarite, 2001; Cole, 2005). Finally, if ARDS develops antepartum, there is a correspondingly high perinatal mortality rate.

■ Definitions

Physiological criteria required for diagnosis of acute respiratory distress syndrome are study dependent. In general, less precise terms are used for clinical care. Most investigators have defined ARDS as radiographically documented pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen ($\text{PaO}_2/\text{FiO}_2$) < 200 , and no evidence of heart failure (Mallampalli, 2010). Recently, the international consensus-revised *Berlin Definition* was reported by the ARDS Definition Task Force (2012). It describes categories of mild ($200 \text{ mm Hg} < \text{PaO}_2/\text{FiO}_2 \leq 300 \text{ mm Hg}$); moderate ($100 \text{ mm Hg} < \text{PaO}_2/\text{FiO}_2 \leq 200 \text{ mm Hg}$); and severe ($\text{PaO}_2/\text{FiO}_2 \leq 100 \text{ mm Hg}$). To date, for most interventional studies, however, a working diagnosis of *acute lung injury* is made when the $\text{PaO}_2/\text{FiO}_2$ ratio is < 300 along with dyspnea, tachypnea, oxygen desaturation, and radiographic pulmonary infiltrates (Wheeler, 2007).

■ Etiopathogenesis

ARDS is a pathophysiological description that begins with acute lung injury from various causes. Several disorders have been implicated as causes of acute pulmonary injury and permeability edema during pregnancy (Table 47-5). Although many are coincidental, some are more common in pregnant women. For example, in nonpregnant patients, sepsis and diffuse infectious pneumonia are the two most common single-agent causes and together account for 60 percent of cases. In pregnancy, however, pyelonephritis, chorioamnionitis, and puerperal pelvic infection are the most frequent causes of sepsis. As discussed previously, severe preeclampsia and obstetrical hemorrhage are also commonly associated with permeability edema. Importantly, more than half of pregnant women with acute respiratory distress syndrome have some combination of sepsis, shock, trauma, and fluid overload. With acute hemorrhage, the contribution of *transfusion-related acute lung injury* (TRALI) is unclear in obstetrical patients (Kopko, 2002). This entity is discussed further in Chapter 41 (p. 818).

TABLE 47-5. Some Causes of Acute Lung Injury and Respiratory Failure in Pregnant Women

Pneumonia—bacterial, viral, aspiration
Sepsis syndrome—chorioamnionitis, pyelonephritis, puerperal infection, septic abortion
Hemorrhage—shock, massive transfusion, transfusion-related acute lung injury (TRALI)
Preeclampsia syndrome
Tocolytic therapy
Embolism—amniotic fluid, trophoblastic disease, air, fat
Connective-tissue disease
Substance abuse
Irritant inhalation and burns
Pancreatitis
Drug overdose
Fetal surgery
Trauma
Sickle-cell disease
Miliary tuberculosis

From Catanzarite, 2001; Cole, 2005; Golombeck, 2006; Jenkins, 2003; Lapinsky, 2005; Martin, 2006; Oram, 2007; Sheffield, 2005; Sibai, 2014; Zeeman, 2003, 2006.

Endothelial injury in the lung capillaries releases cytokines that recruit neutrophils to the site of inflammation. Here, they elaborate more cytokines to worsen tissue injury. There are three stages of ARDS development. First, the *exudative phase* follows widespread injury to microvascular endothelium, including the pulmonary vasculature, and there is also alveolar epithelial injury. These result in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting with resultant arterial hypoxemia. Next, the *fibroproliferative phase* usually begins 3 to 4 days later and lasts up to day 21. Last, the *fibrotic phase* results from healing, and despite this, the long-term prognosis for pulmonary function is surprisingly good (Herridge, 2003; Levy, 2012).

Clinical Course

With pulmonary injury, the clinical condition depends largely on the insult magnitude, the ability to compensate for it, and the disease stage. For example, soon after the initial injury, there commonly are no physical findings except perhaps hyperventilation. And at first, arterial oxygenation usually is adequate. Pregnancy-induced mild metabolic alkalosis may be accentuated by hyperventilation. With worsening, clinical and radiological evidence for pulmonary edema, decreased lung compliance, and increased intrapulmonary blood shunting become apparent. Progressive alveolar and interstitial edema develop with extravasation of inflammatory cells and erythrocytes.

Ideally, pulmonary injury is identified at this early stage, and specific therapy is directed at the insult if possible. Further progression to acute respiratory failure is characterized by marked dyspnea, tachypnea, and hypoxemia. Additional lung volume loss results in worsening of pulmonary compliance

**FIGURE 47-1** Anteroposterior chest radiograph of a second-trimester pregnant woman with marked bilateral parenchymal and pleural opacification secondary to acute respiratory distress syndrome (ARDS).

and increased shunting. There are now diffuse abnormalities by auscultation, and a chest radiograph characteristically demonstrates bilateral lung involvement ([Fig. 47-1](#)). At this phase, the injury ordinarily would be lethal in the absence of high inspired-oxygen concentrations and positive airway pressure by mask or by intubation. When shunting exceeds 30 percent, severe refractory hypoxemia develops along with metabolic and respiratory acidosis that can result in myocardial irritability, dysfunction, and cardiac arrest.

Management

In cases of severe acute lung injury, attempts are made to provide adequate oxygenation of peripheral tissues while ensuring that therapeutic maneuvers do not further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding increase in tissue uptake, but this is difficult to measure (Evans, 1999). Support of systemic perfusion with intravenous crystalloid and blood is imperative. As discussed on page 941, the trial conducted by the National Heart, Lung, and Blood Institute (2006b) showed that pulmonary artery catheterization did not improve outcomes. Because sepsis is commonplace in lung injury, vigorous antimicrobial therapy is given for infection, along with debridement of necrotic tissues. Oxygen delivery can be greatly improved by correction of anemia—each gram of hemoglobin carries 1.25 mL of oxygen when 90-percent saturated. By comparison, increasing the arterial P_{O_2} from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are to attain a P_{aO_2} of 60 mm Hg or 90-percent saturation at an inspired oxygen content of < 50 percent and with positive end-expiratory pressures < 15 mm Hg. With regard to the pregnancy, it remains controversial whether delivery of the fetus improves maternal oxygenation (Cole, 2005; Mallampalli, 2010).

Mechanical Ventilation

Positive pressure ventilation by face mask may be effective in some women in early stages of pulmonary insufficiency (Roy, 2007). In an attempt to maximize the fetal environment, early intubation is preferred in the pregnant woman if respiratory failure is more likely than not, and especially if it appears imminent. There are many successful formulas for mechanical ventilation management (Levy, 2012). High-frequency oscillation ventilation (HFOV) has not been shown effective in ARDS (Ferguson, 2013; Slutsky, 2013; Young, 2013). Adjustments are made to obtain a $\text{PaO}_2 > 60$ mm Hg or a hemoglobin saturation of ≥ 90 percent and a PaCO_2 of 35 to 45 mm Hg. Lower levels for PaO_2 should be avoided, because placental perfusion may be impaired (Levinson, 1974).

For women who require ventilation for any length of time, the maternal mortality rate is approximately 20 percent. In a study of 51 such women, of whom almost half had severe preeclampsia, most required intubation postpartum. Eleven were delivered while being ventilated, and another six were discharged undelivered (Jenkins, 2003). There were two maternal deaths, including a woman who died as a complication of tocolytic treatment. In two other reports, maternal mortality rates were 17 and 25 percent (Chen, 2003; Schneider, 2003). None of these investigators concluded that delivery improved maternal outcome.

Positive End-Expiratory Pressure. With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels of 5 to 15 mm Hg, positive pressure can typically be used safely. At higher levels, impaired right-sided venous return can result in decreased cardiac output, decreased uteroplacental perfusion, alveolar overdistention, falling compliance, and barotrauma (Slutsky, 2013).

Extracorporeal Membrane Oxygenation

As discussed in Chapter 33 (p. 638), extracorporeal membrane oxygenation (ECMO) has been successfully used for neonatal meconium aspiration syndrome. Preliminary observation suggests that it may be useful in adults (Brodie, 2011; Levy, 2012; Peek, 2009). ECMO has been used in pregnant women. In one study, 12 women with influenza-induced lung failure were treated with ECMO, and of four maternal deaths, three were due to anticoagulation-related hemorrhage (Nair, 2011). In other reports, ECMO was used to allow time for lung healing in five pregnant women, and the duration of support in the four survivors was 2 to 28 days (Cunningham, 2006). Technical aspects of ECMO were recently reviewed by Brodie and Bacchetta (2011).

Fetal Oxygenation

The propensity of the hemoglobin molecule to release oxygen is described by the *oxyhemoglobin dissociation curve* (Fig. 47-2). For clinical purposes, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen disso-

FIGURE 47-2 Oxyhemoglobin dissociation curve. With higher oxygen tension (PaO_2) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension in the tissue capillaries. Note that at any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

ciation portion representing the tissue-capillary environment. Shifts of the curve have their greatest impact at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence increased tissue-capillary oxygen interchange. Rightward shifts are produced by hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels. During pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate is increased by approximately 30 percent. This favors oxygen delivery to both the fetus and maternal peripheral tissues (Rorth, 1971).

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. As seen in Figure 47-2, its curve is positioned to the left of the adult curve. To achieve 50-percent hemoglobin saturation in the mother, the PaO_2 must be 27 mm Hg compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease and very low PaO_2 levels, oxygen displacement to fetal tissues is favored. Another example of this comes from pregnant women who live at high altitudes, where despite a maternal PaO_2 of only 60 mm Hg, the fetal PaO_2 is equivalent to that of fetuses at sea level (Subrevilla, 1971).

Intravenous Fluids

Although mortality outcomes are similar, conservative versus liberal fluid management is associated with fewer days of mechanical ventilation (Wiedemann, 2006). There are some pregnancy-induced physiological changes that predispose to a greater risk of permeability edema from vigorous fluid therapy. Colloid oncotic pressure (COP) is determined by serum albumin concentration—1 g/dL exerts approximately 6 mm Hg

pressure. As discussed in Chapter 4 (p. 67), serum albumin concentrations normally decrease in pregnancy. This results in a decline in oncotic pressure from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term and to 17 mm Hg in the puerperium (Benedetti, 1979; Dennis, 2012). With preeclampsia, endothelial activation with leakage causes extravascular albumin loss and decreased serum albumin levels. As a result in these cases, oncotic pressure averages only 16 mm Hg antepartum and 14 mm Hg postpartum (Zinaman, 1985). These changes have a significant clinical impact on the *colloid oncotic pressure/wedge pressure gradient*. Normally, this gradient exceeds 8 mm Hg, however, when it is 4 mm Hg or less, there is an increased risk for pulmonary edema. These associations were recently reviewed by Dennis and Solnordal (2012).

Other Therapy

There were no benefits from *artificial or replacement surfactant therapy* in 725 nonpregnant patients with sepsis-induced lung failure (Anzueto, 1996). Although inhalation of *nitric oxide* was found to cause early improvement, mortality rates were unchanged in two studies (Taylor, 2004; Wheeler, 2007). In a trial conducted by the National Heart, Lung, and Blood Institute (2006a), *prolonged methylprednisolone* therapy did not reduce mortality rates.

Long-Term Outcomes

There are no long-term follow-up studies of pregnant women who recover from respiratory distress syndrome. In nonpregnant subjects, there are significant risks for impaired global cognitive function at 3 and 12 months (Pandharipande, 2013). Data from nonpregnant patients indicate a 1- to 2-year hiatus before basic normal activity is restored in all. In a 5-year

follow-up study, Herridge and associates (2011) reported normal lung function but significant exercise limitation, physical and psychological sequelae, decreased physical quality of life, and increased costs and use of health-care services.

SEPSIS SYNDROME

Sepsis is derived from the ancient Greek *sepein*, “to rot.” The sepsis syndrome is induced by a systemic inflammatory response to bacteria or viruses or their by-products such as endotoxins or exotoxins. The severity of the syndrome is a continuum or spectrum (Fig. 47-3). Infections that most commonly cause the sepsis syndrome in obstetrics are pyelonephritis (Chap. 53, p. 1054), chorioamnionitis and puerperal sepsis (Chap. 37, p. 683), septic abortion (Chap. 18, p. 356), and necrotizing fasciitis (Chap. 37, p. 686). The mortality rate in nonpregnant patients is 20 to 35 percent with severe sepsis and 40 to 60 percent with septic shock (Angus, 2013; Munford, 2012). Mabie and coworkers (1997) reported a 28-percent mortality rate in 18 pregnant women with sepsis and shock. That said, the maternal mortality risk from sepsis is significantly underestimated (Acosta, 2013).

Etiopathogenesis

Most of what is known concerning sepsis pathogenesis comes from study of lipopolysaccharide—LPS or endotoxin (Munford, 2012). The lipid A moiety is bound by mononuclear blood cells, becomes internalized, and stimulates release of mediators and a series of complex downstream perturbations. Clinical aspects of the sepsis syndrome are manifest when cytokines are released that have endocrine, paracrine, and autocrine effects (Angus, 2013).

FIGURE 47-3 The sepsis syndrome begins with a systemic inflammatory response syndrome (SIRS) in response to infection that may progress to septic shock.

Although the sepsis syndrome in obstetrics may be caused by several pathogens, most cases represent a small group. For example, pyelonephritis complicating pregnancy caused by *Escherichia coli* and *Klebsiella* species commonly is associated with bacteremia and sepsis syndrome (Cunningham, 1987; Mabie, 1997). And although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis syndrome are frequently endotoxin-producing Enterobacteriaceae, most commonly *E. coli*. Other pelvic pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. Some strains of group A β -hemolytic streptococci and *Staphylococcus aureus*—including community-acquired methicillin-resistant strains (CA-MRSA)—produce a superantigen that activates T cells to rapidly cause all features of the sepsis syndrome—*toxic shock syndrome* (Moellering, 2011; Soper, 2011). This is discussed further in Chapter 37 (p. 690).

There are also potent bacterial *exotoxins* that can cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens*, toxic-shock-syndrome toxin-1 (TSST-1) from *S. aureus*, and toxic shock-like exotoxin from group A β -hemolytic streptococci (Daif, 2009; Soper, 2011). These last exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse and maternal death (Nathan, 1993; Sugiyama, 2010). In a review discussed subsequently, the maternal mortality rate from these infections was 58 percent (Yamada, 2010).

Thus, the sepsis syndrome begins with an inflammatory response that is directed against microbial endotoxins and exotoxins (Angus, 2013). CD4 T cells and leukocytes are stimulated to produce proinflammatory compounds that include tumor necrosis factor- α (TNF- α), several interleukins, other cytokines, proteases, oxidants, and bradykinin that result in a “cytokine storm” (Que, 2005; Russell, 2006). Many other cellular reactions then follow that include stimulation of pro- and antiinflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Filbin, 2009; Moellering, 2011). It is also likely that IL-6 mediates myocardial suppression (Pathan, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation cause capillary plugging. Worsening endothelial injury causes profound permeability capillary leakage and interstitial fluid accumulation (Fig. 47-4). Depending on the degree of injury and inflammatory response, there is a pathophysiological and clinical continuum as depicted in Figure 47-3. The clinical syndrome begins with subtle signs of sepsis from infection and terminates with *septic shock*, which is defined by hypotension unresponsive to intravenous hydration. In its early stages, clinical shock results primarily from decreased systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion results in lactic acidosis, decreased tissue oxygen extraction, and end-organ dysfunction that includes acute lung and kidney injury.

Clinical Manifestations

The sepsis syndrome has myriad clinical manifestations that, at least in part, are dependent on the specific invading

FIGURE 47-4 Endothelial permeability. The normal interendothelial interface is shown in the left inset. Cytokines and other inflammatory mediators disassemble the cellular junctions, resulting in microvascular leaks (right). (Modified from Lee, 2010.)

microorganism and its particular endo- or exotoxins. Some of the general effects of LPS are as follows:

1. Central nervous system: confusion, somnolence, coma, combativeness, fever, or hypoxemia
2. Cardiovascular: tachycardia, hypotension
3. Pulmonary: tachypnea, arteriovenous shunting with dysoxia and hypoxemia, exudative infiltrates from endothelial-alveolar damage, pulmonary hypertension
4. Gastrointestinal: gastroenteritis—nausea, vomiting, and diarrhea; hepatocellular necrosis—jaundice, hyperglycemia
5. Renal: prerenal oliguria, acute kidney injury
6. Hematological: leukocytosis or leukopenia, thrombocytopenia, activation of coagulation with disseminated intravascular coagulation
7. Cutaneous: acrocyanosis, erythroderma, bullae, digital gangrene.

Thus, although capillary leakage initially causes hypovolemia, if intravenous crystalloid is given at this point, then sepsis hemodynamically can be described as a high cardiac output, low systemic vascular resistance condition (Fig. 47-5). Concomitantly, pulmonary hypertension develops, and despite the high cardiac output, severe sepsis likely also causes myocardial depression (Ognibene, 1988). This is often referred to as the *warm phase* of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, but they can be accompanied by some of the other clinical or laboratory aberrations listed above.

The response to initial intravenous hydration may be prognostic. Most pregnant women who have early sepsis show a salutary response with crystalloid and antimicrobial therapy, and if indicated, debridement of infected tissue. Conversely, if hypotension is not corrected following vigorous fluid infusion, then the prognosis is more guarded. At this juncture, if there also is no response to β -adrenergic inotropic agents, this indicates severe and unresponsive extracellular fluid

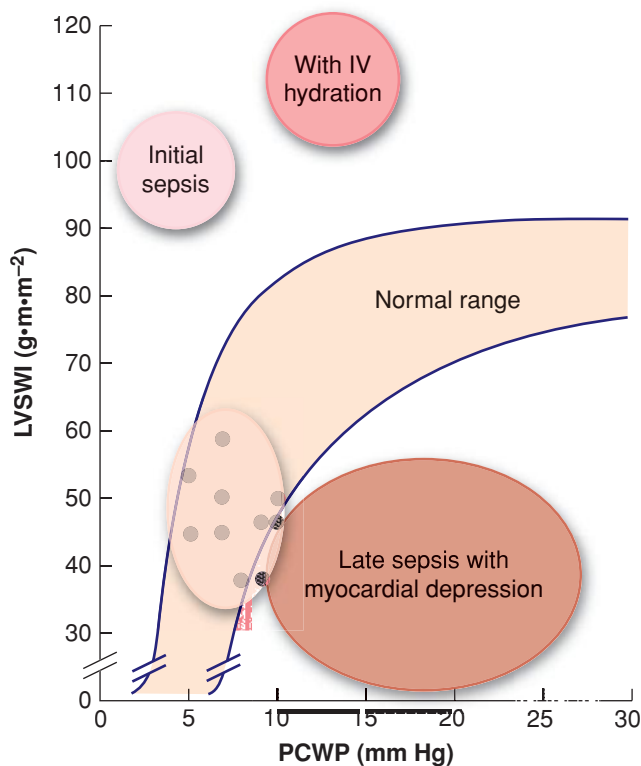

FIGURE 47-5 Hemodynamic effects of sepsis syndrome. Values for normal women at term are shown by dots. With early sepsis, there is high cardiac output and low vascular resistance. With fluid resuscitation, cardiac output increases even more, but so does capillary hydraulic pressure. With continued sepsis, there may be myocardial depression to further increase capillary hydraulic pressure. Decreased plasma oncotic pressure (serum albumin [g] \times 6 mm Hg) contributes to interstitial lung fluid and endo/epithelial leak causes alveolar flooding. LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.

extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock that is rarely survived. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension has been corrected (Angus, 2013). The average risk of death increases by 15 to 20 percent with failure of each organ system. With three systems, mortality rates are 70 percent (Martin, 2003; Wheeler, 1999).

Management

In 2004 an internationally directed consensus effort was launched as the *Surviving Sepsis Campaign* (Dellinger, 2008). The cornerstone of management is *early goal-directed management*, and it stresses prompt recognition of serious bacterial infection and close monitoring of vital signs and urine flow. Institution of this protocol has improved survival rates (Angus, 2013; Barochia, 2010).

An algorithm for management of sepsis syndrome is shown in Figure 47-6. The three basic steps are performed as simultaneously as possible and include evaluation of the sepsis source and its sequelae, cardiopulmonary function assessment, and immediate management. The most important step in sepsis

management is rapid infusion of 2 L and sometimes as many as 4 to 6 L of crystalloid fluids to restore renal perfusion in severely affected women (Vincent, 2013). Simultaneously, appropriately chosen broad-spectrum antimicrobials are begun. There is hemoconcentration because of the capillary leak. Thus, if anemia coexists with severe sepsis, then blood is given along with crystalloid to maintain the hematocrit at approximately 30 percent (Munford, 2012; Rivers, 2001). The use of colloid solution such as hetastarch is controversial, and we as well as others do not recommend its use (Angus, 2013; Ware, 2000). Indeed, a recent Scandinavian randomized trial comparing hydroxyethyl starch and Ringer acetate reported a higher mortality rate with the starch solution (Perner, 2012). Another recent study found equivalent results with 6-percent hydroxyethyl starch compared with normal saline (Myburgh, 2012). In vasopressor-dependent shock, some recommend albumin infusions (Angus, 2013; Vincent, 2013).

Aggressive volume replacement ideally is promptly followed by urinary output of at least 30 and preferably 50 mL/hr, as well as other indicators of improved perfusion. If not, then consideration is given for vasoactive drug therapy. Mortality rates are high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures, as with the acute respiratory distress syndrome discussed on page 943 and depicted in Figure 47-1.

Broad-spectrum antimicrobials are chosen empirically based on the source of infection. They are given promptly in maximal doses after appropriate cultures are taken of blood, urine, or exudates not contaminated by normal flora. In severe sepsis, appropriate empirical coverage results in better survival rates (Barochia, 2010; MacArthur, 2004). Acute pyelonephritis is usually caused by Enterobacteriaceae as discussed in Chapter 53 (p. 1054). For pelvic infections, empirical coverage with regimens such as ampicillin plus gentamicin plus clindamycin generally suffices (Chap. 37, p. 685). Associated incisional and other soft-tissue infections are increasingly likely to be caused by methicillin-resistant *S aureus*, thus vancomycin therapy is added (Klevens, 2007; Rotas, 2007). With a septic abortion, a Gram-stained smear may be helpful in identifying *Clostridium perfringens* or group A streptococcal organisms. This is also true for deep fascial infections.

Surgical Treatment

Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial (Angus, 2013; Mabie, 1997). In obstetrics, the major causes of sepsis are infected abortion, pyelonephritis, and puerperal pelvic infections that include infection of perineal lacerations or of hysterotomy or laparotomy incisions. With an infected abortion, uterine contents must be removed promptly by curettage as described in Chapter 18 (p. 356). Hysterectomy is seldom indicated unless gangrene has resulted.

For women with pyelonephritis, continuing sepsis should prompt a search for obstruction caused by calculi or by a perinephric or intrarenal phlegmon or abscess. Renal sonography or “one-shot” pyelography may be used to diagnose obstruction

FIGURE 47-6 Algorithm for evaluation and management of sepsis syndrome. Rapid and aggressive implementation is paramount for success. The three steps—Evaluate, Assess, and Manage—are carried out as simultaneously as possible.

and calculi. Computed tomography (CT) may be helpful to identify a phlegmon or abscess. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (Chap. 53, p. 1057).

Most cases of puerperal pelvic sepsis are clinically manifested in the first several days postpartum, and intravenous antimicrobial therapy without tissue debridement is generally curative. There are several exceptions. First is massive uterine myonecrosis caused by group A β -hemolytic streptococcal or clostridial infections (Soper, 2011; Sugiyama, 2010; Yamada, 2010). Those with early-onset disease have presenting findings listed in Table 47-6. The mortality rate in these women with gangrene as shown in Figure 47-7 is high, and prompt hysterectomy may be lifesaving (Mabie, 1997; Nathan, 1993). Group A β -hemolytic

streptococci and clostridial colonization or infection also cause toxic-shock syndrome without obvious gangrene as reviewed by Mason and Aronoff (2012). These are due to either streptococcal toxic-shock syndrome-like toxin or clostridial exotoxin that evolved from *S aureus* (Chap. 37, p. 690). In many of these cases, there is bacteremia and widespread tissue invasion, but an intact uterus and abdominal incisions. If uterine necrosis can be excluded—usually by CT scanning—then in our experiences, as well as in others, hysterectomy may not be necessary (Soper, 2011). Still, these infections are highly lethal (Yamada, 2010).

A second exception is necrotizing fasciitis of the episiotomy site or abdominal surgical incision. As described by Gallup and coworkers (2002), these infections are a surgical emergency and are aggressively managed as discussed in Chapter 37 (p. 686).

TABLE 47-6. Clinical Findings in 55 Women with Group A β -Hemolytic Infection Manifest within 12 Hours of Delivery

Finding	Frequency (%)
Multiparous	83
Third-trimester	90
Flu-like symptoms	
High fever	94
Upper respiratory	40
Gastrointestinal	49
Uterine hypertonus	73
Early-onset shock	91
Mortality	
Maternal	58
Perinatal	66

Data from Yamada, 2010.

Third, persistent or aggressive uterine infection with necrosis, uterine incision dehiscence, and severe peritonitis may lead to sepsis (Chap. 37, p. 688). Thus, women following cesarean delivery who are suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation. These infections tend to be less aggressive than necrotizing group A streptococcal infections and develop later postpartum. CT imaging of the abdomen and pelvis can frequently determine if either of these has eventuated. If either is suspected, then prompt surgical exploration is indicated. With incisional necrosis, hysterectomy is usually necessary (Fig. 37-4, p. 688). Last, peritonitis and sepsis much less commonly may result from a ruptured parametrial, intraabdominal, or ovarian abscess (Chap. 37, p. 687).

Adjunctive Therapy

Vasoactive Drugs and Corticosteroids. As shown in Figure 47-6, a septic woman is supported with continuing

FIGURE 47-7 A fatal case of group A β -hemolytic *Streptococcus pyogenes* puerperal infection following an uncomplicated vaginal delivery at term. The infection caused uterine gangrene and overwhelming sepsis syndrome. Arrows point to overtly “ballooned-out” black gangrenous areas of the postpartum uterus at the time of laparotomy for hysterectomy.

crystalloid infusion, blood transfusions, and ventilation. In some cases, other measures may be necessary. Of options, vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. First-line vasopressors are norepinephrine, epinephrine, dopamine, dobutamine, or phenylephrine (Vincent, 2013). Low-dose vasopressin combined with norepinephrine infusion did not improve survival (Russell, 2008).

The use of corticosteroids remains controversial. Serum cortisol levels are typically elevated in sepsis, and higher levels are associated with increased mortality rates (Sam, 2004). Some but not all studies show a salutary effect of corticosteroid administration. It is thought that *critical illness-related corticosteroid insufficiency—CIRCI*—may play a role in recalcitrant hypotension. Thus, corticosteroids may be considered for use in vasopressor-dependent patients (Angus, 2013; Dellinger, 2008).

Coagulopathy. Endotoxin stimulates endothelial cells to upregulate tissue factor and thus procoagulant production (Chap. 41, p. 808). At the same time, it decreases the anticoagulant action of activated protein C. Several agents developed to block coagulation, however, did not improve outcomes—some include *antithrombin III*, *platelet-activating factor antagonist*, and *tissue factor pathway inhibitor* (Abraham, 2003; Suffredini, 2011; Warren, 2001). A 10-year dalliance with recombinant activated protein C—*drotrecogin alfa*—followed after results of an early trial were promising. However, subsequent randomized trials have shown no survival benefits (Ranieri, 2012; Wenzel, 2012). Experience with its use in pregnancy had been limited to case reports (Eppert, 2011; Gupta, 2011; Medve, 2005).

Other Therapies. There are several other therapies that have proven ineffective. Some of these include *antiendotoxin antibody* and *E5 murine monoclonal IgM antiendotoxin antibody*; *anticytokine antibodies* to *IL-1*, *TNF- α* , and *bradykinin*; and a *nitric oxide synthase inhibitor* (Munford, 2012; Russell, 2006).

TRAUMA

Traumatic injuries such as homicide and similar violent events are a leading cause of death in young women. Depending on definitions used, up to 20 percent of pregnant women suffer physical trauma (American College of Obstetricians and Gynecologists, 2010; Romero, 2012). Injury-related deaths are the most commonly identified nonobstetrical cause of maternal mortality (Brown, 2009; Horon, 2001). In a California study of 4.8 million pregnancies, almost 1 in 350 women were hospitalized for injuries from assaults (El Kady, 2005). In an audit from Parkland Hospital, motor vehicle accidents and falls accounted for 85 percent of injuries sustained by 1682 pregnant women (Hawkins, 2007). Homicides and suicides are also a major cause of pregnancy-associated deaths (Lin, 2011; Shadigian, 2005). From the National Violent Death Reporting System, Palladino and colleagues (2011) found that there were 2.0 pregnancy-associated suicides per 100,000 live births. The rate was 2.9 per 100,000 for pregnancy-associated homicides. And interrelated, intimate partner violence may be linked to these suicides (Martin, 2007).

Blunt Trauma

Physical Abuse—Intimate Partner Violence

According to the United States Department of Justice (2013), women aged 16 to 24 years have the highest per capita rates of intimate partner violence—19.4 per 1000. As many as 10 million women each year are physically assaulted, sexually assaulted, or stalked by an intimate partner (Centers for Disease Control and Prevention, 2013a). One goal in violence prevention for Healthy People 2010 was the reduction of physical abuse directed at women by male partners. The Pregnancy Risk Assessment Monitoring Systems—PRAMS—report showed some improvement in these areas (Suellentrop, 2006).

Even more appalling is that physical violence directed at women continues during pregnancy. Most data have been accrued by public institutions, and abuse rates range from 1 to 20 percent during pregnancy (American College of Obstetricians and Gynecologists, 2011b). In Phoenix, more than 13 percent of women who enrolled for prenatal services had a history of physical or sexual abuse (Coonrod, 2007). Abuse is linked to poverty, poor education, and use of tobacco, alcohol, and illicit drugs (Centers for Disease Control and Prevention, 2008). Unfortunately, abused women tend to remain with their abusers, and the major risk factor for intimate partner homicide is prior domestic violence (Campbell, 2007). Finally, women seeking pregnancy termination have a higher incidence of intimate partner violence (Bourassa, 2007).

The woman who is physically abused tends to present late, if at all, for prenatal care. In the study cited above, pregnant women hospitalized in California as a result of assault had significantly increased perinatal morbidity rates (El Kady, 2005). Immediate sequelae included uterine rupture, preterm delivery, and maternal and perinatal death. Subsequent outcomes included increased rates of placental abruption, preterm and low-birthweight infants, and other adverse outcomes. Silverman and associates (2006) reported similar results from PRAMS, which included more than 118,000 pregnancies in 26 states. Others have cited increased preterm birth and depression (Rodriguez, 2008).

Preventatively, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend universal screening for intimate partner violence at the initial prenatal visit, during each trimester, and again at the postpartum visit (Chap. 9, p. 174). Others recommend a case-finding approach based on clinical suspicion (Robertson-Blackmore, 2013; Wathen, 2003).

Sexual Assault

According to the Centers for Disease Control and Prevention (2012), 20 percent of adult women will be sexually assaulted sometime during their lives. More than 90 percent of the nearly 200,000 rape victims in the United States in 2006 were women; 80 percent were younger than 30 years; and 44 percent were younger than 18. Satin and coworkers (1992) reviewed more than 5700 female sexual assault victims in Dallas County and reported that 2 percent were pregnant. Associated physical trauma is common (Sugar, 2004). From a forensic standpoint, evidence collection protocol is not altered (Linden, 2011).

In addition to attention to physical injuries, exposure to sexually transmitted diseases must be considered. The Centers for Disease Control and Prevention (2010) recommends antimicrobial prophylaxis against gonorrhea, chlamydial infection, and trichomoniasis (Table 47-7). If the woman is not pregnant, another very important aspect is emergency contraception, as recommended by the American College of Obstetricians and Gynecologists (2012) and discussed in detail in Chapter 38 (p. 714).

The importance of psychological counseling for the rape victim and her family cannot be overemphasized. There is a 30- to 35-percent lifetime risk each for posttraumatic stress disorder, major depression, and suicide contemplation (Linden, 2011).

Automobile Accidents

At least 3 percent of pregnant women are involved in motor vehicle accidents each year in the United States. Using data from PRAMS, Sirin and colleagues (2007) estimated that 92,500 pregnant women are injured annually. Motor-vehicle crashes are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Brown, 2009; Luley, 2013; Patteson, 2007; Vladutiu, 2013). Mattox and Goetzl (2005) report these accidents to be the leading cause of traumatic fetal deaths as well, and this was also true for Parkland Hospital (Hawkins, 2007). As with all motor vehicle crashes, alcohol use is commonly associated. But sadly, as many as half of accidents occur without seat-belt use, and many of these deaths would likely be preventable by the three-point restraints shown in Figure 47-8 (Klinich, 2008; Luley, 2013; Metz, 2006). Seat belts prevent contact with the steering wheel, and they reduce abdominal impact pressure (Motozawa, 2010).

Original concerns regarding injuries caused by airbag deployment have been somewhat allayed (Matsushita, 2014). One study included 30 such women from 20 to 37 weeks' gestation whose airbag deployed in accidents with a median speed of 35 mph (Metz, 2006). A third were not using seat belts, and there was one fetal death from the single case of placental abruption. Almost 75 percent had contractions, half had abdominal pain, and in 20 percent, there were abnormal fetal heart rate tracings. In a retrospective cohort study that included 2207 pregnant women in crashes with airbag deployment, perinatal outcomes were not clinically different from 1141 controls without airbags (Schiff, 2010). Importantly, 96 percent of both groups used seat belts.

Other Blunt Trauma

Some other common causes of blunt trauma are falls and aggravated assaults. In the California review reported by El Kady and associates (2005), intentionally inflicted injuries were present in approximately a third of pregnant women who were hospitalized for trauma. Less common are blast or crush injury (Sela, 2008). With blunt trauma, there can be serious intraabdominal injuries. Even so, bowel injuries are less frequent because of the protective effect of a large uterus. Still, diaphragmatic, splenic, liver, and kidney injuries may also be sustained. Particularly worrisome is the specter of amniotic-fluid embolism, which has been reported with even mild trauma (Ellingsen, 2007;

TABLE 47-7. Guidelines for Prophylaxis against Sexually Transmitted Disease in Victims of Sexual Assault

Prophylaxis Against	Regimen	Alternative
<i>Neisseria gonorrhoeae</i>	Ceftriaxone 125 mg IM single dose <i>plus</i> Azithromycin 1 g orally single dose	Cefixime 400 mg orally single dose <i>plus</i> Azithromycin 1 g orally single dose <i>or</i> Azithromycin 2 g orally single dose
<i>Chlamydia trachomatis</i>	Azithromycin 1 g orally single dose ^a <i>or</i> Amoxicillin 500 mg orally three times daily for 7 days	Erythromycin-base 500 mg orally four times daily for 7 days <i>or</i> Levofloxacin 500 mg orally once daily for 7 days <i>or</i> Ofloxacin 300 mg orally twice daily for 7 days
Bacterial vaginosis	Metronidazole 2 g orally in a single dose <i>or</i> Metronidazole 500 mg orally twice daily for 7 days	Metronidazole gel 0.75%, 5 g intravaginally daily for 5 days <i>or</i> Clindamycin cream 2%, 5 g intravaginally daily for 7 days
<i>Trichomonas vaginalis</i>	Metronidazole 2 g orally single dose <i>or</i> Tinidazole 2 g orally single dose ^b	Metronidazole 500 mg orally twice daily for 7 days
Hepatitis B (HBV)	If not previously vaccinated, give first dose HBV vaccine, repeat at 1–2 and 4–6 months	
Human immunodeficiency virus (HIV)	Consider retroviral prophylaxis if risk for HIV exposure is high	

^aFor nonpregnant women, doxycycline, 100 mg orally twice daily for 7 days, can be given instead.

^bPregnancy category C.

From Centers for Disease Control and Prevention, 2010, 2012.

FIGURE 47-8 Illustration showing correct use of three-point automobile restraint. The upper belt is *above* the uterus, and the lower belt fits snugly across the upper thighs and well *below* the uterus.

Plumakers, 2007). Retroperitoneal hemorrhage is possibly more common than in nonpregnant women (Takehana, 2011).

Orthopedic injuries are also encountered with some regularity (Desai, 2007). From the Parkland Hospital trauma unit, 6 percent of 1682 pregnant women evaluated had orthopedic injuries. This subset was also at increased risk for placental abruption, preterm delivery, and perinatal mortality (Cannada, 2008). In a review of 101 pelvic fractures during pregnancy, there was a 9-percent maternal and 35-percent fetal mortality rate (Leggon, 2002). In another study of pelvic and acetabular fractures during 15 pregnancies, there was one maternal death, and four of 16 fetuses died (Almog, 2007). Finally, head trauma and neurosurgical care raise unique issues (Qaiser, 2007).

Fetal Injury and Death

Perinatal death rates increase with the severity of maternal injuries. Fetal death is more likely with direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia (Ikossi, 2005; Pearlman, 2008). Motor vehicle accidents caused 82 percent of fetal deaths from trauma. Death was caused by placental injury in half, and by uterine rupture in 4 percent (Weiss, 2001). Patteson and coworkers (2007) reported similar findings.

Although uncommon, fetal skull and brain injuries are more likely if the head is engaged and the maternal pelvis is fractured (Palmer, 1994). Conversely, fetal head injuries,

FIGURE 47-9 Acute deceleration injury occurs when the elastic uterus meets the steering wheel. As the uterus stretches, the inelastic placenta shears from the decidua basalis. Intracranial pressures as high as 550 mm Hg are generated.

presumably from a contrecoup effect, may be sustained in unengaged vertex or non-vertex presentations. Fetal skull fractures are rare and best seen using CT imaging (Sadro, 2012). Sequelae include intracranial hemorrhage (Green-Thompson, 2005). A newborn with paraplegia and contractures associated with a motor vehicle accident sustained several months before birth was described by Weyerts and colleagues (1992). Other injuries have included fetal decapitation or incomplete midabdominal fetal transection at midpregnancy (Rowe, 1996; Weir, 2008).

Placental Injuries—Abruption or Tear

Catastrophic events that occur with blunt trauma include placental injuries—abruption or placental tear or “fracture”—and uterine rupture (Fig. 47-9 and 47-10). Placental separation from trauma is likely caused by deformation of the elastic myometrium around the relatively inelastic placenta (Crosby, 1968). This may result from a deceleration injury as the large uterus meets the immovable steering wheel or seat belt. Some degree of abruption complicates 1 to 6 percent of “minor” injuries and up to 50 percent of “major” injuries

(Pearlman, 1990; Schiff, 2002). Abruption was found to be more likely if vehicle speed exceeded 30 mph (Reis, 2000).

Clinical findings with traumatic abruption may be similar to those for spontaneous placental abruption (Chap. 41, p. 796). Kettel and coworkers (1988) emphasized that traumatic abruption may be occult and unaccompanied by uterine pain, tenderness, or bleeding. Stettler and associates (1992) reviewed our experiences with 13 such women at Parkland Hospital. Of these, 11 had uterine tenderness, but only five had vaginal bleeding. Because traumatic abruption is more likely to be concealed and generate higher intrauterine pressures, associated coagulopathy is more likely than with nontraumatic abruption. Partial separation may also generate uterine activity as described more fully on page 955. Other features are evidence of fetal compromise such as fetal tachycardia, late decelerations, and acidosis and fetal death.

If there is considerable abdominal force associated with trauma, then the placenta can be torn, or “fractured” (see Fig. 47-10). If so, then life-threatening fetal hemorrhage may be encountered either into the amniotic sac or by fetomaternal hemorrhage (Pritchard, 1991). The tear is linear or stellate such as shown in Figure 47-11 and is caused by rapid deformation and reformation. Especially if there is ABO compatibility, fetomaternal hemorrhage is quantified using a

FIGURE 47-10 Mechanism of placental tear or “fracture” caused by a deformation-reformation injury. Placental abruption is seen as blood collecting in the retroplacental space. **Inset.** From here, blood can be forced into placental bed venules and enter maternal circulation. Such maternofetal hemorrhage may be identified with Kleihauer-Betke testing.

FIGURE 47-11 A. Partial placental abruption in which the adherent blood clot has been removed. Note the laceration of the placenta (*arrow*), which caused fetal death from massive fetomaternal hemorrhage. **B.** Kleihauer-Betke stain of a peripheral smear of maternal blood. The dark cells that constituted 4.5 percent of red blood cells are fetal in origin, whereas the empty cells are maternal.

Kleihauer-Betke stain of maternal blood (see Fig. 47-11). A small amount of fetal-maternal bleeding has been described in up to a third of trauma cases, and in 90 percent of these, the volume is < 15 mL (Goodwin, 1990; Pearlman, 1990). Nontraumatic placental abruption is much less often associated with significant fetomaternal hemorrhage because there usually is only minimal fetal bleeding into the intervillous space. With traumatic abruption, however, massive fetomaternal hemorrhage may coexist (Stettler, 1992). In one study there was a 20-fold risk of associated uterine contractions and preterm labor if there is evidence for a fetomaternal bleed (Muench, 2004).

Uterine Rupture

Blunt trauma results in uterine rupture in < 1 percent of severe cases (American College of Obstetricians and Gynecologists, 2010). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantial force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby, 1968). Clinical findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are soon inevitable. Pearlman and Cunningham (1996) described uterine fundal “blowout” with fetal decapitation in a 20-week pregnancy following a high-speed collision. Similarly, Weir and colleagues (2008) described supracervical uterine avulsion and fetal transection at 22 weeks. CT scanning may be useful to diagnose uterine rupture with a dead fetus or placental separation (Kopelman, 2013; Manriquez, 2010; Sadro, 2012; Takehana, 2011).

Penetrating Trauma

In a study of 321 pregnant women with abdominal trauma, Petrone (2011) reported a 9-percent incidence of penetrating injuries—77 percent were gunshot wounds and 23 percent were stab wounds. The incidence of maternal visceral injury

with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. Indeed, although the fetus sustains injury in two thirds of cases with penetrating uterine injuries, maternal visceral injuries are seen in only 20 percent. Still, their seriousness is underscored in that maternal-fetal mortality rates are significantly higher than those seen with blunt abdominal injuries in pregnancy. Specifically, maternal mortality was 7 versus 2 percent, and fetal mortality was 73 versus 10 percent, respectively.

Management of Trauma

Maternal and fetal outcomes are directly related to the severity of injury. That said, commonly used methods of severity scoring do not take into account significant morbidity and mortality rates related to placental abruption and thus to pregnancy outcomes. In a study of 582 pregnant women hospitalized for injuries, the injury severity score did not accurately predict adverse pregnancy outcomes (Schiff, 2005). Importantly, relatively minor injuries were associated with preterm labor and placental abruption. Others have reached similar conclusions (Biester, 1997; Ikossi, 2005). In a study of 317 pregnant women at 24 weeks’ gestation or more who had “minor trauma,” 14 percent had clinically significant uterine contractions requiring extended fetal evaluation past 4 hours (Cahill, 2008).

With few exceptions, treatment priorities in injured pregnant women are directed as they would be in nonpregnant patients (Barraco, 2010; Mirza, 2010). Primary goals are evaluation and stabilization of maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American College of Obstetricians and Gynecologists, 2010; Brown, 2009). Basic rules of resuscitation include ventilation, arrest of hemorrhage, and treatment of hypovolemia with crystalloid and blood products. Importantly, the large uterus is positioned off the

great vessels to diminish its affect on vessel compression and decreased cardiac output.

Following emergency resuscitation, evaluation is continued for fractures, internal injuries, bleeding sites, and placental, uterine, and fetal trauma. Radiography is not proscribed, but special attention is given to indications. One report observed that pregnant trauma victims had less radiation exposure than nonpregnant controls (Ylagan, 2008). Brown and colleagues (2005) advocated screening abdominal sonography followed by CT scanning for positive sonographic findings. Procedures used include the FAST scan—focused assessment with sonography for trauma. This is a 5-minute, four- to six-view imaging study that evaluates perihepatic, perisplenic, pelvic, and pericardial views (Rose, 2004). In general, if fluid is seen in any of these views, then the volume is > 500 mL. However, this amount has not been corroborated for pregnancy. In some cases, open peritoneal lavage may be informative (Tsuei, 2006).

Penetrating injuries in most cases must be evaluated using radiography. Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds. Diagnostic laparoscopy has also been used (Chap. 46, p. 928).

Cesarean Delivery

The necessity for cesarean delivery of a live fetus depends on several factors. Laparotomy itself is not an indication for hysterectomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate treatment or evaluation of other intraabdominal injuries (Tsuei, 2006).

Electronic Monitoring

As for many other acute or chronic maternal conditions, fetal well-being may reflect the status of the mother. Thus, fetal monitoring is another “vital sign” that helps to evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may suggest placental abruption. In a study by Pearlman and coworkers (1990), no woman had an abruption if uterine contractions were less often than every 10 minutes within the 4 hours after trauma was sustained. Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption. In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Conversely, no adverse outcomes were reported in women who had normal monitor tracings (Connolly, 1997). Importantly, if tocolytics are used for these contractions, they may obfuscate findings, and we do not recommend them.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stabilized. The ideal duration of posttrauma monitoring is not precisely known. From data cited above, observation for 4 hours is reasonable with a normal tracing and no other sentinel findings such as contractions, uterine tenderness, or bleeding. Certainly, monitoring should be continued as long

as there are uterine contractions, nonreassuring fetal heart patterns, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (American College of Obstetricians and Gynecologists, 2010). In rare cases, placental abruption has developed days after trauma (Higgins, 1984).

Fetal-Maternal Hemorrhage

It is unclear whether routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims might modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death (Pak, 1998). In a retrospective review of 125 pregnant women with blunt injuries, the Kleihauer-Betke test was reported to have a sensitivity of 56 percent, a specificity of 71 percent, and an accuracy of 27 percent (Towery, 1993). These investigators concluded that the test was of little value during acute trauma management. They also concluded that electronic fetal monitoring or sonography or both were more useful in detecting fetal or pregnancy-associated complications than the Kleihauer-Betke test. Others have reached similar conclusions, although a positive test with fetal cells of 0.1 percent was predictive of uterine contractions or preterm labor (Connolly, 1997; Muench, 2003, 2004).

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered. This may be omitted if a test for fetal bleeding is negative. Even with anti-D immunoglobulin, alloimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells (Chap. 15, p. 311).

Another important aspect of care for the pregnant trauma patient is to ensure that her tetanus immunization is current. When indicated, a dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) is preferred for its neonatal pertussis immunity benefits described in Chapter 9 (p. 184) (Centers for Disease Control and Prevention, 2013b). If unavailable, tetanus toxoid (TT) or tetanus and diphtheria toxoids (Td) are suitable alternatives.

THERMAL INJURY

Treatment of burned pregnant women is similar to that for nonpregnant patients (Pacheco, 2005). With treatment, it is generally agreed that pregnancy does not alter maternal outcome from thermal injury compared with that of nonpregnant women of similar age. As perhaps expected, maternal and fetal survival parallels the percentage of burned surface area. Karimi and colleagues (2009) reported higher mortality rates for both with suicidal attempts and with inhalational injuries. The composite mortality for more than 200 women from six studies increased in a linear fashion as the percent body-surface area burned increased (Fig. 47-12). For 20-, 40-, and 60-percent burns, the maternal mortality rates were approximately 4, 30, and 93 percent, respectively. The corresponding fetal mortality rates were 20, 48, and 96 percent, respectively. With severe burns, the woman usually enters labor spontaneously within a few days to a week and often delivers a stillborn. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the intensely catabolic state associated with these burns (Radosevich, 2013).

FIGURE 47-12 Maternal and fetal mortality rates by burn severity in 211 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk, 1977; Maghsoudi, 2006; Rayburn, 1984; Rode, 1990.)

Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even require surgical decompression and split-skin autografts (Matthews, 1982; Widgerow, 1991). In a follow-up study of seven women with severe circumferential truncal burns sustained at a mean age of 7.7 years, all of 14 subsequent pregnancies were delivered at term without major complications (McCauley, 1991). Loss or distortion of nipples may cause problems in breast feeding (Fig. 47-13). Interestingly, normal abdominal tissue expansion due to pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari, 2004).

■ Electrical and Lightning Injuries

Earlier case reports suggested a high fetal mortality rate with electric shock (Fatovich, 1993). In a prospective cohort study,

FIGURE 47-13 This 22-year-old nullipara sustained severe burns at age 12 years, and massive scarring followed. Both breasts were replaced by scar tissue. Following delivery, a few drops of colostrum were expressed from the left nipple, but no breast engorgement was noted. (Photograph contributed by Drs. A. R. Mahale and A. P. Sakhare, Maharashtra, India.)

however, Einarson and coworkers (1997) showed similar perinatal outcomes in 31 injured women compared with those of noninjured controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than 220-volt currents available in Europe. A woman with iliofemoral thrombosis at 29 weeks' gestation that *may* have been related to a mild electrical shock at 22 weeks was described (Sozen, 2004). Thermal burns may be extensive and require expert wound care.

The pathophysiological effects of lightning injuries can be devastating. García Gutiérrez and associates (2005) reviewed 12 case reports of injuries during pregnancy and added their own.

CARDIOPULMONARY RESUSCITATION

Cardiac arrest is rare during pregnancy. General topics regarding planning and equipment have been reviewed by the American College of Obstetricians and Gynecologists (2011a). There are special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy, and these are outlined in the American Heart Association 2010 guidelines (Vanden Hoek, 2010). The committee acknowledges the following as standards for critically ill pregnant women: (1) relieve possible vena caval compression by left lateral uterine displacement, (2) administer 100-percent oxygen, (3) establish intravenous access above the diaphragm, (4) assess for hypotension that warrants therapy, which is defined as systolic blood pressure < 100 mmHg or < 80 percent of baseline, and (5) review possible causes of critical illness and treat conditions as early as possible.

In nonpregnant women, external chest compression results in a cardiac output approximately 30 percent of normal. In late pregnancy, this may be even less with CPR because of uterine aortocaval compression (Clark, 1997). Thus, it is paramount to accompany other resuscitative efforts with uterine displacement. Displacement can be accomplished by tilting the operating table laterally, by placing a wedge under the right hip—an example is the Cardiff resuscitation wedge, or by pushing the uterus to the left manually (Rees, 1988). If no equipment is available, such as in an out-of-hospital arrest, an individual may kneel on the floor with the maternal back on his or her thighs to form a “human wedge” (Whitty, 2002).

■ Cesarean Delivery

During maternal resuscitation, because of pregnancy-induced hindrances on CPR efforts, emergent *perimortem cesarean delivery* for fetal salvage and improved maternal resuscitation may be considered (Vanden Hoek, 2010). Some have stated that cesarean delivery is indicated with 4 to 5 minutes of beginning CPR if the fetus is viable (Moise, 1997). There is an undeniably inverse correlation between neurologically intact neonatal survival and the cardiac arrest-to-delivery interval in women delivered by perimortem cesarean (Katz, 2012). Specifically, of newborns delivered within 5 minutes of arrest, 98 percent are neurologically intact; within 6 to 15 minutes, 83 percent are intact; within 16 to 25 minutes, 33 percent are intact; and within 26 to 35 minutes, only 25 percent are intact (Clark, 1997). This, coupled with some evidence that delivery *may* also enhance maternal resuscitation, has led the American College of Obstetricians and Gynecologists

(2011a) to recommend *consideration* for cesarean delivery within 4 minutes of cardiac arrest in these cases.

This serious and sometimes contentious issue is far from evidence based. To wit, Katz and associates (2005) reviewed 38 perimortem cesarean deliveries with a “large selection bias.” They concluded that these reports supported—but “fell far from proving”—that perimortem cesarean delivery within 4 minutes of maternal cardiac arrest improves maternal and fetal outcomes. Even so, as emphasized by Clark and coworkers (1997), and in our experiences, these goals rarely can be met in actual practice. For example, most cases of cardiac arrest occur in uncontrolled circumstances, and thus, the time to CPR initiation alone would exceed the first 5 minutes. Thus “crash” cesarean delivery would supersede resuscitative efforts, be necessarily done without appropriate anesthesia or surgical equipment, and more likely than not, would lead to maternal death. Moreover, the distinction between a perimortem versus postmortem cesarean operation is imperative (Katz, 2012). Last, in the balance, any choice *may* favor survival of the mother over the fetus, or vice versa, and thus there are immediate unresolvable ethical concerns. Katz (2012) has recently provided a scholarly review of perimortem cesarean delivery.

■ Maternal Brain Death

Occasionally, a pregnant woman with a supposedly healthy intact fetus will be kept on somatic support to await fetal viability or maturity. This is discussed in Chapter 60 (p. 1199).

■ Envenomation

According to their review, Brown and colleagues (2013) reported that clinically significant envenomations in pregnant women are from snakes, spiders, scorpions, jellyfish, and hymenoptera such as bees, wasps, hornets, and ants. Adverse outcomes are related to maternal effects. They conclude that limited evidence supports the use of a venom-specific approach that includes symptomatic care, antivenom administration when appropriate, anaphylaxis treatment, and fetal assessment.

CHAPTER 48

Obesity

GENERAL CONSIDERATIONS	961
MORBIDITY AND MORTALITY ASSOCIATED WITH OBESITY	963
TREATMENT OF OBESITY	964
PREGNANCY AND OBESITY	964

Excessive weight is a major health problem in the United States and other affluent societies. For a number of years, obesity was said to be *epidemic*—strictly defined, this implies a *temporary* widespread outbreak of greatly increased frequency and severity. Unfortunately, obesity more correctly is *endemic*—a condition that is habitually present. By 1991, approximately a third of adults in the United States were overweight, and thus a stated goal of *Healthy People 2000* was to reduce the prevalence of overweight people to 20 percent or less by the end of the 20th century (Public Health Service, 1990). Not only was this goal not achieved, but by 2000, more than half of the population was overweight. In 2010, a third of all adults were obese (Ogden, 2012).

The adverse health aspects of obesity are staggering. Obesity-related diseases include diabetes, heart disease, hypertension, stroke, and osteoarthritis. Obese women who become pregnant—and their fetuses—are predisposed to various serious pregnancy-related complications. Moreover, long-term maternal and fetal effects include significant and increased morbidity and mortality rates.

GENERAL CONSIDERATIONS

Definitions

A number of systems have been used to define and classify obesity. The *body mass index* (*BMI*), also known as the *Quetelet index*,

is currently most often used. The BMI is calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). Calculated BMI values are available in various chart and graphic forms, such as the one shown in [Figure 48-1](#). The National Institutes of Health (2000) classifies adults according to BMI as follows: *normal* (18.5 to 24.9 kg/m^2); *overweight* (25 to 29.9 kg/m^2); and *obese* ($\geq 30 \text{ kg}/\text{m}^2$). Obesity is further divided into: *class 1* (30 to 34.9 kg/m^2); *class 2* (35 to 39.9 kg/m^2); and *class 3* ($\geq 40 \text{ kg}/\text{m}^2$).

Prevalence

By 2000, 28 percent of men and 33 percent of women were obese (Ogden, 2012). For the period 2009 to 2010, among men and women these percentages were almost identical at approximately 35 percent. Shown in [Figure 48-2](#) are the prevalences of obesity among girls and women. Obesity increases with age as well as with ethnic minority, and almost 60 percent of black women were obese in 2010. This is also true among indigent individuals (Drewnowski, 2004).

Adipose Tissue as an Organ System

Fat tissue is much more complex than its energy storage function. Many cell types in fat tissue communicate with all other tissues via endocrine and paracrine factors—*adipokines*, or *adipocytokines*. Some of those with metabolic functions include adiponectin, leptin, tumor necrosis factor- α (TNF- α), interleukin 6 (IL-6), resistin, visfatin, apelin, vascular endothelium growth factor (VEGF), lipoprotein lipase, and insulin-like growth factor (Briana, 2009; Scherer, 2006). A principal adipokine is adiponectin, which is a 30-kDa protein. It enhances insulin sensitivity, blocks hepatic release of glucose, and has cardioprotective effects on circulating plasma lipids. An adiponectin deficit leads to diabetes, hypertension, endothelial cell activation, and cardiovascular disease.

FIGURE 48-1 Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.

Adipocytokines in Pregnancy

Cytokines that result in insulin resistance—leptin, resistin, TNF- α , and IL-6—are increased during pregnancy. Indeed, these may be the primary stimulant of insulin resistance. Secretion of the remaining adipokines is either unchanged or decreased. Specific patterns have been variously described with gestational diabetes, preeclampsia, and fetal-growth restriction (Briana, 2009). In a

longitudinal study of 55 pregnant women, Meyer and associates (2013) confirmed that higher BMIs are associated with lower adiponectin but higher leptin levels.

Metabolic Syndrome

Given its multifaceted endocrine and paracrine functions, it is not surprising that excessive fat tissue is detrimental (Cornier, 2011). One major drawback is that obesity interacts with inherited factors to cause *insulin resistance* and in some cases, the metabolic syndrome. This resistance is characterized by impaired glucose metabolism and a predisposition to type 2 diabetes. Insulin resistance also causes several subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension, which define the metabolic syndrome.

Criteria used by the National Institutes of Health (2001) to define the metabolic syndrome are shown in Table 48-1. Virtually all obese women with hypertension demonstrate elevated plasma insulin levels. These are even higher in women with excessive fat in the abdomen—an apple shape—compared with those whose fat is in the hips and thighs—a pear shape (American College of Obstetricians and Gynecologists, 2003).

Prevalence

Ford and colleagues (2002) did a follow-up study of men and women enrolled in the Third National Health and Nutrition

FIGURE 48-2 Prevalence of obesity in girls and women in the United States for 2009–2010. (Data from Flegal, 2012; Ogden, 2012.)

FIGURE 48-3 Estimated hazard ratios (95% CI) for death due to cardiovascular disease according to body mass index among 1.46 million white adult men and women. (Data from de Gonzalez, 2010.)

Excessive weight is associated with increased rates of early mortality, as shown by Peeters (2003) and Fontaine (2003) and their colleagues in follow-up studies from both the Framingham Heart Study and the NHANES III cohort. Mortality results from pooled data from 19 prospective studies are shown in Figure 48-3. In these and other studies, mortality risk from cardiovascular disease and cancer increased directly with increasing BMI.

TREATMENT OF OBESITY

Weight loss is tremendously difficult for obese individuals. If achieved, long-term maintenance poses equivalent or even more daunting difficulties. Even the most legitimate non-surgical methods are fraught with frequent failure. If they are successful, slow and inexorable return to preintervention weight usually follows (Yanovski, 2005). Successful weight loss approaches include behavioral, pharmacological, and surgical techniques or a combination of these methods (Eckel, 2008; Zimmet, 2012). As such, obstetrician-gynecologists are encouraged to aid assessment and management of obesity in adult women. Weight loss and lifestyle changes have been shown to reduce the associated metabolic syndrome (Crist, 2012). When used in conjunction with bariatric surgery, there is improved glucose control with type 2 diabetes (Mingrone, 2012; Schauer, 2012).

PREGNANCY AND OBESITY

Obese women unequivocally have reproductive disadvantages. This translates into difficulty in achieving pregnancy, early and recurrent pregnancy loss, preterm delivery, and a myriad

increased obstetrical, medical, and surgical complications with pregnancy, labor, delivery, and the puerperium (American College of Obstetricians and Gynecologists, 2013a). Obesity in pregnancy is also associated with increased health-care utilization and costs (Pauli, 2013). Finally, infants—and later, adults—of obese mothers have correspondingly increased rates of morbidity, mortality, and obesity (Reynolds, 2013).

Obesity results in subfertility due to increased insulin resistance as in polycystic ovarian syndrome. Leptin dysregulation also results in loss of gonadotropin secretory rhythms (Maguire, 2012). Impaired fecundity has been linked to women with a BMI > 30 kg/m² (Neill, 2001). In 6500 in vitro fertilization-intracytoplasmic sperm injection cycles, Bellver and associates (2010) found that implantation, pregnancy, and livebirth rates were progressively and significantly reduced with each unit of maternal BMI. As discussed in Chapter 8 (p. 157), obesity is associated with increased risk of first-trimester and recurrent miscarriage (Lashen, 2004; Metwally, 2008). In the many overweight and obese women who achieve pregnancy, there is a litany of increased and interrelated adverse perinatal outcomes that are discussed subsequently.

Prevalence

As expected from reviewing Figure 48-2, obesity complicating pregnancy has increased substantially in this country. Before adoption of the BMI, investigators used various definitions of obesity to assess risks during pregnancy. For example, in an earlier study from the University of Alabama at Birmingham, four definitions were used, but regardless of how obesity was defined, all groups showed at least twofold increases in prevalence during the 20-year period (Lu, 2001). Equivalent findings were reported from a 15-year study done in Cleveland (Ehrenberg, 2002). Our experience at Parkland Hospital is similar, as shown in the three epochs depicted in Figure 48-4.

FIGURE 48-4 Increasing prevalence of obesity during three epochs in pregnant women classified at the time of their first prenatal visit at Parkland Hospital. (Data courtesy of Dr. Don McIntire.)

Maternal Weight Gain and Energy Requirement

The Institute of Medicine (2009) updated its previous comprehensive reviews of maternal weight gain determinants in relation to biological, metabolic, and social predictors. Its recommended weight gains for various BMI categories are shown in Table 9-5 (p. 177). For overweight women, weight gain of 15 to 25 pounds is recommended. For obese women, the Institute recommends a gain of 11 to 20 pounds. This is because fat deposition is greater in women with high BMIs, and thus, energy costs are significantly lower (Butte, 2004). Kinoshita and Itoh (2006) found that during the third trimester, increases were predominantly in visceral fat. Despite these stores, maternal catabolism is—at least intuitively—not good for fetal growth and development. The American College of Obstetricians and Gynecologists (2013c) has endorsed these Institute guidelines.

These Institute guidelines for obese women have some, although minimal, foundation in scientific evidence (Rasmussen, 2010). In a study of 2080 obese women, there was no advantage to weight gain > 20 pounds (Vesco, 2011). However, Chu and coworkers (2009) reported in the United States in 2004 to 2005 that 40 percent of normal-weight and 60 percent of overweight women gained excessive weight during pregnancy. The Maternal-Fetal Medicine Units Network arrived at similar conclusions. Seventy-five percent of nearly 8300 nulliparas gained more weight than the Institute recommendations (Johnson, 2013). Additionally, women who gained more than the recommended amount had excessive postpartum weight gain at 3, 8, and 15 years after delivery (Nehring, 2011; Rooney, 2002).

Maternal Morbidity

Some of the excess perinatal morbidity due to obesity is listed in Table 48-3. In studies, various definitions of obesity in pregnant women have included 150 percent of ideal body weight, BMI > 35 kg/m², BMI > 40 kg/m², BMI > 50 kg/m², and > 150 pounds over ideal body weight (Cedergren, 2004; Crane, 2013; Denison, 2008; Kabiru, 2004; Kumari, 2001; Stamilio, 2013). In one study, Weiss and colleagues (2004) reported similar adverse outcomes and maternal morbidity in a prospective multicenter study of more than 16,000 women from the FASTER trial (First- and Second-Trimester Evaluation of Risk). As shown in Figures 48-5 and 48-6, especially striking are the marked increases in gestational diabetes and hypertension. Lipkind and associates (2013) showed obesity to be an independent risk factor for “near-miss” maternal morbidity (Chap. 1, p. 6).

Not shown in Figure 48-5 are the cesarean delivery rates. These were 33.8 percent for obese and 47.4 percent for morbidly obese women compared with only 20.7 percent for the normal-weight control group (Weiss, 2004). Similar results were subsequently described by Garabedian and coworkers (2011). Haeri and colleagues (2009) also found increased rates of cesarean delivery and gestational diabetes in obese adolescents. More worrisome is that obese women also have increased rates of *emergency* cesarean delivery (Lynch, 2008; Poobalan, 2009). Finally, wound infections are more common. Alanis and associates (2010) reported this complication in 30 percent in women whose BMI was > 50 kg/m².

There are also reports of increased adverse pregnancy outcomes in overweight women whose BMI is 25 to 29.9 kg/m² (Hall, 2005). Shown in Table 48-3 were results of two studies that included more than 285,000 singleton pregnancies.

TABLE 48-3. Adverse Pregnancy Effects in Overweight and Obese Women

Complication	Prevalence (%) in Women with Normal BMI 20–24.9 n = 176,923	Increased Complications (Odds Ratio ^a)	
		Overweight BMI 25–29.9 n = 79,014	Obese BMI > 30 n = 31,276
Gestational diabetes	0.8	1.7–3.5	3.0–3.6
Preeclampsia	0.7	1.5–1.9	2.1
Postterm pregnancy	0.13	1.2 ^b	1.7
Emergency cesarean delivery	7.8	1.3–1.4	1.7–1.8
Elective cesarean delivery	4.0	1.2	1.3–1.4
Postpartum hemorrhage	10.4	1.04–1.2	1.0–1.4
Pelvic infection	0.7	1.2	1.3
Urinary tract infection	0.7	1.2	1.4
Wound infection	0.4	1.3	2.2
Fetal macrosomia	9.0	1.6	2.4
Stillbirth	0.4	1.4	1.4–1.6
Thrombosis	—	1.6	0.97 ^b

^aOdds ratios (99% CI) are significant except when denoted.

^bNot significantly different.

BMI = body mass index.

Data from Ovesen, 2011; Sebire, 2001.

FIGURE 48-5 Incidence of selected pregnancy outcomes in 16,102 women enrolled in the FASTER (First- and Second-Trimester Evaluation of Risk) trial according to body mass index (BMI) status. (Data from Weiss, 2004.)

Although not as magnified as in the obese cohort, almost all complications are significantly increased in overweight women compared with those whose BMI is normal.

Obesity is detrimental to the accuracy of obstetrical ultrasound examination (Weichert, 2011). Other morbidity includes a higher incidence of failed trial of labor with a prior cesarean delivery (Bujold, 2005; Goodall, 2005; Hibbard, 2006; Robinson, 2005). Obesity and hypertension are common cofactors in causing peripartum heart failure (Cunningham, 1986, 2012). And, obese women present anesthesia challenges that include difficult epidural and spinal analgesia placement and complications from failed or difficult intubations (Hood, 1993; Mace, 2011). Second-trimester dilatation and evacuation was reported to take longer and be more difficult in women whose BMI was 30 kg/m² or greater (Dark, 2002).

Obese women are less likely to breast feed than normal-weight women (Li, 2003). They also have greater weight retention 1 year

after delivery (Catalano, 2007; National Research Council and Institute of Medicine, 2007; Rode, 2005). Finally, there is evidence that quality-of-life measures are negatively affected by obesity during pregnancy (Amador, 2008). LaCoursiere and Varner (2009) found that postpartum depression was significantly increased in obese women in relation to the degree of obesity—class 1, 23 percent; class 2, 32 percent; and class 3, 40 percent.

Gestational Diabetes

Obesity and gestational diabetes are inextricably linked. Their coexistence with and adverse effects on pregnancy outcomes are discussed in Chapter 57 (p. 1139).

Preeclampsia

There is no doubt that obesity is a consistent risk factor for preeclampsia (see Fig. 48-6). In a review of studies that included more than 1.4 million women, O'Brien and associates (2003) found that the preeclampsia risk doubled with each 5 to 7 kg/m² increase in prepregnancy BMI. In The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study (2010), the incidence of preeclampsia increased almost geometrically with each BMI category. Obesity and the metabolic syndrome discussed on page 962 are characterized by insulin resistance causing low-grade inflammation and endothelial activation (Catalano, 2010). These have a central and integral role in development of preeclampsia as discussed in Chapter 40 (p. 733). Wolf and colleagues (2001) linked these two conditions, and Ramsay and coworkers (2002) confirmed that obese pregnant women had significantly elevated serum levels of IL-6 and C-reactive protein and impaired endothelial function. Obese gravidas were found to have significantly higher levels of triglycerides, very-low-density lipoprotein cholesterol, insulin, and leptin compared with normal-weight pregnant woman.

Contraception

Most studies report that oral contraceptive failure is more likely in overweight women. This is discussed in detail in Chapter 38 (p. 695).

FIGURE 48-6 Frequency of preeclampsia according to body mass index. (Data from the Hyperglycemia and Adverse Pregnancy Outcome [HAPO] Study Cooperative Research Group, 2010.)

■ Perinatal Mortality

Stillbirths are more prevalent as the degree of obesity increases (see Table 48-3). Indeed, in a review of almost 100 population-based studies, Flenady and associates (2011) found that obesity was the highest ranking modifiable risk factor for stillbirth. Chronic hypertension with superimposed preeclampsia associated with obesity is one cause of excessive stillbirths. An increased incidence of otherwise inexplicable late-pregnancy stillbirths and early neonatal deaths is also associated with obesity (Cnattingius, 1998; Stephansson, 2001; Waldenström, 2014; Yao, 2014). In one metaanalysis, there was a 1.5-fold increased risk for stillbirth in overweight and a 2.1-fold risk in obese women (Chu, 2007). A Scottish study of more than 186,000 nulliparas described an almost fourfold increased stillbirth rate in women with a BMI ≥ 35 kg/m² compared with women of normal size (Denison, 2008). Increased prepregnancy weight was the factor most strongly associated with unexplained fetal deaths even after adjusting for maternal age and excluding women with diabetes and hypertensive disorders (Huang, 2000; Nohr, 2005; Ovesen, 2011).

■ Perinatal Morbidity

Both fetal and neonatal complications are increased in obese women. The Atlantic Birth Defects Risk Factor Surveillance Study found a two- to threefold increased incidence in various anomalies in obese women (Watkins, 2003). Rasmussen and coworkers (2008) performed a metaanalysis and found 1.2-, 1.7-, and 3.1-fold increased risks for neural-tube defects in overweight, obese, and severely obese women, respectively. Another metaanalysis found that maternal obesity was significantly associated with an increased risk of a wide range of anomalies (Stothard, 2009). The National Birth Defect Prevention Study reported a correlation between BMI and congenital heart defects (Gilboa, 2010). According to Biggio and colleagues (2010), however, this may be related to diabetes as a cofactor. Already mentioned is concern for unreliable fetal anatomy sonographic screening in obese women (Dashe, 2009; Thornburg, 2009; Weichert, 2011).

Two important and interrelated cofactors that contribute to excessive rates of perinatal morbidity are chronic hypertension and diabetes mellitus, both of which are associated with obesity. Affected women have increased rates of preterm delivery and fetal-growth restriction (McDonald, 2010; Waldenström, 2014; Wang, 2011). As discussed above, pregestational diabetes increases the birth defect rate, and gestational diabetes is complicated by excessive numbers of large-for-gestational age and macrosomic fetuses (Chap. 44, p. 884).

Even without diabetes, the prevalence of macrosomic newborns is increased in obese women (Cedergren, 2004; Ovesen, 2011). The group from MetroHealth Medical Center in Cleveland has conducted studies of prepregnancy obesity, gestational weight gain, and prepregnancy and gestational diabetes and their relationship to newborn weight and fat mass (Catalano, 2005, 2007; Ehrenberg, 2004; Sewell, 2006). Although each of these variables was found to be associated with larger and more corpulent newborns, prepregnancy BMI had the strongest influence on the prevalence of macrosomic neonates. They attributed this increased prevalence of macrosomic infants to the marked frequency of overweight or obese

women in pregnancy—47 percent—rather than the 4 percent of pregnant women with diabetes. More recently, Edlow and associates (2013) have shown that genes expressed in the adult metabolic syndrome may be initiated in the fetus.

Morbidity in Children Born to Obese Women

It appears that obese women beget obese children, who themselves become obese adults. Whitaker (2004) studied low-income children in the Special Supplemental Food Program for Women, Infants, and Children (WIC) and found a linear association between early pregnancy maternal BMI and prevalence of overweight children at 2, 3, and 4 years. Schack-Nielson and associates (2005) reported a direct association between maternal, newborn, and childhood BMI. This association strengthened as offspring progressed to adulthood. Catalano and coworkers (2005) studied offspring at a median age of 7 years and found a direct association with maternal prepregnancy obesity and childhood obesity. They also reported associations with central obesity, elevated systolic blood pressure, increased insulin resistance, and decreased high-density lipoprotein (HDL) cholesterol levels—all elements of the metabolic syndrome. In their analysis of 28,540 women, Reynolds and associates (2013) found increased rates of cardiovascular disease and all-cause mortality in offspring of overweight and obese mothers. Boney and colleagues (2005) studied offspring of women with or without gestational diabetes. They observed that children who were large for gestational age at birth and whose mothers were either obese or had gestational diabetes had significantly increased risks for developing metabolic syndrome.

It also appears that excessive maternal weight gain in pregnancy may predict adulthood obesity in their offspring. Schack-Nielsen and associates (2005) found a linear association of maternal weight gain with the subsequent BMI in their children. Analyzing data from Project Viva, Oken (2006) confirmed this. However, not all studies concur. In their analysis of children in the WIC program cited above, Whitaker and associates (2004) found no obvious linear association between gestational weight gain and childhood obesity. This is also discussed in some detail in Chapter 44 (p. 876).

Fetal Programming and Childhood Morbidity

Epidemiological studies have addressed the association of childhood, adolescent, and even adult adverse health outcomes in relation to the fetal environment. Adverse outcomes include obesity, diabetes, hypertension, and the metabolic syndrome. Variables studied have included maternal prepregnancy BMI, obesity, gestational weight gain, and pregestational or gestational diabetes. The most robust evidence suggests a direct association between children born to women who had prepregnancy obesity or gestational diabetes and being overweight in childhood and adulthood.

The potential biological causes and mechanisms of these associations are not clear. Elucidation is limited by insufficient data on potential maternal and genetic predisposing factors and on the environment of the infant and child in relation to diet and activity. The science of *epigenetics* has provided some support for the possibility that perturbations of the maternal-fetal environment can adversely alter postdelivery events (Aagard-Tillery, 2006). Perhaps more likely are contributions of the

maternal-child environment subsequent to birth (Gluck, 2009). These and other factors regarding fetal programming are discussed in Chapter 44 (p. 876).

Antepartum Management

Dietary Intervention in Pregnancy

Weight reduction is not advisable during pregnancy (Catalano, 2013). As noted, recommended weight gain in obese women is 11 to 20 pounds, and several dietary interventions to limit weight gain to these targets have been reported. These include lifestyle interventions and physical activity (Petrella, 2013). Reviews by Quinlivan (2011) and Tanentsapf (2011) found that randomized trials generally reported successful results with intervention. On the other hand, in many other studies, either these have been unsuccessful or the results were insufficient to permit a conclusion (Campbell, 2011; Dodd, 2010; Guelinckx, 2010; Nascimento, 2011; Ronnberg, 2010). Special attention to psychological aspects of pregnancy has been recommended by some (Skouteris, 2010).

Prenatal Care

Close prenatal surveillance detects most early signs of diabetes or hypertension. Standard screening tests for fetal anomalies are sufficient, while being mindful of sonographic limitations for detection of fetal anomalies. Accurate assessment of fetal growth usually requires serial sonography. Antepartum and intrapartum external fetal heart rate monitoring are likewise more difficult, and sometimes these are even impossible.

Surgical and Anesthetic Concerns

Evaluation by the anesthesia team is performed at a prenatal visit or on arrival at the labor unit (American College of Obstetricians and Gynecologists, 2013b). Anesthetic risks and complications faced by obese women are discussed in Chapter 25 (p. 505). Special attention is given to complications that might arise during labor and delivery. Vricella and coworkers (2010) reported the following frequencies of anesthetic complications in 142 morbidly obese women at cesarean delivery. These included technical problems with regional analgesia—up to 6 percent; use of general anesthesia—6 percent; hypotension—3 percent; and overall anesthetic complications of 8.4 percent.

For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to allow access to the fetus and to effect the best wound closure with the least intervening tissue (Alexander, 2006). One technique is shown in Figure 48-7. Others prefer a transverse abdominal incision (Alanis, 2010). Individual differences in maternal body habitus preclude naming any one approach as superior (Gilstrap, 2002; McLean, 2012). Although some have reported similar wound complications with either incision, others reported a fourfold wound complication rate when a vertical abdominal incision was compared with a transverse incision—31 versus 8 percent (Houston, 2000; Thornburg, 2012; Wall, 2003). Finally, a mid-abdomen transverse incision has been advocated by some (Tixier, 2009).

Attention to closure of the subcutaneous layer is important. Chelmon and associates (2004) performed a metaanalysis

FIGURE 48-7 Abdominal incision for the obese woman. **A.** Frontal view. The dotted line indicates an appropriate skin incision for abdominal entry relative to the panniculus. As shown by the uterus in the background, selection of this periumbilical site permits access to the lower uterine segment. **B.** Sagittal view.

of subcutaneous closure in 887 women undergoing cesarean delivery whose wound thickness was greater than 2 centimeters. Subcutaneous closure resulted in a modest but significant 6-percent decrease in wound disruption. The frequency of abdominal wound infections is directly related to BMI (Norman, 2013). Comorbid diabetes apparently increases this risk (Leth, 2011). Several reports describe a wound complication rate of 15 to 45 percent. Alanis and colleagues (2010) reported a 30-percent rate in 194 women whose BMI was $> 50 \text{ kg/m}^2$. Of these, 90-percent were wound disruptions to the fascia, but there was only one evisceration. As indicated above, the transverse abdominal incision had fewer complications. Walsh and coworkers (2009) have reviewed the prevention and management of surgical site infections in morbidly obese women.

To lower thromboembolic complications, graduated compression stockings, hydration, and early mobilization after cesarean delivery in obese women are recommended by the American College of Obstetricians and Gynecologists (2013a). Some also recommend “mini-dose” heparin prophylaxis, but we do not routinely use this (Chap. 52, p. 1044).

Bariatric Surgery

Several surgical procedures have been designed to treat morbid obesity either by decreasing gastric volume—*restrictive*, or by bypassing gastrointestinal absorption—*restrictive malabsorptive* (Adams, 2007; Kushner, 2012). In nonpregnant patients, these procedures have been shown to improve or resolve diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea (Buchwald, 2007; Mingrone, 2012; Schauer, 2012).

Pregnancy

Because of these successes, bariatric surgery currently has become popular, and many women are becoming pregnant following weight-reduction surgery (Abodeely, 2008). Several observational studies have reported improved fertility rates and reduced risks of obstetrical complications in women following bariatric surgery and compared with morbidly obese controls (Alatishe, 2013; Guelinckx, 2009; Kjaer, 2013a; Lesko, 2012; Tan, 2012). The largest of these studies is from the Swedish Birth Register, which included 681 women with a pregnancy following bariatric surgery (Josefsson, 2011). Despite surgical treatments, half of these women were still obese by the time of their first pregnancy following bypass, however, the proportion with morbid obesity was smaller. The frequency of large-for-gestational age infants decreased from 9.1 to 3.2 percent and that of small-for-gestational age neonates *increased* from 2.1 to 5.6 percent. In a recent systematic review, Kjaer and Nilas (2013b) reported a decreased risk after bariatric surgery for diabetes, preeclampsia, and large-for-gestational age infants. Most studies confirmed a higher risk for small-for-gestational age fetuses.

Restrictive Procedures

The prototypical vertical banded gastroplasty has been largely replaced by the laparoscopic adjustable silicone gastric banding (LASGB) operation. With the two approved LASGB procedures—*LAPBAND* and *REALIZE*, an adjustable band is placed 2 cm below the gastroesophageal junction to create a small pouch. The pouch size is controlled by a saline reservoir in the band. Salutory effects on pregnancy outcomes involve before-and-after cohorts as well as pregnancies in postsurgical women compared with obese, nonsurgical controls (Vrebosch, 2012). In a report by Dixon and colleagues (2005), pregnancy outcomes were compared with their preprocedural outcomes and with a matched cohort of obese women. Following banding, the incidences of gestational hypertension—10 versus 45 percent—and gestational diabetes—6 versus 15 percent—were significantly lower compared with their preprocedural pregnancies. Incidences in banded patients were also significantly lower than those in the obese cohort, whose rates for hypertension were 38 percent, and for diabetes, 19 percent. The results from these and other studies are shown in [Table 48-4](#).

TABLE 48-4. Pregnancy Outcomes Following Gastric Banding Surgery and Roux-en-Y Gastric Bypass

Outcome ^a	Gastric Banding ^b (n = 258)	Roux-en-Y Gastric Bypass ^c (n = 236)
Hypertension	8%	6%
Gestational diabetes	12%	4%
Cesarean delivery	25%	23%
Mean birthweight	3000 g	3300 g
Small for gestational age	10%	17%
Stillbirth	4/1000	6/1000

^aData not reported identically—frequencies are approximations.

^bData from Bar-Zohar, 2006; Dixon, 2001; Ducarme, 2013; Martin, 2000; Skull, 2004.

^cFrom review by Abodeely, 2008.

Reported complications have been few and include excessive nausea and vomiting that abated with band adjustment (Martin, 2000). Rarely, women may have band slippage associated with hyperemesis or with advancing gestation (Pilone, 2012; Suffee, 2012). One newborn died after fetal cerebral hemorrhage developed from vitamin K deficiency associated with band slippage (Van Mieghem, 2008).

Restrictive Malabsorptive Procedures

There are three procedures to accomplish gastric restriction and selective malabsorption. The most commonly used is the laparoscopically performed *Roux-en-Y gastric bypass* and *bilio-pancreatic diversion with duodenal switch*. With the Roux-en-Y procedure, the proximal stomach is completely transected to leave a 30-mL pouch. A gastroenterotomy is then created by connecting the proximal end of the distal jejunum to the pouch. A Roux-en-Y enteroenterostomy is also completed 60 cm distal to this gastrojejunostomy to allow drainage of the unused stomach and proximal small intestine.

As with other bariatric procedures, pregnancy outcomes are changed remarkably following Roux-en-Y bypass (Wittgrove, 1998). As shown in [Table 48-4](#), rates of hypertension, gestational diabetes, and fetal macrosomia are reduced. Serious complications are uncommon. Intussusception and small bowel obstruction develop from internal herniation, and maternal deaths from herniation and obstruction have been reported (Kakarla, 2005; Moore, 2004; Renault, 2012; Wax, 2007). Bowel obstruction is notoriously difficult to diagnose, and Wax and associates (2013) caution for a high index of suspicion.

Recommendations

The American College of Obstetricians and Gynecologists (2013a) recommends that women who have undergone bariatric surgery be assessed for vitamin and nutritional sufficiency. When indicated, vitamin B₁₂ and D, folic acid, and calcium supplementation are given. Vitamin A deficiency has also been reported (Chagas, 2013). Women with a gastric band should

be monitored by their bariatric team during pregnancy because adjustments of the band may be necessary. Finally, special vigilance is appropriate for signs of intestinal obstruction.

DISEASES OF THE AORTA	992
ISCHEMIC HEART DISEASE	994

Heart disease complicates more than 1 percent of all pregnancies and is now the leading cause of indirect maternal deaths—accounting for 20 percent of all cases (Simpson, 2012). In an analysis of maternal mortality in the United States between 1987 and 2005, the causes previously responsible for most maternal deaths—hemorrhage and hypertensive disorders—had progressively decreased rates, whereas deaths attributable to cardiovascular diseases had the greatest percentage increase (Berg, 2010). Similarly, in the United Kingdom, the rate of maternal mortality due to cardiac disease increased from 1.65 to 2.31 per 100,000 births between 1997–1999 and 2006–2008 (Centre for Maternal and Child Enquiries, 2011).

Cardiovascular diseases also account for significant maternal morbidity and are a leading cause of obstetrical intensive care unit admissions (Small, 2012).

The increasing prevalence of cardiovascular diseases complicating pregnancy is likely due to a number of causes, including higher rates of obesity, hypertension, and diabetes. Indeed, according to the United States National Center for Health Statistics, almost half of adults aged 20 and older have at least one risk factor for cardiovascular disease (Fryar, 2012). And as shown in [Figure 49-1](#), the prevalence of these risk factors among reproductive-aged women is dramatic. Other related factors include delayed childbearing. From 1970 to 2006 the proportion of first births to women aged 35 years or older increased nearly eightfold (Mathews, 2009). Finally, as discussed subsequently, an increasing number of patients with congenital heart disease are now becoming pregnant.

PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY

Cardiovascular Physiology

The marked pregnancy-induced anatomical and functional changes in cardiac physiology can have a profound effect on underlying heart disease (Chap. 4, p. 58). Some of these changes are listed in [Table 49-1](#). Importantly, cardiac output increases approximately 40 percent during pregnancy. Almost half of this total increase takes place by 8 weeks and is maximal by midpregnancy (Capeless, 1989). The early increase stems from augmented stroke volume that results from decreased vascular resistance. Later in pregnancy, resting pulse and stroke volume increase even more because of increased end-diastolic ventricular volume that results from pregnancy hypervolemia. This along with an increase in heart rate translates to increased cardiac output that continues to rise across pregnancy to average 40 percent higher at term.

FIGURE 49-1 Prevalence of risk factors for cardiovascular disease among reproductive-aged women. DM = diabetes mellitus. (From Centers for Disease Control and Prevention, 2011.)

These changes are even more profound in multifetal pregnancy (Kametas, 2003; Kuleva, 2011).

An important study by Clark and colleagues (1989) contributed greatly to the understanding of cardiovascular physiology during pregnancy. Using right-sided heart catheterization, hemodynamic function was measured in 10 healthy primigravid volunteers, and pregnancy values were compared with those measured again at 12 weeks postpartum. As shown in Table 49-1, the cardiac output near term in the lateral recumbent position increased 43 percent. Systemic and pulmonary vascular resistances were concomitantly decreased. Importantly, intrinsic left ventricular contractility did not change. Thus, normal left ventricular function is maintained during pregnancy, that is, pregnancy is not characterized by hyperdynamic function or a high cardiac-output state.

Women with underlying cardiac disease may not always accommodate these changes, and ventricular dysfunction leads to cardiogenic heart failure. A few women with severe cardiac dysfunction may experience evidence of heart failure before midpregnancy. In others, heart failure may develop after 28 weeks when pregnancy-induced hypervolemia and cardiac output reach their maximum. In most, however, heart failure develops peripartum when labor, delivery, and a number of

common obstetrical conditions add undue cardiac burdens. Some of these include preeclampsia, hemorrhage and anemia, and sepsis syndrome. In a report of 542 women with heart disease, eight of 10 maternal deaths were during the puerperium (Etheridge, 1977).

Ventricular Function in Pregnancy

Ventricular volumes increase to accommodate pregnancy-induced hypervolemia. This is reflected by increasing end-systolic as well as end-diastolic dimensions. At the same time, however, there is no change in septal thickness or in ejection fraction. This is because these changes are accompanied by substantive ventricular remodeling—*plasticity*—which is characterized by eccentric expansion of left-ventricular mass that averages 30 to 35 percent near term. All of these adaptations return to prepregnancy values within a few months postpartum.

Certainly for clinical purposes, ventricular function during pregnancy is normal as estimated by the *Braunwald ventricular function* graph depicted in Figure 4-9 (p. 59). For given filling pressures, there is appropriate cardiac output so that cardiac function during pregnancy is eudynamic. Despite these findings, it remains controversial whether myocardial function per se is normal, enhanced, or depressed. Myocardial performance is measured by preload, afterload, contractility, and heart rate. Because these depend on ventricular geometry, they can only be measured indirectly (Savu, 2012). In nonpregnant subjects with a normal heart who sustain a high-output state, the left ventricle undergoes *longitudinal remodeling*, and echocardiographic functional indices of its deformation provide normal values. In pregnancy, there instead appears to be *spherical remodeling*, and these calculated indices that measure longitudinal deformation are depressed. Thus, these normal indices are likely inaccurate when used to assess function in pregnant women because they do not take into account the spherical eccentric hypertrophy characteristic of normal pregnancy.

DIAGNOSIS OF HEART DISEASE

The physiological adaptations of normal pregnancy can induce symptoms and alter clinical findings that may confound the diagnosis of heart disease. For example, in normal pregnancy, functional systolic heart murmurs are common; respiratory effort is accentuated and at times suggests dyspnea; edema in the lower extremities after midpregnancy is common; and fatigue and exercise intolerance develop in most women. Some systolic flow murmurs may be loud, and normal changes in the various heart sounds depicted in Figure 49-2 may suggest cardiac disease.

Clinical findings that may suggest heart disease are listed in Table 49-2. Pregnant women with none of these rarely have serious heart disease. As an interesting aside, Melchiorre and associates (2011) found that the prevalence of previously undiagnosed maternal cardiac structural abnormalities is significantly increased in women with high midtrimester uterine artery Doppler resistance indices (Chap. 17, p. 345).

TABLE 49-1. Hemodynamic Changes in 10 Normal Pregnant Women at Term Compared with Repeat Values Obtained 12 Weeks Postpartum	
Parameter	Change (%)
Cardiac output	+43
Heart rate	+17
Left ventricular stroke work index	+17
Vascular resistance	
Systemic	−21
Pulmonary	−34
Mean arterial pressure	+4
Colloid osmotic pressure	−14

Persistent neck vein distention	
Systolic murmur grade 3/6 or greater	
Diastolic murmur	
Cardiomegaly	
Persistent arrhythmia	
Persistent split second sound	
Criteria for pulmonary hypertension	

Diagnostic Studies

In most women, noninvasive cardiovascular studies such as electrocardiography, chest radiography, and echocardiography will provide data necessary for evaluation. In some situations, such as complex congenital heart disease, transesophageal echocardiography may be useful. Albumin or red cells tagged with technetium-99m are rarely needed during pregnancy to evaluate ventricular function. That said, the estimated fetal radiation exposure from nuclear medicine studies of myocardial perfusion are calculated to range between 5 and 17 mGy depending on the technique employed (Colletti, 2013). If indicated, cardiac catheterization can be performed with limited fluoroscopy time. During coronary angiography, the mean radiation exposure to the unshielded abdomen is 1.5 mGy, and less than 20 percent of this reaches the fetus because of tissue attenuation (European Society of Cardiology, 2011). Shielding the fetus from direct radiation and shortening the fluoroscopic time help to minimize radiation exposure. In women with clear indications, any minimal theoretical fetal risk is outweighed by maternal benefits (Chap. 46, p. 932).

Electrocardiography

As the diaphragm is elevated in advancing pregnancy, there is an average 15-degree left-axis deviation in the electrocardiogram (ECG), and mild ST changes may be seen in the inferior leads. Atrial and ventricular premature contractions are relatively frequent (Carruth, 1981). Pregnancy does not alter voltage findings.

Chest Radiography

Anteroposterior (AP) and lateral chest radiographs are useful, and when a lead apron shield is used, fetal radiation exposure is minimal (Chap. 46, p. 931). Gross cardiomegaly can usually be excluded, but slight heart enlargement cannot be detected accurately because the heart silhouette normally is larger in pregnancy. This is accentuated further with a portable AP chest radiograph.

Echocardiography

Widespread use of echocardiography has allowed accurate diagnosis of most heart diseases during pregnancy. It allows noninvasive evaluation of structural and functional cardiac factors. Some normal pregnancy-induced changes include slightly but significantly increased tricuspid regurgitation, left atrial end-diastolic dimension, and left ventricular mass. Savu (2012) and Vitarelli (2011) and their coworkers have provided normal morphological and functional echocardiographic parameters for pregnancy, which are listed in the Appendix (p. 1293).

Classification of Functional Heart Disease

There is no clinically applicable test for accurately measuring functional cardiac capacity. The clinical classification of the New York Heart Association (NYHA) was first published in 1928, and it was revised for the eighth time in 1979. This classification is based on past and present disability and is uninfluenced by physical signs:

- Class I. *Uncompromised—no limitation of physical activity:* These women do not have symptoms of cardiac insufficiency or experience anginal pain.
- Class II. *Slight limitation of physical activity:* These women are comfortable at rest, but if ordinary physical activity is undertaken, discomfort in the form of excessive fatigue, palpitation, dyspnea, or anginal pain results.
- Class III. *Marked limitation of physical activity:* These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.
- Class IV. *Severely compromised—inability to perform any physical activity without discomfort:* Symptoms of cardiac insufficiency or angina may develop even at rest. If any physical activity is undertaken, discomfort is increased.

Siu and associates (2001b) expanded the NYHA classification and developed a scoring system for predicting cardiac complications during pregnancy. The system is based on a prospective analysis of 562 consecutive pregnant women with heart disease during 617 pregnancies in 13 Canadian teaching hospitals. Predictors of cardiac complications included the following: (1) prior heart failure, transient ischemic attack, arrhythmia, or

stroke; (2) baseline NYHA class III or IV or cyanosis; (3) left-sided obstruction defined as mitral valve area $< 2 \text{ cm}^2$, aortic valve area $< 1.5 \text{ cm}^2$, or peak left ventricular outflow tract gradient $> 30 \text{ mm Hg}$ by echocardiography; (4) ejection fraction less than 40 percent. The risk of pulmonary edema, sustained arrhythmia, stroke, cardiac arrest, or cardiac death was substantially increased with one of these factors and even more so with two or more.

At least two studies have been conducted using these latter risk criteria. Khairy and colleagues (2006) reviewed 90 pregnancies in 53 women with congenital heart disease at Brigham and Women's Hospital. There were no maternal deaths, and heart failure and symptomatic arrhythmias developed in 16.7 and 2.8 percent of the women, respectively. Similar to the Canadian study cited above, the most important predictors of complications were prior congestive heart failure, depressed ejection fraction, and smoking. In a German study that also used these predefined risk predictors, they were found to be accurate in assessing most cardiac outcomes (Stangl, 2008).

Preconceptional Counseling

Women with severe heart disease will benefit immensely from counseling before undertaking pregnancy, and they usually are referred for maternal-fetal medicine or cardiology consultation (Clark, 2012; Seshadri, 2012).

Maternal mortality rates generally vary directly with functional classification, and this relationship may change as pregnancy progresses. In the Canadian study, Siu and colleagues (2001b) observed significant worsening of NYHA class in 4.4 percent of 579 pregnancies in which the baseline class was I or II. Their experiences, however, as well as those of McFaul and coworkers (1988), were that there were no maternal deaths in 1041 women with class I or II disease. As described later, some women have life-threatening cardiac abnormalities that can be reversed by corrective surgery, and subsequent pregnancy becomes less dangerous. In other cases, such as women with mechanical valves taking warfarin, fetal considerations predominate.

The World Health Organization Risk Classification of Cardiovascular Disease and Pregnancy is useful for assessing maternal risk associated with various cardiovascular conditions and for preconceptional counseling and planning (Thorne, 2006). Maternal risk is divided among four progressively worsening classes as shown in Table 49-3. Its use has been recommended by the European Society of Cardiology (2011).

Congenital Heart Disease in Offspring

Many congenital heart lesions appear to be inherited as polygenic characteristics, which are discussed in Chapter 13 (p. 274). Because of this, some women with congenital heart lesions give birth to similarly affected infants, the risk of which varies widely as shown in Table 49-4. Environmental factors are also important. One example is a study from Tibet in which the prevalence of fetal heart disease was increased among women living at higher altitudes (> 3600 meters) and was presumably due to lower oxygen concentrations (Chen, 2008).

TABLE 49-3. World Health Organization (WHO) Risk Classification of Cardiovascular Disease and Pregnancy

Risk Category	Associated Conditions
WHO 1—Risk no higher than general population	Uncomplicated, small, or mild: Pulmonary stenosis Ventricular septal defect Patent ductus arteriosus Mitral valve prolapse with no more than trivial mitral regurgitation Successfully repaired simple lesions: Ostium secundum atrial septal defect Ventricular septal defect Patent ductus arteriosus Total anomalous pulmonary venous drainage Isolated ventricular extrasystoles and atrial ectopic beats
WHO 2—Small increase in risk of maternal mortality and morbidity	If otherwise uncomplicated: Unoperated atrial septal defect Repaired Fallot tetralogy Most arrhythmias
WHO 2 or 3—depends on individual case	Mild left ventricular impairment Hypertrophic cardiomyopathy Native or tissue valvular heart disease not considered WHO 4 Marfan syndrome without aortic dilation Heart transplantation Mechanical valve
WHO 3—Significantly increased risk of maternal mortality or expert cardiac and obstetrical care required	Systemic right ventricle—congenitally corrected transposition, simple transposition post-Mustard or -Senning repair Post-Fontan operation Cyanotic heart disease Other complex congenital heart disease
WHO 4—Very high risk of maternal mortality or severe morbidity; pregnancy contraindicated and termination discussed	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (NYHA III-IV or LVEF < 30%) Previous peripartum cardiomyopathy with any residual impairment of left ventricular function Severe left heart obstruction Marfan syndrome with aorta dilated > 40 mm

Modified from Thorne, 2006.

TABLE 49-4. Risks for Fetal Heart Lesions Related to Affected Family Members

Cardiac Lesion	Congenital Heart Disease in Fetus (%)		
	Previous Sibling Affected	Father Affected	Mother Affected
Marfan syndrome	NS	50	50
Aortic stenosis	2	3	15–18
Pulmonary stenosis	2	2	6–7
Ventricular septal defect	3	2	10–16
Atrial septal defect	2.5	1.5	5–11
Patent ductus arteriosus	3	2.5	4
Coarctation of the aorta	NS	NS	14
Fallot tetralogy	2.5	1.5	2–3

NS = not stated.
Data from Lupton, 2002.**PERIPARTUM MANAGEMENT CONSIDERATIONS**

In most instances, management involves a team approach with an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. With complex lesions or with women who are especially at risk, evaluation by a multidisciplinary team is recommended early in pregnancy. During consultation, cardiovascular changes likely to be poorly tolerated by an individual woman are identified, and plans are formulated to minimize these. In some, pregnancy termination may be advisable. Maxwell (2010) has provided an in-depth checklist that considers detailed management options. The four changes that affect management that are emphasized by the American College of Obstetricians and Gynecologists (1992) include decreased vascular resistance, increased blood volume and cardiac output and their fluctuations peripartum, and hypercoagulability. Within this framework, both prognosis and management are influenced by the type and severity of the specific lesion and by the patient's functional classification.

With rare exceptions, women in NYHA class I and most in class II negotiate pregnancy without morbidity. Special attention should be directed toward both prevention and early recognition of heart failure as discussed on page 990. Infection with sepsis syndrome is an important factor in precipitating cardiac failure. Moreover, bacterial endocarditis is a deadly complication of valvular heart disease (p. 990). Each woman should receive instructions to avoid contact with persons who have respiratory infections, including the common cold, and to report at once any evidence for infection. Pneumococcal and influenza vaccines are recommended.

Cigarette smoking is prohibited, because of both its cardiac effects and its propensity to cause upper respiratory infections. Illicit drug use may be particularly harmful, an example being the cardiovascular effects of cocaine or amphetamines. In addition, intravenous drug use increases the risk of infective endocarditis.

Fortunately, cases of NYHA class III and IV are uncommon today. In the Canadian study, only 3 percent of approximately 600 pregnancies were complicated by NYHA class III heart disease, and no women had class IV when first seen (Siu, 2001b). In a Turkish study, 8 percent of pregnancies in women with cardiac diseases were NYHA class III or IV (Madazli, 2010). An important question in these women is whether pregnancy should be undertaken. If women make that choice, they must understand the risks, and they are encouraged to be compliant with planned care. In some, prolonged hospitalization or bed rest is often necessary with continued pregnancy.

■ Labor and Delivery

In general, vaginal delivery is preferred, and labor induction is usually safe (Oron, 2004). Cesarean delivery is limited to obstetrical indications, and considerations are given for the specific cardiac lesion, overall maternal condition, and availability of experienced anesthesia personnel and general support facilities. Some of these women tolerate major surgical procedures poorly and are best delivered in a unit experienced with management of complicated cardiac disease. In some women, pulmonary artery catheterization may be indicated for hemodynamic monitoring (Chap. 47, p. 941). In our experiences, however, invasive monitoring is rarely indicated.

Based on her review, Simpson (2012) recommends cesarean delivery for women with the following: (1) dilated aortic root > 4 cm or aortic aneurysm; (2) acute severe congestive heart failure; (3) recent myocardial infarction; (4) severe symptomatic aortic stenosis; (5) warfarin administration within 2 weeks of delivery; and (6) need for emergency valve replacement immediately after delivery. Although we agree with most of these, we have some caveats. For example, we prefer aggressive medical stabilization of pulmonary edema followed by vaginal delivery if possible. Also, warfarin anticoagulation can be reversed with vitamin K, plasma, or prothrombin concentrates.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with lateral tilt. Vital signs are taken frequently between contractions. Increases in pulse rate much above 100 bpm or respiratory rate above 24 per minute, particularly when associated with dyspnea, may

suggest impending ventricular failure. If there is any evidence of cardiac decompensation, intensive medical management must be instituted immediately. It is essential to remember that delivery itself does not necessarily improve the maternal condition and in fact, may worsen it. Moreover, emergency operative delivery may be particularly hazardous. Clearly, both maternal and fetal status must be considered in the decision to hasten delivery under these circumstances.

Analgesia and Anesthesia

Relief from pain and apprehension is important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended for most. The major problem with conduction analgesia is maternal hypotension (Chap. 25, p. 514). This is especially dangerous in women with intracardiac shunts in whom flow may be reversed. Blood passes from right to left within the heart or aorta and thereby bypasses the lungs. Hypotension can also be life-threatening if there is pulmonary arterial hypertension or aortic stenosis because ventricular output is dependent on adequate preload. In women with these conditions, narcotic conduction analgesia or general anesthesia may be preferable.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given with intravenous sedation often suffices. This has been shown to minimize intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Subarachnoid blockade is not generally recommended in women with significant heart disease. For cesarean delivery, epidural analgesia is preferred by most clinicians with caveats for its use with pulmonary arterial hypertension (p. 987). Finally, general endotracheal anesthesia with thiopental, succinylcholine, nitrous oxide, and at least 30-percent oxygen has also proved satisfactory.

Intrapartum Heart Failure

Cardiovascular decompensation during labor may manifest as pulmonary edema with hypoxia or as hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. For example, decompensated mitral stenosis with pulmonary edema due to fluid overload is often best approached with aggressive diuresis. If precipitated by tachycardia, heart rate control with β -blocking agents is preferred. Conversely, the same treatment in a woman suffering decompensation and hypotension due to aortic stenosis could prove fatal. Unless the underlying pathophysiology is understood and the cause of the decompensation is clear, empirical therapy may be hazardous. Heart failure is discussed in more detail on page 990.

■ Puerperium

Women who have shown little or no evidence of cardiac compromise during pregnancy, labor, or delivery may still decompensate postpartum when fluid mobilization into the intravascular compartment and reduction of peripheral vascular resistance place higher demands on myocardial performance. Therefore, it is important that meticulous care be continued into the puerperium (Keizer, 2006; Zeeman, 2006).

Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure (Cunningham, 1986). In addition to increased cardiac work, many of these—for example, sepsis and severe preeclampsia—cause or worsen pulmonary edema because of endothelial activation and capillary-alveolar leakage (Chap. 47, p. 947).

Sterilization and Contraception

If indicated, tubal sterilization is performed at cesarean delivery. If it is to be performed after vaginal delivery, the procedure can be delayed up to several days to ensure that the mother has become hemodynamically near normal and that she is afebrile, not anemic, and ambulating normally. Other women are given detailed contraceptive advice. Special considerations for contraception in women with various cardiac disorders are discussed in some of the following sections and in Table 38-3 (p. 698).

SURGICALLY CORRECTED HEART DISEASE

Most clinically significant congenital heart lesions are repaired during childhood. Examples of those frequently not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner, 2000). In some cases, the defect is mild and surgery is not required. In others, a significant structural anomaly is amenable to surgical correction. With successful repair, many women attempt pregnancy. In some instances, surgical corrections have been performed during pregnancy.

Valve Replacement before Pregnancy

Numerous reports describe subsequent pregnancy outcomes in women who have a prosthetic mitral or aortic valve. The type of valve is paramount, and pregnancy is undertaken only after serious consideration in women with a prosthetic mechanical valve. This is because anticoagulation is requisite, and at least when not pregnant, warfarin is necessary. As shown in Table 49-5, a number of serious complications can develop with mechanical valves. Both thromboembolisms involving the prosthesis and hemorrhage from anticoagulation are of extreme concern. This is in addition to deterioration in cardiac function. Overall, the maternal mortality rate is 3 to 4 percent with mechanical valves, and fetal loss is common.

Porcine tissue valves are much safer during pregnancy, primarily because thrombosis is rare and anticoagulation is not required (see Table 49-5). Despite this, valvular dysfunction with cardiac deterioration or failure is common and develops in 5 to 25 percent of involved pregnancies. Another drawback is that bioprostheses are not as durable as mechanical ones, and valve replacement longevity averages 10 to 15 years. Based on their longitudinal study of 100 reproductive-aged women with a biological heart valve prosthesis, Cleuziou and colleagues (2010) concluded that pregnancy does not accelerate the risk for replacement.

TABLE 49-5. Outcomes Reported Since 1990 in Pregnancies Complicated by a Heart-Valve Replacement

Type of Valve	Total	Complications ^a	
		Maternal	Perinatal
Mechanical	567 ^b	38 thromboses 17 emboli 19 hemorrhages 14 deaths	107 miscarriages/ abortions 37 stillbirths
Porcine	265 ^c	32 valve failures or deterioration	9 abortions 3 stillbirths

^aNumbers estimated in some because definitions are not consistent.

Anticoagulation

This is critical for women with mechanical prosthetic valves. Unfortunately, warfarin is the most effective anticoagulant for preventing maternal thromboembolic complications but causes significant fetal morbidity and mortality. Anticoagulation with heparin is less hazardous for the fetus, however, the risk of maternal thromboembolic complications is much higher (McLintock, 2011).

As noted, warfarin, despite its effective anticoagulation, is teratogenic and causes miscarriage, stillbirths, and fetal malformations (Chap. 12, p. 252). In one study of 71 pregnancies in women given warfarin throughout pregnancy, the rates of miscarriage were 32 percent; stillbirth, 7 percent; and embryopathy, 6 percent (Cotrufo, 2002). The risk was highest when the mean daily dose of warfarin exceeded 5 mg. From a systematic review, Chan and coworkers (2000) concluded that the best maternal outcomes were achieved with warfarin anticoagulation but with a 6.4-percent embryopathy rate. And although heparin substituted before 12 weeks' gestation eliminated embryopathy, thromboembolic complications during that time were increased significantly.

In examining heparin, anticoagulation for mechanical valves using low-dose unfractionated heparin is definitely inadequate and has a high associated maternal mortality rate (Chan, 2000; Iturbe-Alessio, 1986). Even *full* anticoagulation with either unfractionated heparin (UFH) or one of the low-molecular-weight heparins (LMWH) is associated with valvular thrombosis (Leyh, 2002, 2003; Rowan, 2001). Thus, many authorities recommend warfarin. However, the American College of Chest Physicians has recommended use of any of several regimens that include adjusted-dose UFH or LMWH heparin given throughout pregnancy as subsequently discussed (Bates, 2012).

Recommendations for Anticoagulation. A number of different treatment options—none of which are completely ideal—have been proposed and are principally based on

TABLE 49-6. American College of Chest Physicians Guidelines for Anticoagulation of Pregnant Women with Mechanical Prosthetic Valves

Any one of the following anticoagulant regimens is recommended:

Adjusted-dose LMWH twice daily throughout pregnancy. The doses should be adjusted to achieve the manufacturer's peak anti-Xa level 4 hours after subcutaneous injection

Adjusted-dose UFH administered every 12 hours throughout pregnancy. The doses should be adjusted to keep the midinterval aPTT at least twice control or attain an anti-Xa level of 0.35 to 0.70 U/mL

LMWH or UFH as above until 13 weeks' gestation, then warfarin substitution until close to delivery when LMWH or UFH is resumed

In women judged to be at very high risk of thromboembolism and in whom concerns exist about the efficacy and safety of LMWH or UFH as dosed above—some examples include older-generation prosthesis in the mitral position or history of thromboembolism—warfarin treatment is suggested throughout pregnancy with replacement by UFH or LMWH (as above) close to delivery. In addition, low-dose aspirin—75 to 100 mg daily—should be orally administered

aPTT = activated partial thromboplastin time; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin. Adapted from Bates, 2012.

consensus opinion. For this reason, they differ and allow more than one scheme. For example, and as shown in [Table 49-6](#), the most recent guidelines of the American College of Chest Physicians for the management of pregnant women with mechanical prosthetic valves offer several different treatment options.

Heparin is discontinued just before delivery. If delivery supervenes while the anticoagulant is still effective, and extensive bleeding is encountered, then protamine sulfate is given intravenously. Anticoagulant therapy with warfarin or heparin may be restarted 6 hours following vaginal delivery, usually with no problems. Following cesarean delivery, full anticoagulation is withheld, but the duration is not exactly known. The American College of Obstetricians and Gynecologists (2011b) advises resuming unfractionated or low-molecular-weight heparin 6 to 12 hours after cesarean delivery. It is our practice, however, to wait at least 24 hours, and preferably 48 hours, following a major surgical procedure.

Because warfarin, low-molecular-weight heparin, and unfractionated heparin do not accumulate in breast milk, they do not induce an anticoagulant effect in the infant. Therefore, these anticoagulants are compatible with breast feeding (American College of Obstetricians and Gynecologists, 2011b).

Contraception

Because of their possible thrombogenic action, estrogen-progestin oral contraceptives are relatively contraindicated in women with prosthetic valves. Because these women are generally fully anticoagulated, however, any increased risk is speculative. Contraceptive options are discussed in Chapters 38 and 39. Sterilization should be considered because of the serious pregnancy risks faced by women with significant heart disease.

Cardiac Surgery During Pregnancy

Although usually postponed until after delivery, valve replacement or other cardiac surgery during pregnancy may be lifesaving. Several reviews confirm that such surgery is associated with major maternal and fetal morbidity and mortality. Sutton and

associates (2005) found that maternal mortality rates with cardiopulmonary bypass are between 1.5 and 5 percent. Although these are similar to those for nonpregnant women, the fetal mortality rate approaches 20 percent. In a longitudinal study from the Mayo Clinic, John and coworkers (2011) reported the outcomes of 21 pregnant women who underwent cardiothoracic surgery requiring cardiopulmonary bypass between 1976 and 2009. The procedures included eight aortic valve replacements, six mitral valve repairs or replacements, two myxoma excisions, two aortic aneurysm repairs, one patent foramen ovale closure, one prosthetic aortic valve thrombectomy, and one septal myectomy. Median cardiopulmonary bypass time was 53 minutes, with a range of 16 to 185 minutes. One woman died two days after surgery, and three other deaths occurred 2, 10, and 19 years postoperatively. Three fetuses died, and 52 percent delivered before 36 weeks. To optimize outcomes, Chandrasekhar and coworkers (2009) recommend the following: surgery done electively when possible, pump flow rate maintained > 2.5 L/min/m², normothermic perfusion pressure > 70 mm Hg, pulsatile flow used, and hematocrit kept > 28 percent.

Mitral Valvotomy During Pregnancy

Tight mitral stenosis that requires intervention during pregnancy was previously treated by closed mitral valvotomy (Pavankumar, 1988). More recently, however, percutaneous transcatheter balloon dilatation of the mitral valve has largely replaced surgical valvotomy during pregnancy (Fawzy, 2007). Rahimtoola (2006) summarized outcomes of 36 women—25 of whom were NYHA class III or IV—who underwent balloon commissurotomy at an average gestational age of 26 weeks. Surgery was successful in 35 women, and left atrial and pulmonary artery pressures were reduced as the mitral valve area was increased from 0.74 to 1.59 cm². Esteves and associates (2006) described similarly good outcomes in 71 pregnant women with tight mitral stenosis and heart failure who underwent percutaneous valvuloplasty. At delivery, 98 percent were either NYHA class I or II. At a mean of 44 months, the total event-free maternal survival rate was 54 percent, however, eight women

required another surgical intervention. The 66 infants who were delivered at term all had normal growth and development.

Pregnancy after Heart Transplantation

The first successful pregnancy in a heart-transplant recipient was reported 25 years ago by Löwenstein and associates (1988). Since that time, more than 50 pregnancies in heart-transplant recipients have been described. Key (1989) and Kim (1996) and their colleagues provide detailed data to show that the transplanted heart responds normally to pregnancy-induced changes. Despite this, complications are common during pregnancy (Dashe, 1998).

Armenti (2002) from the National Transplantation Pregnancy Registry and Miniero (2004), each with their coworkers, described outcomes of 53 pregnancies in 37 heart recipients. Almost half developed hypertension, and 22 percent suffered at least one rejection episode during pregnancy. They were delivered—usually by cesarean—at a mean of 37 to 38 weeks. Three fourths of infants were liveborn. At follow-up, at least five women had died more than 2 years postpartum. From Scandinavia, Estensen and associates (2011) detailed the outcomes of 19 women who had received a heart transplant and six who received both a heart and lung transplant. These 25 women had 42 pregnancies, and there were no maternal deaths. Major complications included two rejections during the early puerperium, two cases of renal failure, and 11 spontaneous abortions. Five women died 2 to 12 years after delivery. Ethical considerations of counseling and caring for such women related to pregnancy were summarized by Ross (2006).

VALVULAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, availability of penicillin, and

evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease (Roeder, 2011).

Mitral Stenosis

Rheumatic endocarditis causes most mitral stenosis lesions. The normal mitral valve surface area is 4.0 cm², and when stenosis narrows this to < 2.5 cm², symptoms usually develop (Desai, 2000). The contracted valve impedes blood flow from the left atrium to the ventricle. The most prominent complaint is dyspnea due to pulmonary venous hypertension and edema. Fatigue, palpitations, cough, and hemoptysis are also common.

With more severe stenosis, the left atrium dilates, left atrial pressure is chronically elevated, and significant passive pulmonary hypertension develops (Table 49-7). These women have a relatively fixed cardiac output, and thus the increased preload of normal pregnancy, as well as other factors that increase cardiac output, may cause ventricular failure and pulmonary edema. Indeed, a fourth of women with mitral stenosis have cardiac failure for the first time during pregnancy (Caulin-Glaser, 1999). Because the murmur may not be heard in some women, this clinical picture at term may be confused with idiopathic peripartum cardiomyopathy (Cunningham, 1986, 2012).

Also with significant stenosis, tachycardia shortens ventricular diastolic filling time and increases the mitral gradient. This raises left atrial as well as pulmonary venous and capillary pressures and may result in pulmonary edema. Thus, sinus tachycardia is often treated prophylactically with β -blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively. Atrial fibrillation also predisposes to mural thrombus formation and cerebrovascular embolization that can cause stroke (Chap. 60, p. 1192). Atrial thrombosis can develop despite a sinus rhythm, and

TABLE 49-7. Major Cardiac Valve Disorders

Type	Cause	Pathophysiology	Pregnancy
Mitral stenosis	Rheumatic valvulitis	LA dilation and passive pulmonary hypertension Atrial fibrillation	Heart failure from fluid overload, tachycardia
Mitral insufficiency	Rheumatic valvulitis Mitral-valve prolapse LV dilatation	LV dilatation and eccentric hypertrophy	Ventricular function improves with afterload decrease
Aortic stenosis	Congenital bicuspid valve	LV concentric hypertrophy, decreased cardiac output	Moderate stenosis is tolerated; severe is life-threatening with decreased preload, e.g., obstetrical hemorrhage or regional analgesia
Aortic insufficiency	Rheumatic valvulitis Connective-tissue disease Congenital	LV hypertrophy and dilatation	Ventricular function improves with afterload decrease
Pulmonary stenosis	Rheumatic valvulitis Congenital	Severe stenosis associated with RA and RV enlargement	Mild stenosis usually well tolerated; severe stenosis associated with right heart failure and atrial arrhythmias

LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

Hameed (2005) reported three such women. One suffered an embolic stroke, and another had pulmonary edema causing maternal hypoxemia leading to fetal encephalopathy.

Pregnancy Outcomes

In general, complications are directly associated with the degree of valvular stenosis. Recall that investigators from the large Canadian study found that women with a mitral-valve area $< 2 \text{ cm}^2$ were at greatest risk. In another study, Hameed (2001) described 46 pregnant women with mitral stenosis—43 percent developed heart failure and 20 percent developed arrhythmias. Fetal-growth restriction was more common in those women with a mitral valve area $< 1.0 \text{ cm}^2$.

Prognosis is also related to maternal functional capacity. Among 486 pregnancies complicated by rheumatic heart disease—predominantly mitral stenosis—Sawhney (2003) reported that eight of 10 maternal deaths were in women in NYHA classes III or IV.

Management

Limited physical activity is generally recommended in women with mitral stenosis. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretics are given (Siva, 2005). A β -blocker drug is usually given to slow the ventricular response to activity (Maxwell, 2010). If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin, a β -blocker, or a calcium-channel blocker is given to slow ventricular response. Therapeutic anticoagulation with heparin is indicated with persistent fibrillation. Some recommend heparin anticoagulation for those with severe stenosis even if there is a sinus rhythm (Hameed, 2005).

Labor and delivery are particularly stressful for women with symptomatic mitral stenosis. Uterine contractions increase cardiac output by increasing circulating blood volume. Pain, exertion, and anxiety cause tachycardia with possible rate-related heart failure. Epidural analgesia for labor is ideal, but with strict attention to avoid fluid overload. Abrupt increases in preload may increase pulmonary capillary wedge pressure and cause pulmonary edema. The effects of labor on pulmonary pressures in women with mitral stenosis are shown in Figure 49-3. Wedge pressures increase most immediately postpartum. Clark and colleagues (1985) hypothesize that this is likely due to loss of the low-resistance placental circulation along with the venous “autotransfusion” from a now-empty uterus and from the lower extremities and pelvis.

Most consider vaginal delivery to be preferable in women with mitral stenosis. Elective induction is reasonable so that labor and delivery are attended by a scheduled, experienced team. With severe stenosis and chronic heart failure, insertion of a pulmonary artery catheter may help guide management.

Mitral Insufficiency

A trivial degree of mitral insufficiency is found in most normal patients (Maxwell, 2010). But if there is improper coaptation of mitral valve leaflets during systole, abnormal degrees of

FIGURE 49-3 Mean pulmonary capillary wedge pressure measurements (red graph line) in eight women with mitral valve stenosis. Shaded yellow and blue boxes are mean (± 1 SD) pressures in nonlaboring normal women at term. **A.** First-stage labor. **B.** Second-stage labor 15 to 30 minutes before delivery. **C.** Postpartum 5 to 15 minutes. **D.** Postpartum 4 to 6 hours. **E.** Postpartum 18 to 24 hours. (Data from Clark, 1985, 1989.)

mitral regurgitation may develop. This is eventually followed by left ventricular dilatation and eccentric hypertrophy (see Table 49-7). Chronic mitral regurgitation has a number of causes, including rheumatic fever, mitral valve prolapse, or left ventricular dilatation of any etiology—for example, dilated cardiomyopathy. Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations—*Libman-Sacks endocarditis*—are relatively common in women with antiphospholipid antibodies (Roldan, 1996; Shroff, 2012). These sometimes coexist with systemic lupus erythematosus (Chap. 59, p. 1170). In contrast, acute mitral insufficiency is caused by chordae tendineae rupture, papillary muscle infarction, or leaflet perforation from infective endocarditis.

In nonpregnant patients, symptoms from mitral valve incompetence are rare, and valve replacement is seldom indicated unless infective endocarditis develops. Likewise, mitral regurgitation is well tolerated during pregnancy, probably because decreased systemic vascular resistance results in less regurgitation. Heart failure only rarely develops during pregnancy, and occasionally tachyarrhythmias require treatment.

Mitral Valve Prolapse

This diagnosis implies the presence of a pathological connective tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets themselves, the annulus, or the chordae tendineae. Mitral insufficiency may develop. Most women with mitral valve prolapse are asymptomatic and are diagnosed by routine examination or while undergoing echocardiography. The small percentage of women with symptoms have anxiety, palpitations, atypical chest pain, dyspnea with exertion, and syncope (Guy, 2012).

Pregnant women with mitral valve prolapse rarely have cardiac complications. Hypervolemia may even improve alignment of the mitral valve, and women without pathological

myxomatous change generally have excellent pregnancy outcomes (Leśniak-Sobelga, 2004; Rayburn, 1987). In a study of 3100 women in the Taiwanese Birth Registry with mitral valve prolapse, however, the preterm birth rate was 1.2 times higher than among controls (Chen, 2011).

For women who are symptomatic, β -blocking drugs are given to decrease sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias. According to the American College of Obstetricians and Gynecologists (2011a), mitral valve prolapse is not considered an indication for infective endocarditis prophylaxis.

Aortic Stenosis

Usually a disease of aging, aortic stenosis in women younger than 30 years is most likely due to a congenital lesion. This stenosis is less common since the decline in incidences of rheumatic diseases, and the most frequent cause in this country is a bicuspid valve (Friedman, 2008). A normal aortic valve has an area of 3 to 4 cm², with a pressure gradient of less than 5 mm Hg. If the valve area is < 1 cm², there is severe obstruction to flow and a progressive pressure overload on the left ventricle (Carabello, 2002; Roeder, 2011). Concentric left ventricular hypertrophy follows, and if severe, end-diastolic pressures become elevated, ejection fraction declines, and cardiac output is reduced (see Table 49-7). Characteristic clinical manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. Life expectancy averages only 5 years after exertional chest pain develops, and valve replacement is indicated for symptomatic patients.

Pregnancy

Clinically significant aortic stenosis is infrequent during pregnancy. Mild to moderate degrees of stenosis are well tolerated, however, severe disease is life threatening. The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, a number of events acutely decrease preload further and thus aggravate the fixed cardiac output. These include vena caval occlusion, regional analgesia, and hemorrhage. Importantly, these also decrease cardiac, cerebral, and uterine perfusion. It follows that severe aortic stenosis may be extremely dangerous during pregnancy. From the large Canadian multicenter study cited above, there were increased complications if the aortic valve area was < 1.5 cm² (Siu, 2001b). And in the report by Hameed and associates (2001) described earlier, the maternal mortality rate with aortic stenosis was 8 percent. Women with valve gradients exceeding 100 mm Hg appear to be at greatest risk.

Management

For the asymptomatic woman with aortic stenosis, no treatment except close observation is required. Management of the symptomatic woman includes strict limitation of activity and prompt treatment of infections. If symptoms persist despite bed rest, valve replacement or valvotomy using cardiopulmonary bypass must be considered. In general, balloon valvotomy for aortic valve disease is avoided because of serious complications, which exceed 10 percent. These include stroke, aortic

rupture, aortic valve insufficiency, and death (Reich, 2004). In rare cases, it may be preferable to perform valve replacement during pregnancy (Datt, 2010).

For women with critical aortic stenosis, intensive monitoring during labor is important. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt decreases in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus, the management key is avoidance of decreased ventricular preload and the maintenance of cardiac output. During labor and delivery, such women should be managed on the “wet” side, maintaining a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare, even with moderate volume overload.

During labor, narcotic epidural analgesia seems ideal, thus avoiding potentially hazardous hypotension, which may be encountered with standard conduction analgesia techniques. Easterling and coworkers (1988) studied the effects of epidural analgesia in five women with severe stenosis and demonstrated immediate and profound effects of decreased filling pressures. Xia and associates (2006) emphasize slow administration of dilute local anesthetic agents into the epidural space. Forceps or vacuum delivery is used for standard obstetrical indications in hemodynamically stable women. Late cardiac events include pulmonary edema, arrhythmias, cardiac interventions, and death, which were identified within 1 year of delivery in 70 pregnancies (Tzemos, 2009).

Aortic Insufficiency

Aortic valve regurgitation or insufficiency allows diastolic flow of blood from the aorta back into the left ventricle. Frequent causes of abnormal insufficiency are rheumatic fever, connective-tissue abnormalities, and congenital lesions. With Marfan syndrome, the aortic root may dilate, resulting in regurgitation. Acute insufficiency may develop with bacterial endocarditis or aortic dissection. Aortic and mitral valve insufficiency have been linked to the appetite suppressants fenfluramine and dexfenfluramine and to the ergot-derived dopamine agonists cabergoline and pergolide (Gardin, 2000; Schade, 2007; Zanettini, 2007). With chronic insufficiency, left ventricular hypertrophy and dilatation develop and are followed by slow-onset fatigue, dyspnea, and edema, although rapid deterioration usually follows (see Table 49-7).

Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve incompetence, diminished vascular resistance is thought to improve hemodynamic function. If symptoms of heart failure develop, diuretics are given and bed rest is encouraged.

Pulmonic Stenosis

The pulmonary valve is affected by rheumatic fever far less often than the other valves. Instead, pulmonic stenosis is usually

congenital and also may be associated with Fallot tetralogy or Noonan syndrome. The clinical diagnosis is typically identified by auscultating a systolic ejection murmur over the pulmonary area that is louder during inspiration.

Increased hemodynamic burdens of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis. Surgical correction ideally is done before pregnancy, but if symptoms progress, a balloon angioplasty may be necessary antepartum (Maxwell, 2010; Siu, 2001a). In a study of 81 pregnancies in 51 Dutch women with pulmonic stenosis, cardiac complications were infrequent (Drenthen, 2006). NYHA classification worsened in two women, and nine experienced palpitations or arrhythmias. No changes in pulmonary valvular function or other adverse cardiac events were reported. However, noncardiac complications were increased—17 percent had preterm delivery; 15 percent had hypertension; and 4 percent developed thromboembolism. Interestingly, two of the offspring were diagnosed with pulmonic stenosis, and another had complete transposition and anencephaly.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States is approximately 8 per 1000 liveborn infants. Approximately a third of these have critical disease that requires cardiac catheterization or surgery during the first year of life. Others require surgery in childhood, and it is currently estimated that there are nearly 1 million adults in this country with congenital heart disease (Bashore, 2007).

According to an analysis from the Nationwide Inpatient Sample discharge database, more than 30,000 women admitted for delivery between 1998 and 2007 had congenital heart disease—a rate of 71.6 per 100,000 deliveries (Opatowsky, 2012). After statistical adjustments, women with congenital heart disease were found to be eight times more likely to sustain an adverse cardiovascular event that included death, heart failure, arrhythmia, and cerebrovascular or embolic event. Of these, arrhythmia was the most common, and the rate of maternal death was approximately 1.5 per 1000. Thompson and coworkers (2014) found similar risks.

■ Septal Defects

Atrial Septal Defects

After bicuspid aortic valve, these are the most frequently encountered adult congenital cardiac lesions. Indeed, a fourth of all adults have a patent foramen ovale (Kizer, 2005). Most are asymptomatic until the third or fourth decade. The secundum-type defect accounts for 70 percent, and associated mitral valve myxomatous abnormalities with prolapse are common. Most recommend repair if discovered in adulthood. Pregnancy is well tolerated unless pulmonary hypertension has developed, but this is uncommon (Maxwell, 2010; Zuber, 1999). Treatment is indicated for congestive heart failure or an arrhythmia. Based on their review, Aliaga and associates (2003) concluded that the risk of endocarditis with an atrial septal defect is negligible.

With the potential to shunt blood from right to left, a *paradoxical embolism*, that is, entry of a venous thrombus through the septal defect and into the systemic arterial circulation, is possible and may cause an embolic stroke (Chap. 60, p. 1192). Erkut and associates (2006) described a woman who developed an entrapped thrombus in a patent foramen ovale postpartum. In asymptomatic women, thromboembolism prophylaxis is problematic, and recommendations include either observation or antiplatelet therapy such as low-dose aspirin (Kizer, 2005; Maxwell, 2010). Compression stockings and prophylactic heparin for a pregnant woman with a septal defect and concurrent immobility or other risk factors for thromboembolism have also been recommended (Head, 2005).

Ventricular Septal Defects

These lesions close spontaneously during childhood in 90 percent of cases. Most defects are paramembranous, and physiological derangements are related to lesion size. In general, if the defect is less than 1.25 cm², pulmonary hypertension and heart failure do not develop. If the effective defect size exceeds that of the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension and have a high incidence of bacterial endocarditis (Brickner, 2000; Maxwell, 2010).

Pregnancy is well tolerated with small to moderate left-to-right shunts. If pulmonary arterial pressures reach systemic levels, however, there is reversal or bidirectional flow—*Eisenmenger syndrome* (p. 985). When this develops, the maternal mortality rate is significantly increased, and thus, pregnancy is not generally advisable. Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (p. 991). As shown in Table 49-4, up to 15 percent of offspring born to these women also have a ventricular septal defect.

Atrioventricular Septal Defects

These account for approximately 3 percent of all congenital cardiac malformations and are distinct from isolated atrial or ventricular septal defects. An atrioventricular (AV) septal defect is characterized by a common, ovoid AV junction. This defect is associated with aneuploidy, Eisenmenger syndrome, and other malformations, but still, some of these women become pregnant. Compared with simple septal defects, complications are more frequent during pregnancy. In a review of 48 pregnancies in 29 such women, complications included persistent deterioration of NYHA class in 23 percent, significant arrhythmias in 19 percent, and heart failure in 2 percent (Drenthen, 2005b). Congenital heart disease was identified in 15 percent of the offspring.

■ Persistent (Patent) Ductus Arteriosus

The ductus connects the proximal left pulmonary artery to the descending aorta just distal to the left subclavian artery. Functional closure of the ductus from vasoconstriction occurs shortly after term birth (Akintunde, 2011). The

physiological consequences of persistence of this structure are related to its size. Most significant lesions are repaired in childhood, but for individuals who do not undergo repair, the mortality rate is high after the fifth decade (Brickner, 2000). In some younger women with an unrepaired ductus during pregnancy, however, pulmonary hypertension, heart failure, or cyanosis will develop if systemic blood pressure falls and leads to shunt reversal of blood from the pulmonary artery into the aorta (Maxwell, 2010). A sudden blood pressure decline at delivery—such as with conduction analgesia or hemorrhage—may lead to fatal collapse. Therefore, hypotension should be avoided whenever possible and treated vigorously if it develops. Prophylaxis for bacterial endocarditis may be indicated at delivery for unrepaired defects (p. 991). As shown in Table 49-4, the incidence of inheritance is approximately 4 percent.

■ Cyanotic Heart Disease

When congenital heart lesions are associated with right-to-left shunting of blood past the pulmonary capillary bed, cyanosis develops. The classic and most commonly encountered lesion in adults and during pregnancy is the *Fallot tetralogy* (Maxwell, 2010). It is characterized by a large ventricular septal defect, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, the shunt increases and cyanosis worsens. Women who have undergone repair and who do not have a recurrence of cyanosis do well in pregnancy.

Some women with *Ebstein anomaly* with a malpositioned, malformed tricuspid valve may reach reproductive age. Right ventricular failure from volume overload and appearance or worsening of cyanosis are common during pregnancy. In the absence of cyanosis, these women usually tolerate pregnancy well.

Women with cyanotic heart disease generally do poorly during pregnancy. With uncorrected Fallot tetralogy, for example, maternal mortality rates approach 10 percent. Moreover, any disease complicated by severe maternal hypoxemia is likely to lead to miscarriage, preterm delivery, or fetal death. There is a relationship between chronic hypoxemia, polycythemia, and pregnancy outcome. When hypoxemia is intense enough to stimulate a rise in hematocrit above 65 percent, pregnancy wastage is virtually 100 percent.

Pregnancy after Surgical Repair

Some of the more complex lesions cannot be successfully repaired. But with satisfactory surgical correction of cyanotic lesions before pregnancy, maternal and fetal outcomes are much improved (Maxwell, 2010).

Fallot Tetralogy. Balci (2011) and Kamiya (2012) and their associates described a total of 197 pregnancies in 99 women with surgically corrected Fallot tetralogy. Pregnancy was usually well tolerated, and there were no maternal deaths. Still, almost 9 percent of pregnancies were complicated by adverse cardiac

events including new onset or worsening of arrhythmias and heart failure. For women with a pulmonary valve replacement, Oosterhof and coworkers (2006) reported that pregnancy did not adversely affect graft function.

Transposition of the Great Vessels. Pregnancy following surgical correction of transposition also has risks. Canobbio (2006) and Drenthen (2005a), each with their colleagues, described outcomes of 119 pregnancies in 68 women—90 percent had a Mustard procedure and 10 percent a Senning procedure. During pregnancy, a fourth had arrhythmias. Twelve percent developed heart failure, and one of these patients subsequently required cardiac transplantation. One woman died suddenly a month after delivery, and another died 4 years later. A third of the newborns were delivered preterm, but no infant had heart disease. In a more recent study, Metz and associates (2011) reported that five of 14 pregnancies resulting in live births were complicated by symptomatic intracardiac baffle obstruction, which required postpartum stenting. In review, baffles are surgically constructed conduits that redirect anomalous cardiac blood flow and are integral to initial transposition correction.

Successful—although eventful—pregnancies in women with previously repaired *truncus arteriosus* and *double-outlet right ventricle* have also been described (Drenthen, 2008; Hoendermis, 2008).

Single Functional Ventricle. Feinstein and associates (2012) recently reviewed the remarkably improved treatments for patients with *hypoplastic left heart syndrome*. Almost 70 percent of these women are now expected to survive into adulthood and frequently become pregnant. Those who have undergone a *Fontan repair* are at particularly high risk for complications, which include atrial arrhythmias and peripartum heart failure (Nitsche, 2009). In a report of four pregnancies post-Fontan repair, there were no maternal deaths, but complications were frequent (Hoare, 2001). All were delivered preterm, two had supraventricular arrhythmias, and two developed ventricular failure. Similarly high complication rates were described by Jain and coworkers (2011) in 15 women with a systemic right ventricle, that is, one in which the right ventricle rather than the left pumps blood to the support systemic circulation.

Eisenmenger Syndrome

This describes secondary pulmonary hypertension that develops from any cardiac lesion. The syndrome develops when pulmonary vascular resistance exceeds systemic resistance and leads to concomitant right-to-left shunting. The most common underlying defects are atrial or ventricular septal defects and persistent ductus arteriosus (Fig. 49-4). Patients are asymptomatic for years, but eventually pulmonary hypertension becomes severe enough to cause right-to-left shunting, and few persons survive into the fifth decade (Makaryus, 2006; Maxwell, 2010).

The prognosis for pregnancy depends on the severity of pulmonary hypertension but survival has improved during the past 50 years. Women with Eisenmenger syndrome tolerate

FIGURE 49-4 Eisenmenger syndrome due to a ventricular septal defect (VSD). **A.** Substantial left-to-right shunting through the VSD leads to morphological changes in the smaller pulmonary arteries and arterioles. Specifically, medial hypertrophy, intimal cellular proliferations, and fibrosis lead to narrowing or closure of the vessel lumen. These vascular changes create pulmonary hypertension and a resultant reversal of the intracardiac shunt (**B**). With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. Although a VSD is shown here, Eisenmenger syndrome may also develop in association with a large atrial septal defect or patent ductus arteriosus.

hypotension poorly, and the cause of death usually is right ventricular failure with cardiogenic shock. Management is discussed subsequently. In a review of 44 cases through 1978, maternal and perinatal mortality rates approximated 50 percent (Gleicher, 1979). In a later review of 73 pregnancies, Weiss and coworkers (1998) cited a 36-percent maternal death rate. Three of 26 deaths were antepartum, and the remainder died intrapartum or within a month of delivery. In a more recent study of 13 pregnant women, there was one maternal death 17 days after delivery, and there were five perinatal deaths (Wang, 2011).

PULMONARY HYPERTENSION

Normal resting mean pulmonary artery pressure is 12 to 16 mm Hg. In the study by Clark and colleagues (1989), pulmonary vascular resistance in late pregnancy was approximately 80 dyn/sec/cm⁻⁵, which was 34-percent less than the nonpregnant value of 120 dyne/sec/cm⁻⁵. *Pulmonary hypertension* is a hemodynamic observation and not a diagnosis and is defined in nonpregnant individuals as a mean pulmonary pressure > 25 mm Hg.

The World Health Organization classification shown in Table 49-8 has been adopted by the American College of Cardiology and the American Heart Association (McLaughlin, 2009). There are important prognostic and therapeutic distinctions between group I pulmonary hypertension and the

other groups. Group I indicates that a specific disease affects pulmonary arterioles. It includes idiopathic or primary pulmonary arterial hypertension as well as those cases secondary to a known cause such as connective-tissue disease. Approximately a third of women with scleroderma and 10 percent with systemic lupus erythematosus have pulmonary hypertension (Rich, 2005). Other causes in young women are sickle-cell disease and thyrotoxicosis (Sheffield, 2004). Another is plexogenic pulmonary arteriopathy associated with cirrhosis and portal hypertension, and this has been reported to cause a maternal death (Sigel, 2007).

Group II disorders are the most commonly encountered in pregnant women. These are secondary to pulmonary *venous* hypertension caused by left-sided atrial, ventricular, or valvular disorders. A typical example is mitral stenosis discussed on page 981. In contrast, groups III through V are seen infrequently in young otherwise healthy women.

Diagnosis

Symptoms may be vague, and dyspnea with exertion is the most common. With group II disorders, orthopnea and nocturnal dyspnea are also usually present. Angina and syncope occur when right ventricular output is fixed, and they suggest advanced disease. Chest radiography commonly shows enlarged pulmonary hilar arteries and attenuated peripheral markings. It also may disclose parenchymal causes of hypertension. Although cardiac catheterization remains the standard criterion

TABLE 49-8. World Health Organization Classification of Some Causes of Pulmonary Hypertension

I Pulmonary arterial hypertension
Idiopathic—previously “primary” pulmonary hypertension
Familial—chromosome 2 gene in TGF superfamily
Associated with: collagen-vascular disorders, congenital left-to-right cardiac shunts, HIV infection, thyrotoxicosis, sickle hemoglobinopathies, antiphospholipid antibody syndrome, diet drugs, portal hypertension
Persistent pulmonary hypertension of the newborn
Other
II Pulmonary hypertension with left-sided heart disease
Left-sided atrial or ventricular disease
Left-sided valvular disease
III Pulmonary hypertension associated with lung disease
Chronic obstructive pulmonary disease
Interstitial lung disease
Other
IV Pulmonary hypertension due to chronic thromboembolic disease
V Miscellaneous

HIV = human immunodeficiency virus; TGF = transforming growth factor.

Adapted from Simmoneau, 2004.

for the measurement of pulmonary artery pressures, noninvasive echocardiography is often used to provide an estimate. In 33 pregnant women who underwent both echocardiography and cardiac catheterization, pulmonary artery pressures were significantly overestimated by echocardiography in a third of cases (Penning, 2001).

■ Prognosis

Longevity depends on the severity and cause of pulmonary hypertension at discovery. For example, although invariably fatal, idiopathic pulmonary hypertension has a 3-year survival rate of 60 percent, whereas that due to collagen-vascular diseases has only a 35-percent rate (McLaughlin, 2004). Some disorders respond to pulmonary vasodilators, calcium-channel blockers, prostacyclin analogues, or endothelin-receptor blockers, all which may improve quality of life. The prostacyclin analogues epoprostenol and treprostinil significantly lower pulmonary vascular resistance but must be given parenterally (Humbert, 2004; Roeleveld, 2004). Preconceptional counseling is imperative as emphasized by Easterling and associates (1999).

■ Pulmonary Hypertension and Pregnancy

The maternal mortality rate is appreciable, but this is especially so with idiopathic pulmonary hypertension. In the past, there

were frequently poor distinctions in identifying both causes and severity of hypertension. Thus, although most severe cases of idiopathic pulmonary arterial hypertension had the worst prognosis, it was erroneously assumed that all types of pulmonary hypertension were equally dangerous. With widespread use of echocardiography, less-severe lesions with a better prognosis are now separable. Curry (2012) and Weiss (1998) and their colleagues reviewed 36 cases of pulmonary hypertension in pregnancy and found an approximate 30-percent mortality rate. Bédard and coworkers (2009) reported that mortality statistics improved during the decade ending in 2007 compared with those for the decade ending in 1996. Mortality rates were 25 and 38 percent, respectively. Importantly, almost 80 percent of the deaths were during the first month postpartum.

Pregnancy is contraindicated with severe disease, especially those with pulmonary arterial changes—most cases in group I. With milder disease from other causes—group II being the most common—the prognosis is much better. With the more frequent use of echocardiography and pulmonary artery catheterization in young women with heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerate pregnancy, labor, and delivery well. One example described by Sheffield and Cunningham (2004) is that of pulmonary hypertension that develops with thyrotoxicosis but is reversible with treatment (Chap. 58, p. 1151). Similarly, Boggess and colleagues (1995) described nine women with interstitial and restrictive lung disease with varying degrees of pulmonary hypertension, and all tolerated pregnancy reasonably well.

Management

Treatment of symptomatic pregnant women includes activity limitation and avoidance of the supine position in late pregnancy. Diuretics, supplemental oxygen, and vasodilator drugs are standard therapy for symptoms. Some recommend anticoagulation (Hsu, 2011; Larson, 2010). In addition, there are many reports describing the successful use of intravenous pulmonary artery vasodilators in both singleton and twin gestations (Badalian, 2000; Easterling, 1999; Garabedian, 2010). Prostacyclin analogues that can be administered parenterally include epoprostenol and treprostinil, whereas iloprost is inhaled. There are reports of successful use of each in pregnant women, but data are insufficient to prefer one over another. Inhaled nitric oxide is also an option that has been employed in cases of acute cardiopulmonary decompensation during pregnancy or the puerperium (Lane, 2011).

Labor and Delivery

These women are at greatest risk during labor and delivery when there is diminished venous return and decreased right ventricular filling—both associated with most maternal deaths. To avoid hypotension, assiduous attention is given to epidural analgesia induction and to blood loss prevention and treatment at delivery. Parneix and coworkers (2009) describe low-dose spinal-epidural analgesia for cesarean delivery. Women with group I severe hypertension have been delivered successfully while using either inhaled nitric oxide or iloprost (Lam, 2001; Weiss, 2000).

CARDIOMYOPATHIES

The American Heart Association defines cardiomyopathies as a heterogeneous group of myocardial diseases associated with mechanical and/or electrical dysfunction. Affected women usually—but not invariably—have inappropriate ventricular hypertrophy or dilatation. Cardiomyopathies are due to various causes that frequently are genetic (Maron, 2006). In general, and as shown in Table 49-9, cardiomyopathies may be divided into two major groups:

- *Primary*—cardiomyopathies solely or predominantly confined to heart muscle—examples include hypertrophic cardiomyopathy, dilated cardiomyopathies, and peripartum cardiomyopathy.
- *Secondary*—cardiomyopathies due to generalized systemic disorders that produce pathological myocardial involvement—examples are diabetes, lupus, and thyroid disorders.

Hypertrophic Cardiomyopathy

Epidemiological studies suggest that the disorder is common, affecting approximately 1 in 500 adults (Maron, 2004). The condition—characterized by cardiac hypertrophy, myocyte disarray, and interstitial fibrosis—is caused by mutations in any one of more than a dozen genes that encode cardiac sarcomere proteins. Inheritance is autosomal dominant, and genetic screening is complex and not currently clinically available

TABLE 49-9. Some Primary and Secondary Causes of Cardiomyopathy

Primary Causes
Genetic—hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysplasia, left ventricular noncompaction, glycogen storage diseases, conduction system disease, mitochondrial myopathies, ion-channelopathies
Mixed—predominantly nongenetic—dilated and restrictive cardiomyopathy
Acquired—myocarditis, stress (takotsubo), peripartum cardiomyopathy
Secondary Causes
Infiltrative—amyloidosis, Gaucher disease, Hurler and Hunter diseases
Storage—hemochromatosis
Toxicity—drugs, heavy metals
Endomyocardial—hypereosinophilic syndrome
Granulomatous—sarcoidosis
Endocrine—diabetes mellitus, thyroid dysfunction
Cardiofacial—Noonan syndrome
Neuromuscular/neurological—Friedrich ataxia, neurofibromatosis
Autoimmune—systemic lupus erythematosus, scleroderma

Adapted from Maron, 2006.

(Osio, 2007; Spirito, 2006). The myocardial muscle abnormality is characterized by left ventricular myocardial hypertrophy with a pressure gradient to left ventricular outflow. Diagnosis is established by echocardiographic identification of a hypertrophied and nondilated left ventricle in the absence of other cardiovascular conditions.

Most affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most common form of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms are usually worsened by exercise.

Pregnancy

Although limited reports suggest that pregnancy is well tolerated, adverse cardiac events are common. Thaman and coworkers (2003) reviewed 271 pregnancies in 127 affected women. Although there were no maternal deaths, more than a fourth had at least one adverse cardiac symptom—including dyspnea, chest pain, or palpitations. Singla and associates (2011) described a pregnant patient with undiagnosed hypertrophic cardiomyopathy who presented with preeclampsia and an acute myocardial infarction.

Management is similar to that for aortic stenosis. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. Likewise, drugs that evoke diuresis or diminish vascular resistance are generally not used. If symptoms develop, especially angina, β -adrenergic or calcium-channel blocking drugs are given. The delivery route is determined by obstetrical indications. Choice of anesthesia is controversial, and in the opinion of some authors, general anesthesia is considered safest (Pitton, 2007). Infants rarely demonstrate inherited lesions at birth.

Dilated Cardiomyopathy

This is characterized by left and/or right ventricular enlargement and reduced systolic function in the absence of coronary, valvular, congenital, or systemic disease known to cause myocardial dysfunction. Although there are many known causes of dilated cardiomyopathy—both inherited and acquired, the etiology remains undefined in approximately half of cases (Stergiopoulos, 2011). Some cases are result from viral infections, including myocarditis and human immunodeficiency virus (Barbaro, 1998; Felker, 2000). Other causes, which are potentially reversible, include alcoholism, cocaine abuse, and thyroid disease. Watkins and colleagues (2011) reviewed the many complex genetic mutations associated with inherited forms of dilated cardiomyopathy.

Peripartum Cardiomyopathy

This disorder is very similar to other forms of nonischemic dilated cardiomyopathy except for its unique relationship with pregnancy (Pyatt, 2011). Currently, it is a diagnosis of exclusion following a concurrent evaluation for peripartum heart failure. Although the term peripartum cardiomyopathy has been used widely, at least until recently, there was little evidence to

FIGURE 49-5 Peripartum cardiomyopathy with mild pulmonary edema. Anterior-posterior projection chest radiograph of a woman with an abnormally enlarged heart and mild perihilar opacification consistent with dilated cardiomyopathy.

support a unique pregnancy-induced cardiomyopathy. Pearson (2000) reported findings of a workshop of the National Heart, Lung, and Blood Institute and the Office of Rare Diseases that established the following diagnostic criteria:

1. Development of cardiac failure in the last month of pregnancy or within 5 months after delivery,
2. Absence of an identifiable cause for the cardiac failure,
3. Absence of recognizable heart disease prior to the last month of pregnancy, and
4. Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria, such as depressed ejection fraction or fractional shortening along with a dilated left ventricle (Fig. 49-5).

The etiology of peripartum cardiomyopathy remains unknown, and many potential causes—including viral myocarditis, abnormal immune response to pregnancy, abnormal response to the increased hemodynamic burden of pregnancy, hormonal interactions, malnutrition, inflammation, and apoptosis—have been proposed but not proven (Elkayam, 2011). Another theory suggests that oxidative stress during late pregnancy leads to the proteolytic cleavage of prolactin (Hilfiker-Kleiner, 2007). The resulting 16-kDa prolactin fragment has been found to be cardiotoxic and can impair the metabolism and contractility of cardiomyocytes. Based on this proposed mechanism, bromocriptine therapy has been suggested because it inhibits prolactin secretion (Chap. 36, p. 673). Indeed, there has been at least one preliminary study in which bromocriptine improved recovery of affected women (Sliwa, 2010).

Another intriguing mechanism to explain the etiology of peripartum cardiomyopathy was described by Patten (2012). It links peripartum cardiomyopathy to preeclampsia syndrome. This is biologically plausible given that hypertensive disorders frequently coexist with peripartum cardiomyopathy (Cunningham, 2012; Fong, 2014; Gunderson, 2011). These investigators showed that antiangiogenic factors—already known

to be associated with preeclampsia—can induce peripartum cardiomyopathy in susceptible mice. Thus, they posit peripartum cardiomyopathy to be a vascular disease precipitated by antiangiogenic factors that act in a host made susceptible because of insufficient proangiogenic factors.

In the absence of a proven etiology, the diagnosis of peripartum cardiomyopathy currently requires that other causes of cardiac dysfunction be excluded. Bültmann and coworkers (2005) studied endomyocardial biopsy specimens from 26 women with peripartum cardiomyopathy and reported that more than half had histological evidence of “borderline myocarditis.” They noted viral genomic material for parvovirus B19, human herpesvirus 6, Epstein-Barr virus, and cytomegalovirus. They attributed these findings to reactivation of latent viral infection that triggered an autoimmune response. Another report described 28 women at Parkland Hospital who had peripartum heart failure of obscure etiology who were initially thought to have idiopathic peripartum cardiomyopathy (Cunningham, 1986). In 21 of these, heart failure was found to be caused by hypertensive heart disease, clinically silent mitral stenosis, obesity, or viral myocarditis. Particularly important were the silent cardiomyopathic effects that even intermediate-duration chronic hypertension may have on ventricular function.

After exclusion of an underlying cause for heart failure, the default diagnosis is idiopathic or peripartum cardiomyopathy. Thus, its incidence is highly dependent on the diligence of the search for a cause. Because of this, the cited incidence varies from approximately 1 in 2500 to 1 in 15,000 births. In a review of the National Hospital Discharge Survey database of 3.6 million births, a prevalence of 1 in 3200 births was computed (Mielniczuk, 2006). Two other large population-based studies cited a frequency of 1 in 2000 to 2800 (Gunderson, 2011; Harper, 2012). In an earlier study from Parkland Hospital, we identified idiopathic cardiomyopathy in only approximately 1 in 15,000 deliveries—an incidence similar to that of idiopathic cardiomyopathy in young nonpregnant women (Cunningham, 1986).

Prognosis. The distinction between heart failure from an identifiable cause and peripartum cardiomyopathy is of obstetrical importance. Women with a true cardiomyopathy do not fare well overall as a group, and their immediate and 1-year mortality rate is 2 to 15 percent (Harper, 2012; Mielniczuk, 2006). Approximately 50 percent of women suffering from peripartum cardiomyopathy recover baseline ventricular function within 6 months of delivery, but in those with persistent cardiac failure, the mortality rate approaches 85 percent over 5 years (Moioli, 2010).

A study from India described the outcomes of 36 women with peripartum cardiomyopathy (Mandal, 2011). Five women died either from heart failure or cerebrovascular accident. Of six women who had a subsequent pregnancy, one woman died and two developed heart failure. In a follow-up study from Haiti, Fett and coworkers (2009) performed echocardiography every 6 months in 116 women with peripartum cardiomyopathy. Only 28 percent of these women recovered a left ventricular ejection fraction > 0.51, and in three fourths of these, this

level was not attained until after a year. With a mean follow-up of 39 months, de Souza and colleagues (2001) reported that 18 percent of 44 such women had died from end-stage heart failure. Similar long-term outcomes were assessed by a survey of members of the American College of Cardiology (Elkayam, 2001). Respondents reported that a return to normal ventricular function does not guarantee a problem-free pregnancy, and that if another pregnancy is undertaken in women with an ejection fraction persistently < 0.5 , it should be with great trepidation.

■ Other Primary Causes of Cardiomyopathy

Arrhythmogenic Right Ventricular Dysplasia

This unique cardiomyopathy is defined histologically by progressive replacement of right ventricular myocardium with adipose and fibrous tissue. As described on page 992, this disorder predisposes to ventricular tachyarrhythmias. It has an estimated prevalence is 1 in 5000 and is a cause of sudden death, particularly in younger people (Elliott, 2008). The additional risk of pregnancy in women with arrhythmogenic right ventricular cardiomyopathy is unknown. However, based on a systematic review, Krul and associates (2011) advise against pregnancy.

Restrictive Cardiomyopathy

This inherited cardiomyopathy is probably the least common type. It is characterized by a ventricular filling pattern in which increased myocardial stiffness causes ventricular pressure to rise precipitously with only a small increase in volume (Elliott, 2008). Due to the severe clinical course in nonpregnant patients and the poor prognosis in general, pregnancy is not advised (Krul, 2011).

HEART FAILURE

Regardless of the underlying condition that causes cardiac dysfunction, women who develop peripartum heart failure almost always have obstetrical complications that either contribute to or precipitate heart failure. For example, preeclampsia is common and may precipitate afterload failure. High-output states caused by hemorrhage and acute anemia increase cardiac workload and magnify the physiological effects of compromised ventricular function. Similarly, infection and sepsis syndrome increase cardiac output and oxygen utilization tremendously, and sepsis can depress myocardial function (Chap. 47, p. 948).

As described in Chapter 50 (p. 1003), in many populations, chronic hypertension with superimposed preeclampsia is the most frequent cause of heart failure in pregnant women. Many of these women have concentric left ventricular hypertrophy. In some, mild antecedent undiagnosed hypertension causes covert cardiomyopathy, and when superimposed preeclampsia develops, together they may cause otherwise inexplicable peripartum heart failure. As discussed throughout Chapter 48 (p. 963), obesity is a common cofactor with chronic hypertension, and it leads to eccentric ventricular hypertrophy. In the Framingham Heart Study, obesity alone was associated with a doubling of the heart failure risk in nonpregnant individuals (Kenchaiah, 2002).

■ Diagnosis

Congestive heart failure can have a gradual onset or may present as acute “flash” pulmonary edema. The first warning sign is likely to be persistent basilar rales, frequently accompanied by a nocturnal cough (Jesup, 2003). A sudden decline in the ability to complete usual duties, increased dyspnea on exertion, and/or attacks of smothering with cough are symptoms of serious heart failure. Clinical findings may include hemoptysis, progressive edema, tachypnea, and tachycardia. Dyspnea is universal, and other symptoms include orthopnea, palpitations, and substernal chest pain (Sheffield, 1999). Hallmark findings usually include cardiomegaly and pulmonary edema (see Fig. 49-5). Acutely, there is usually systolic failure, and echocardiographic findings include an ejection fraction < 0.45 or a fractional shortening < 30 percent, or both, and an end-diastolic dimension > 2.7 cm/m² (Hibbard, 1999). Coincidental diastolic failure may also be found, depending on the underlying cause.

■ Management

Pulmonary edema from heart failure usually responds promptly with diuretic administration to reduce preload. Hypertension is common, and afterload reduction is accomplished with hydralazine or another vasodilator. Because of marked fetal effects, angiotensin-converting enzyme inhibitors are withheld until the woman is delivered (Chap. 12, p. 247). With chronic heart failure, there is a high incidence of associated thromboembolism, and thus prophylactic heparin is often recommended.

Left ventricular assist devices (LVADs) are employed more frequently for acute and chronic heart failure treatment. However, there are only a few reports describing their use during pregnancy (LaRue, 2011; Sims, 2011). *Extracorporeal membrane oxygenation (ECMO)* was reported to be lifesaving in a woman with fulminating cardiomyopathy (Smith, 2009).

INFECTIVE ENDOCARDITIS

Bacterial infection of a heart valve involves cardiac endothelium and usually results in valvular vegetations. In this country, those at greatest risk are women with congenital heart lesions, intravenous drug use, degenerative valve disease, and intracardiac devices (Karchmer, 2012). *Subacute bacterial endocarditis* usually is due to a low-virulence bacterial infection superimposed on an underlying structural lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most often viridans-group streptococci or *Staphylococcus* or *Enterococcus* species. Among intravenous drug abusers and those with catheter-related infections, *Staphylococcus aureus* is the predominant organism. *Staphylococcus epidermidis* frequently causes prosthetic valve infections. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may occasionally cause acute, fulminating disease. Antepartum endocarditis has also been described with *Neisseria sicca* and *Neisseria mucosa*, the latter causing maternal death (Cox, 1988; Deger, 1992). Only a few cases of group B streptococcal endocarditis have been described (Kangavari, 2000). Endocarditis due to *Escherichia coli* following cesarean delivery was described in an otherwise healthy young woman (Kulaš, 2006).

Diagnosis

Endocarditis symptoms are variable and often develop insidiously. Fever, often with chills, is seen in 80 to 90 percent of cases, a murmur is heard in 80 to 85 percent, and anorexia, fatigue, and other constitutional symptoms are common. The illness is frequently described as “flulike” (Karchmer, 2012). Other findings are anemia, proteinuria, and manifestations of embolic lesions, including petechiae, focal neurological manifestations, chest or abdominal pain, and ischemia in an extremity. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is found, and a high index of suspicion is necessary.

Diagnosis is made using the *Duke criteria*, which include positive blood cultures for typical organisms and evidence of endocardial involvement (Hoen, 2013; Pierce, 2012). Echocardiography may be diagnostic, but lesions < 2 mm in diameter or those on the tricuspid valve may be missed. If uncertain, transesophageal echocardiography (TEE) is accurate and informative. Importantly, a negative echocardiographic study does not exclude endocarditis.

Management

Treatment is primarily medical with appropriate timing of surgical intervention if necessary. Knowledge of the infecting organism and its sensitivities is imperative for sensible antimicrobial selection. Guidelines for appropriate antibiotic treatment are published by professional societies and are updated regularly (Hoen, 2013). Most streptococci are sensitive to penicillin G, ceftriaxone, or vancomycin given intravenously for 4 to 6 weeks, along with gentamicin for 2 to 4 weeks. Complicated infections are treated longer, and women allergic to penicillin are either desensitized or given intravenous ceftriaxone or vancomycin for 4 weeks. Staphylococci, enterococci, and other organisms are treated according to microbial sensitivity for 4 to 6 weeks (Darouiche, 2004; Karchmer, 2012). Prosthetic valve infections are usually treated for 6 weeks. Recalcitrant bacteremia and heart failure due to valvular dysfunction are but a few reasons that persistent valvular infection may require replacement.

Endocarditis in Pregnancy

Infective endocarditis is uncommon during pregnancy and the puerperium. Treatment is the same as that described above. During a 7-year period, the incidence of endocarditis at Parkland Hospital was approximately 1 in 16,000 births, and two of seven women died (Cox, 1988). From their reviews, Seaworth (1986) and Cox (1989) cited a maternal mortality rate of 25 to 35 percent.

Endocarditis Prophylaxis

For years, patients with real or imagined heart valve problems were given periprocedural antibiotic prophylaxis for endocarditis. This was despite the questioned efficacy of antimicrobial prophylaxis. Currently, however, recommendations are more stringent. The American Heart Association recommends prophylaxis for dental procedures in those with prosthetic valves; prior endocarditis; unrepaired or incompletely repaired cyanotic heart defects or during the 6 months following complete repair; and valvulopathy after heart transplantation (Wilson, 2007). In

TABLE 49-10. Antibiotic Prophylaxis for Infective Endocarditis in High-Risk Patients

ACOG (2011a):

Standard (IV): ampicillin 2 g or cefazolin or ceftriaxone 1 g
Penicillin-allergic (IV): cefazolin or ceftriaxone 1 g or
clindamycin 600 mg
Oral: amoxicillin 2 g

American Heart Association (Wilson, 2007):

Standard: ampicillin 2 g IV or IM or amoxicillin 2 g PO
Penicillin-allergic: clarithromycin or azithromycin 500 mg
PO; cephalexin 500 mg PO; clindamycin 600 mg PO,
IV, or IM; or cefazolin or ceftriaxone 1 g IV or IM

ACOG = American College of Obstetricians and Gynecologists; IM = intramuscular; IV = intravenous; PO = orally.

agreement with this, the American College of Obstetricians and Gynecologists (2011a) does not recommend endocarditis prophylaxis for either vaginal or cesarean delivery in the absence of pelvic infection. Exceptions are the small subset of patients cited above. Women at highest risk for endocarditis are those with cyanotic cardiac disease, prosthetic valves, or both.

When indicated, and for women not already receiving intrapartum antimicrobial therapy for another indication that would also provide coverage against endocarditis, prophylactic regimens are shown in [Table 49-10](#). These are administered as close to 30 to 60 minutes before the anticipated delivery time as is feasible. Despite these new recommendations, prophylaxis is still overused, likely because of prior liberal recommendations. In a study from one institution, only six of 50 women who received antibiotics for endocarditis prophylaxis were judged to have an appropriate indication (Pocock, 2006).

ARRHYTHMIAS

Both preexisting and new-onset cardiac arrhythmias are often encountered during pregnancy, labor, delivery, and the puerperium (Gowda, 2003). In a study of 73 women with a history of supraventricular tachycardia, paroxysmal atrial flutter or fibrillation, or ventricular tachycardia, recurrence rates during pregnancy were 50, 52, and 27 percent, respectively (Silversides, 2006). The mechanism(s) responsible for the increased incidence of arrhythmias during pregnancy are not well elucidated. According to Eghbali and associates (2006), adaptive electric cardiac remodeling of potassium-channel genes may be important. Perhaps the normal but mild hypokalemia of pregnancy and/or the physiological increase in heart rate serves to induce arrhythmias (Chap. 4, p. 58). Alternatively, detection of arrhythmias may be increased because of the frequent visits typical of normal prenatal care.

Bradyarrhythmias

Slow heart rhythms, including complete heart block, are compatible with a successful pregnancy outcome. Some women

with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary (Hidaka, 2006). In our experiences, as well as those of Hidaka (2011) and Jaffe (1987) and their associates, women with permanent artificial pacemakers usually tolerate pregnancy well. With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

■ Supraventricular Tachycardias

The most common arrhythmia seen in reproductive-aged women is *paroxysmal supraventricular tachycardia* (Robins, 2004). If diagnosed when nonpregnant, approximately a third of women have an occurrence during pregnancy (Maxwell, 2010). Conversely, rarely do *atrial fibrillation* and *atrial flutter* present for the first time during pregnancy. Indeed, new-onset atrial fibrillation should prompt a search for underlying etiologies including cardiac anomalies, hyperthyroidism, pulmonary embolism, drug toxicity, and electrolyte disturbances (DiCarlo-Meacham, 2011). Major complications include embolic stroke, and when associated with mitral stenosis, pulmonary edema may develop in later pregnancy if the ventricular rate is increased.

Treatment of supraventricular tachycardias include vagal maneuvers—Valsalva, carotid sinus massage, bearing down, and immersion of the face in ice water—which serve to increase vagal tone and block the atrioventricular node (Link, 2012). Intravenous adenosine is a very short-acting endogenous nucleotide that also blocks atrioventricular nodal conduction. Our experiences are similar to those of others in that adenosine is safe and effective for cardioversion in hemodynamically stable pregnant women (Maxwell, 2010; Robins, 2004). Transient fetal bradycardia has been described with adenosine (Dunn, 2000).

Electrical cardioversion with standard energy settings is not contraindicated in pregnancy, but vigilance is important. Barnes and associates (2002) described a case in which direct current cardioversion led directly to a sustained uterine contraction and fetal bradycardia. If cardioversion fails or is unsafe because of concurrent thrombus, then long-term anticoagulation and heart rate control with medication are necessary (DiCarlo-Meacham, 2011).

Pregnancy may predispose otherwise asymptomatic women with *Wolff-Parkinson-White (WPW) syndrome* to exhibit arrhythmias (Maxwell, 2010). In a study of 25 women who had supraventricular tachycardia diagnosed before pregnancy, three of 12 women with WPW syndrome and six of 13 without the condition developed supraventricular tachycardia during pregnancy. In some patients, accessory pathway ablation may be indicated (Pappone, 2003). For this, the typical fluoroscopic procedure-related fetal radiation dose is < 1 cGy (Damilakis, 2001).

■ Ventricular Tachycardia

This form of arrhythmia is uncommon in healthy young women without underlying heart disease. Brodsky and associates (1992) described seven pregnant women with new-onset

ventricular tachycardia and reviewed 23 reports. Most of these women were not found to have structural heart disease. In 14 cases, tachycardia was precipitated by physical exercise or psychological stress. Abnormalities found included two cases of myocardial infarction, two of prolonged QT interval, and anesthesia-provoked tachycardia in another. They concluded that pregnancy events precipitated the tachycardia and recommended β -blocker therapy for control. As previously discussed, arrhythmogenic right ventricular dysplasia will result occasionally in ventricular tachyarrhythmias (Lee, 2006). If unstable, emergency cardioversion is indicated, and standard adult energy settings are adequate (Jeejeebhoy, 2011; Nanson, 2001).

■ Prolonged QT-Interval

This conduction anomaly may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes* (Roden, 2008). Two studies involving a combined total of 502 pregnant women with *long QT syndrome* both reported a significant increase in cardiac events postpartum but not during pregnancy (Rashba, 1998; Seth, 2007). It was hypothesized that the normal increase in heart rate during pregnancy may be partially protective. Paradoxically, β -blocker therapy has been shown to decrease the risk of torsades de pointes in patients with long QT syndrome and should be continued during pregnancy and postpartum (Gowda, 2003; Seth, 2007). Importantly, many medications, including some used during pregnancy such as azithromycin, erythromycin, and clarithromycin, may predispose to QT prolongation (Al-Khatib, 2003; Ray, 2012; Roden, 2004).

DISEASES OF THE AORTA

■ Aortic Dissection

Marfan syndrome and coarctation are two aortic diseases that place the pregnant woman at increased risk for aortic dissection. Indeed, half of cases in young women are related to pregnancy (O'Gara, 2004). Other risk factors are bicuspid aortic valve and Turner or Noonan syndrome. Pepin and colleagues (2000) also reported a high rate of aortic dissection or rupture in patients with Ehlers-Danlos syndrome (Chap. 59, p. 1181). Although the mechanism(s) involved are unclear, the initiating event is a tear in the aorta's intima layer, followed by hemorrhage into the media layer, and finally rupture.

In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing. Diminution or loss of peripheral pulses in conjunction with a recently acquired aortic insufficiency murmur is an important physical finding. The differential diagnosis of aortic dissection includes myocardial infarction, pulmonary embolism, pneumothorax, and aortic valve rupture as well as obstetrical catastrophes, especially placental abruption and uterine rupture (Lang, 1991).

More than 90 percent of patients with aortic dissection have an abnormal chest radiograph. Aortic angiography is the most definitive method for confirming the diagnosis. However, non-invasive imaging—sonography, computed tomography, and

magnetic resonance (MR) imaging—is used more frequently. The urgency of the clinical situation frequently dictates which procedure is best.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, and the aortic valve replaced if necessary. Distal dissections are more complex, and many may be treated medically. Survival in non-pregnant patients is not improved by elective repair of abdominal aortic aneurysms smaller than 5.5 cm (Lederle, 2002).

■ Marfan Syndrome

This autosomal dominant disorder has a high degree of penetrance. The incidence is 2 to 3 per 10,000 individuals and is without racial or ethnic predilection (Ammash, 2008). Prenatal diagnosis is usually possible using linkage analysis (Chap. 13, p. 277). The syndrome is due to abnormal *fibrillin*—a constituent of elastin—caused by any of dozens of mutations in the *FBN1* gene located on chromosome 15q21 (Biggin, 2004). Thus, Marfan syndrome is a connective-tissue disorder characterized by generalized tissue weakness that can result in dangerous cardiovascular complications. Because all tissues are involved, other defects are frequent and include joint laxity and scoliosis. Progressive aortic dilatation causes aortic valve insufficiency, and there may be infective endocarditis and mitral valve prolapse with insufficiency. Aortic dilatation and dissecting aneurysm are the most serious abnormalities. Early death is due either to valvular insufficiency and heart failure or to a dissecting aneurysm.

Effect of Pregnancy on Marfan Syndrome

In the past, case reports reflected biased outcomes, and the maternal mortality rate was inaccurately magnified (Elkayam, 1995). In a prospective evaluation of 21 women during 45 pregnancies cared for at the Johns Hopkins Hospital, only two had dissection, and one died postpartum from graft infection (Rossiter, 1995). Although there were no maternal deaths among 14 women followed by Rahman and coworkers (2003), two required surgical correction of an aortic aneurysm. These investigators concluded that aortic dilatation > 40 mm or mitral valve dysfunction are high-risk factors for life-threatening cardiovascular complications during pregnancy. Conversely, women with minimal or no dilatation, and those with normal cardiac function by echocardiography, are counseled regarding the small but serious potential risk of aortic dissection.

The aortic root usually measures approximately 2 cm, and during normal pregnancy, it increases slightly (Easterling, 1991). With Marfan syndrome, if aortic root dilatation reaches 4 cm, then dissection is more likely. If dilatation reaches 5 to 6 cm, then elective surgery should be considered before pregnancy (Gott, 1999; Williams, 2002). Prophylactic β -blocker therapy has become the standard medical approach for pregnant women with Marfan syndrome because it reduces hemodynamic stress on the ascending aorta and slows the rate of dilation (Simpson, 2012). Vaginal delivery with regional analgesia and an assisted second stage seem safe for women with an aortic root diameter < 4 cm.

When the aortic root measures 4 to 5 cm or greater, elective cesarean delivery is recommended with consideration of postpartum replacement of the proximal aorta with a prosthetic graft (Simpson, 2012). Successful aortic root replacement during pregnancy has been described, but the surgery has also been associated with fetal hypoxic-ischemic cerebral damage (Mul, 1998; Seeburger, 2007). There are a number of case reports describing emergency cesarean deliveries in women with acute type A dissection that was repaired successfully at the time of delivery (Guo, 2011; Haas, 2011; Papatsonis, 2009).

Perinatal Outcomes

Obstetrical outcomes of 63 women with Marfan syndrome with a total of 142 pregnancies were reviewed by Meijboom and coworkers (2006). Of 111 women delivered after 20 weeks, 15 percent had preterm delivery, and 5 percent had preterm prematurely ruptured membranes. There were eight perinatal deaths, and half of the neonate survivors were subsequently diagnosed with Marfan syndrome.

■ Aortic Coarctation

This is a relatively rare lesion often accompanied by abnormalities of other large arteries. A fourth of affected patients have a bicuspid aortic valve, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the coarctation remodels and expands, often to a striking extent, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings include hypertension in the upper extremities but normal or reduced pressures in the lower extremities. Several authors have described diagnosis during pregnancy using MR imaging (Dizon-Townson, 1995; Sherer, 2002; Zwiers, 2006).

Effect of Pregnancy on Coarctation

Major complications include congestive heart failure after longstanding severe hypertension, bacterial endocarditis of the bicuspid aortic valve, and aortic rupture. Because hypertension may worsen in pregnancy, antihypertensive therapy using β -blocking drugs is usually required. Aortic rupture is more likely late in pregnancy or early postpartum. Cerebral hemorrhage from *circle of Willis aneurysms* may also develop. Beauchesne and associates (2001) described the outcomes of 188 pregnancies from the Mayo Clinic. A third had hypertension that was related to significant coarctation gradients, and one woman died from dissection at 36 weeks. Using the United States Nationwide Inpatient Sample between 1998 and 2007, Krieger and colleagues (2011) studied nearly 700 deliveries among women with coarctation. Hypertensive complications of pregnancy were increased three- to fourfold in women with coarctation. Importantly, almost 5 percent of women with coarctation had an adverse cardiovascular outcome—maternal death, heart failure, arrhythmia, cerebrovascular or other embolic event—compared with 0.3 percent of controls. A total of 41 percent of women with coarctation underwent cesarean delivery compared with 26 percent of controls.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. Some authors have recommended that resection of the coarctation be undertaken during pregnancy to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant risk, especially for the fetus, because all the collaterals must be clamped for variable periods.

Some authors recommend cesarean delivery to prevent transient blood pressure elevations that might lead to rupture of the aorta or coexisting cerebral aneurysms. Available evidence, however, suggests that cesarean delivery should be limited to obstetrical indications.

ISCHEMIC HEART DISEASE

United States statistics indicate that the mortality rate from coronary heart disease among all women aged 35 to 44 years has been increasing by an average of 1.3 percent per year since 1997 (Ford, 2007). Still, *coronary artery disease* and *myocardial infarction* are rare complications of pregnancy. In a review of California hospital discharge records between 1991 and 2000, Ladner and associates (2005) reported myocardial infarction in 2.7 per 100,000 deliveries. James and coworkers (2006) used the Nationwide Inpatient Sample database and reported acute myocardial infarction in 6.2 per 100,000 deliveries. In Canadian hospitals between 1970 and 1998, MacArthur and colleagues (2006) reported the incidence of peripartum myocardial ischemia to be 1.1 per 100,000 deliveries.

Pregnant women with coronary artery disease commonly have classic risk factors such as diabetes, smoking, hypertension, hyperlipidemia, and obesity (James, 2006). As an aside, a large, prospective population-based study from Germany found that women who had experienced recurrent spontaneous abortions or stillbirths were also at a substantially higher risk of myocardial infarction later in life (Kharazmi, 2011). Although the reason(s) for this association were not specifically studied, there are a number of conditions—such as certain thrombophilias—which are associated with both (Chap. 59, p. 1173).

Bagg and colleagues (1999) reviewed the course of 22 diabetic pregnant women with White class H ischemic heart disease (Chap. 57, p. 1126). These and other authors documented unusually high mortality rates in those who suffered myocardial infarction (Pombar, 1995; Reece, 1986). Coronary artery occlusion in two pregnant smokers with hypercholesterolemia has been described following a routine intramuscular injection of 0.5-mg ergometrine (Mousa, 2000; Sutaria, 2000). Finally, Schulte-Sasse (2000) described myocardial ischemia associated with prostaglandin E₁ vaginal suppositories for labor induction.

Diagnosis during pregnancy is not different from the nonpregnant patient. Measurement of serum levels of the cardiac-specific contractile protein *troponin I* provides an accurate diagnosis (Shade, 2002). Troponin I was reported by Shivvers and colleagues (1999) to be undetectable near term (Appendix, p. 1291). Kosciwa and colleagues (2002) found that levels do not increase following either vaginal or cesarean delivery. Importantly, however, levels of troponin I are higher in preeclamptic women than in normotensive controls (Atalay, 2005; Yang, 2006).

Pregnancy with Prior Ischemic Heart Disease

The advisability of pregnancy after a myocardial infarction is unclear. Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy in most of these women seems inadvisable. Vinatier and associates (1994) reviewed 30 pregnancies in women who had sustained an *infarction remote from pregnancy*. Although none of these women died, four had congestive heart failure and four had worsening angina during pregnancy. Pombar and coworkers (1995) reviewed outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy increases cardiac workload, and all of these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography before conception. If there is no significant ventricular dysfunction, pregnancy will likely be tolerated.

For the woman who becomes pregnant before these studies are performed, echocardiography should be done. Exercise tolerance testing may be indicated, and radionuclide ventriculography results in minimal radiation exposure for the fetus (Chap. 46, p. 932). Zaidi and associates (2008) described the use of serial T2-weighted cardiovascular MR imaging in a woman who suffered a myocardial infarction during the first trimester to better define the extent and severity of infarction.

Myocardial Infarction During Pregnancy

The mortality rate with myocardial infarction in pregnancy is increased compared with age-matched nonpregnant women. Hankins and coworkers (1985) reviewed 68 cases and reported an overall maternal mortality rate of approximately 35 percent. Hands and colleagues (1990) found an overall mortality rate of 30 percent, and this was highest in the third trimester. Later studies are more reassuring. In a Nationwide Inpatient Sample study totaling 859 pregnancies complicated by acute infarction during 2000 to 2002, there was a 5.1-percent death rate (James, 2006). Women who sustain an infarction less than 2 weeks before delivery are at especially high risk of death due to the increased myocardial demand during labor or delivery (Esplin, 1999).

Treatment is similar to that for nonpregnant patients (Maxwell, 2010; Roth, 2008). Acute management includes administration of oxygen, nitroglycerin, low-dose aspirin, heparin, and β -blocking drugs with close blood pressure monitoring. Lidocaine is used to suppress malignant arrhythmias and calcium-channel blockers or β -blockers are given if indicated. *Tissue plasminogen activator* has been used in pregnant women, but only those remote from delivery because of hemorrhage. In some women, invasive or surgical procedures may be indicated because of acute or unrelenting disease. A number of reports describe successful percutaneous transluminal coronary angioplasty and stent placement during pregnancy (Balmain, 2007; Duarte, 2011; Dwyer, 2005). Cardiopulmonary resuscitation

may be required, and maternal and perinatal effects are discussed in Chapter 47 (p. 956).

If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and epidural analgesia is ideal for labor (Esplin, 1999).

PREGNANCY-AGGRAVATED HYPERTENSION OR SUPERIMPOSED PREECLAMPSIA	1007
FETAL ASSESSMENT	1007
DELIVERY	1007
POSTPARTUM HYPERTENSION	1008

Chronic hypertension is one of the most common serious complications encountered during pregnancy. This is not surprising because, according to the National Health and Nutrition Examination Survey (NHANES) from the Centers for Disease Control and Prevention (2011), the average prevalence of hypertension in women aged 18 to 39 years is approximately 7 percent. The incidence of chronic hypertension in pregnancy is variable depending on population vicissitudes. In a study of more than 56 million deliveries from the Nationwide Patient Sample, 1.8 percent of births in 2007 and 2008 were in women with chronic hypertension (Bateman, 2012). The incidence was 1.0 percent in more than 530,000 singleton pregnancies in California in 2006 (Yanit, 2012). And according to the American College of Obstetricians and Gynecologists (2012), the incidence may be up to 5 percent. Despite this substantive prevalence, optimal management has not been well studied. It is known that chronic hypertension usually improves during early pregnancy. This is followed by

variable behavior later in pregnancy and importantly, by its unpredictable development of superimposed preeclampsia, which carries increased risks for maternal and perinatal morbidity and mortality.

GENERAL CONSIDERATIONS

To define chronic hypertension, first, the range of normal blood pressure levels must be established. This is not a simple task because, like all polygenic-determined biological variants, blood pressure norms differ between populations. And, within these norms, there are wide variations between individuals. Moreover, these are also greatly influenced by numerous epigenetic factors. For example, blood pressure not only varies between races and gender, but the pressures—especially systolic—increase directly with increasing age and weight. Pragmatically then, normal adults have a wide range of blood pressures, but so do those with chronic hypertension.

After these variables are acknowledged, an important consideration for any population is the attendant risks of chronic hypertension. There is an increasing incremental rate of cardiovascular, cerebrovascular, and renal disease that follows increasing levels of both diastolic and systolic pressures (Kotchen, 2012).

Definition and Classification

For the foregoing reasons, it seems logical that chronic hypertension would be defined as some level of sustained blood pressure that is associated with an increase in acute or long-term adverse effects. For many years in the United States, these values were based primarily on actuarial tables constructed using data derived from white adult males and compiled by life insurance companies. These “norms” disregarded interrelated factors such as ethnicity and gender as well as other important covariants. The importance of race, for example, was emphasized by

TABLE 50-1. Eighth Joint National Committee (JNC 8)—2014 Chronic Hypertension Guidelines and Recommendations

Evidence-based recommendations from randomized controlled trials
Definitions hypertension and prehypertension not addressed
Lifestyle modifications endorsed from the Lifestyle Work Group (Eckel, 2013)
Recommend selection among four specific medication classes: angiotensin-converting enzyme inhibitors (ACE-I), angiotensin-receptor blockers (ARB), calcium-channel blockers, or diuretics:
General population < 60 years old—initiate pharmacological therapy to lower diastolic pressure \leq 90 mm Hg and systolic pressure \leq 140 mm Hg
Diabetics—lower pressure < 140/90 mm Hg
Chronic kidney disease—lower pressure < 140/90 mm Hg. Also add ACE-I or ARB to improve outcomes
General nonblack population—initial therapy should include thiazide-type diuretic, calcium-channel blocker, ACE-I, or ARB
General black population—primary antihypertensive therapy should include thiazide-type diuretic or calcium-channel blocker
Assess monthly, and after 1 month, if goals not met, then increase primary drug dose or add second drug. If no response, increase either or add third drug; then if no response, refer to hypertension specialist

Summarized from James, 2013.

Kotchen (2012), who cites statistics derived from 65 million American adults. In this study, the incidence of hypertension—defined as blood pressure > 140/90 mm Hg—was 34 percent in blacks, 29 percent in whites, and 21 percent in Mexican Americans.

For many years, guidelines for diagnosis, classification, and management of chronic hypertension have been promulgated by the Joint National Committee. In 2008, the National Heart Lung and Blood Institute discontinued these guidelines, and the Joint National Committee 8 (JNC 8) was instead asked to provide an evidence-based review (James, 2013). Findings pertinent to caring for young women with chronic hypertension are summarized in [Table 50-1](#).

■ Treatment and Benefits for Nonpregnant Adults

There are proven benefits that accrue with treatment of otherwise normal adults who have sustained hypertension. A myriad studies evaluating many combinations of antihypertensive therapy have been conducted with salutary results. Some of these include the ACCORD, ASCOT, ACCOMPLISH, ALLHAT, SPRINT, TOHMS, TROPY, and VALUE studies. Importantly, these trials evaluated monotherapy versus combination therapeutic regimens as well as ethnospecific benefits. Most evaluated cardiovascular outcomes, but many also confirmed risk reduction in cerebrovascular accidents, renal insufficiency, and overall mortality rates. Because of these incontrovertible benefits, the JNC 8 recommends the treatment outlined in [Table 50-1](#).

Thus, even for mildly elevated blood pressures cited in [Table 50-1](#), interventions to reduce pressure are beneficial. Moreover, it is clear that antihypertensive therapy in nonpregnant reproductive-aged women with sustained diastolic pressures \geq 90 mm Hg would be considered standard. Not clear from these observations, however, is what constitutes the best

management for the woman being treated who contemplates pregnancy, or the best management of the woman undergoing treatment who becomes pregnant, or the woman who is first identified to have chronic hypertension during pregnancy (August, 2014). In these and similar women, the benefits and safety of instituting antihypertensive therapy are less clear, as subsequently discussed.

■ Preconceptional Counseling

Women with chronic hypertension should ideally be counseled before pregnancy. The duration of hypertension, degree of blood-pressure control, and current therapy are ascertained. Home measurement devices should be checked for accuracy. Those who require multiple medications for control or those who are poorly controlled are also at increased risk for adverse pregnancy outcomes. General health, daily activities, and dietary habits are also assessed as shown in [Table 50-2](#).

In those with hypertension for more than 5 years or in diabetic women, cardiovascular and renal function should be assessed (August, 2014; Gainer, 2005). Women with evidence for organ dysfunction or those with prior adverse events such as cerebrovascular accident, arrhythmias, ventricular failure, or myocardial infarction are at markedly increased risk for a recurrence or worsening during pregnancy. Renal function is assessed by serum creatinine measurement, and proteinuria is quantified if the urine spot protein/creatinine ratio is abnormally high (Hladunewich, 2011). The Working Group Report on High Blood Pressure in Pregnancy (2000) of the National Heart, Lung, and Blood Institute concluded that the risks of fetal loss and accelerated deterioration of renal disease are increased if serum creatinine level is above 1.4 mg/dL (Chap. 53, p. 1061).

Although pregnancy is considered by many to be contraindicated in women with severe, poorly controlled hypertension, there is not a consensus regarding this. Certainly, pregnancy

TABLE 50-2. Lifestyle Modifications for Hypertensive Patients—American Heart Association and American College of Cardiology

Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts; limits sweets and red meats—e.g. DASH dietary pattern, USDA Food Pattern, or the AHA Diet
Lower sodium intake—consume no more than 2400 mg sodium/day; 1500 mg/day desirable
Engage in aerobic physical activity three to four sessions per week, lasting on average 40 minutes per session, and involving moderate-to-vigorous intensity physical activity

AHA = American Heart Association; DASH = Dietary Approaches to Stop Hypertension; USDA = United States Department of Agriculture. Summarized from Eckel, 2013.

is at least relatively contraindicated in women who maintain persistent diastolic pressures of ≥ 110 mm Hg despite therapy, who require multiple antihypertensives, or who have a serum creatinine > 2 mg/dL. Even stronger contraindications include prior cerebrovascular accident, myocardial infarction, or cardiac failure.

DIAGNOSIS AND EVALUATION IN PREGNANCY

Classification of the hypertensive disorders complicating pregnancy is discussed in Chapter 40 (p. 728). Women are diagnosed with chronic hypertension if it is documented to precede pregnancy or if hypertension is identified before 20 weeks' gestation. In some women without overt chronic hypertension, there is a history of repeated pregnancies complicated by gestational hypertension with or without the preeclampsia syndrome. Each is a risk marker for latent chronic hypertension, and this is especially so for preeclampsia, especially early-onset preeclampsia. In many ways, gestational hypertension is analogous to gestational diabetes in that such women have a *chronic hypertensive diathesis*, in which heredity plays a major role (Chap. 40, p. 769).

Although uncommon, secondary causes of hypertension are always a possibility in these women. Thus, consideration is given to an underlying pheochromocytoma, connective-tissue disease, Cushing syndrome, chronic renal disease, and myriad other causes. That said, most pregnant women with antecedent hypertension will have uncomplicated disease. As discussed above, some women—especially those with long-term or untreated hypertension—have complications that increase the risk of adverse pregnancy events. Thus, if not already accomplished, assessment during pregnancy is done for the cardiovascular system, the kidneys, and the cerebrovascular circulation.

Associated Risk Factors

Several factors increase the likelihood that pregnant women will have chronic hypertension. Three of those most frequently cited are ethnicity, obesity, and diabetes. As previously discussed, chronic hypertension has a population incidence that is highest in black and lower in white and Mexican-American women (Kotchen, 2012). Related to this, hundreds of blood pressure-related phenotypes and genomic regions have been identified,

including candidate genes for preeclampsia and chronic hypertension (Cowley, 2006; Lévesque, 2004).

The *metabolic syndrome* with superimposed preeclampsia is a risk marker for persistent hypertension postpartum (Spaan, 2012). This is not surprising because obesity may increase the prevalence of hypertension tenfold, and it is an important factor predisposing to chronic hypertension (Chap. 48, p. 963). In addition, obese women are more likely to develop superimposed preeclampsia. Diabetes is also prevalent in chronically hypertensive women, and its interplay with obesity and preeclampsia is overwhelming. In the study of more than 56 million births cited above, the most common comorbidities associated with chronic hypertension were pregestational diabetes—6.6 percent, thyroid disorders—4.1 percent, and collagen-vascular disease—0.6 percent (Bateman, 2012). Similar comorbidities were described by Cruz and associates (2011).

Effects of Pregnancy on Chronic Hypertension

Blood pressure falls in early pregnancy in most women with chronic hypertension. It rises again during the third trimester (Fig. 50-1). According to studies by Tihtonen and coworkers

FIGURE 50-1 Mean systolic and diastolic blood pressures across pregnancy in 107 untreated chronically hypertensive women (yellow) compared with blood pressures across pregnancy in 4589 healthy nulliparous women (blue). (Data from August, 2014; Levine, 1997; Sibai, 1990a.)

(2007), women with chronic hypertension have persistently elevated vascular resistance and possibly a reduced intravascular volume increase. There is no doubt that adverse outcomes in these women are dependent largely on whether superimposed preeclampsia develops. This may be related to observations reported by Hibbard and colleagues (2005, 2014) that arterial mechanical properties are most marked in women with superimposed preeclampsia.

ADVERSE PREGNANCY EFFECTS

Chronic hypertension is associated with several adverse maternal and perinatal outcomes listed in [Table 50-3](#). The recurring theme is that these are directly related to severity and duration of hypertension before pregnancy and whether superimposed preeclampsia develops, especially early in gestation. In women with mild chronic hypertension, outcomes are also related to blood pressure levels during pregnancy (Ankumah, 2013).

Maternal Morbidity and Mortality

Most women whose hypertension is well controlled with monotherapy before pregnancy will do well. Even these women, however, are at increased risk for adverse outcomes. Complications are more likely with severe baseline hypertension and especially with documented end-organ damage (Czeizel, 2011; Odibo, 2013). In a study of pregnancy outcomes in nearly 30,000 chronically hypertensive women, Gilbert and associates (2007) reported markedly increased maternal morbidity including stroke, pulmonary edema, and renal failure. These observations were verified in the report from the Nationwide Patient Sample of more than 56 million deliveries by Bateman and colleagues (2012). Complications of hypertension included stroke—2.7 per 1000, acute renal failure—5.9 per 1000, pulmonary edema—1.5 per 1000, mechanical ventilation—3.8 per 1000, and in-house maternal mortality—0.4 per 1000. The contribution of hypertension to pregnancy-related strokes is discussed in Chapter 60 (p. 1191) and to hypertensive and idiopathic peripartum hypertensive cardiomyopathy in Chapter 49 (p. 988).

TABLE 50-3. Some Adverse Effects of Chronic Hypertension on Maternal and Perinatal Outcomes

Maternal	Perinatal
Superimposed preeclampsia	Fetal death
HELLP syndrome	Growth restriction
Stroke	Preterm delivery
Acute kidney injury	Neonatal death
Heart failure	Neonatal morbidity
Hypertensive cardiomyopathy	
Myocardial infarction	
Placental abruption	
Maternal death	

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

Pregnancy-aggravated hypertension may be due to gestational hypertension or to superimposed preeclampsia. In either instance, blood pressures can be dangerously elevated. As emphasized by Clark and Hankins (2012), systolic pressure ≥ 160 mm Hg or diastolic pressure ≥ 110 mm Hg will rapidly cause renal or cardiopulmonary dysfunction or cerebral hemorrhage. With superimposed severe preeclampsia or eclampsia, the maternal prognosis is poor unless the pregnancy is ended. Placental abruption is a common and serious complication (Chap. 41, p. 793). In addition to hypertensive heart failure mentioned above, aortic dissection has been described by Weissman-Brenner and coworkers (2004) and is discussed in Chapter 49 (p. 992).

Chronic hypertension has been associated with a fivefold risk for maternal death (Gilbert, 2007). This is emphasized by the report by Berg (2010) describing 4693 pregnancy-related deaths in the United States from 1998 through 2005. Hypertensive disorders, including chronic hypertension and preeclampsia syndrome, accounted for 12.3 percent of these deaths. Undoubtedly related were other causes of death such as cardiovascular conditions—12.4 percent, cerebrovascular conditions—6.3 percent, and cardiomyopathy—11.5 percent. Moodley (2007) reported similar findings with 3406 maternal deaths from South Africa. Interestingly, Sibai and associates (2011) reported that chronically hypertensive women with a history of preeclampsia were not at higher risk for complications compared with hypertensive women without such a history.

Superimposed Preeclampsia

Because there is no precise definition of superimposed preeclampsia in women with chronic hypertension, the reported incidence is variable. The risk is directly related to the severity of baseline hypertension. In a Maternal-Fetal Medicine Units Network trial, Caritis and coworkers (1998) identified superimposed preeclampsia in 25 percent. It was 29 percent in the California database study cited above (Yanit, 2012). According to the American College of Obstetricians and Gynecologists (2012), mild chronic hypertension has a 20-percent incidence for superimposed preeclampsia, whereas with severe hypertension, it is 50 percent. August and colleagues (2014) posit that this predilection may be because of similarities of genetic, biochemical, and metabolic abnormalities. In the study cited above, a history of superimposed preeclampsia did not increase the risk for recurrence, however, it was a marker for increased preterm delivery (Sibai, 2011).

Thus far, prognostic and predictive tests for superimposed preeclampsia have been disappointing when used clinically (American College of Obstetricians and Gynecologists, 2012; Conde-Agudelo, 2014; Zeeman, 2003). For example, Di Lorenzo and colleagues (2012) studied serum markers for Down syndrome and reported a sensitivity of 60 percent with a 20-percent false-positive rate. Similar results were found using antiangiogenic factors to discriminate among chronic hypertension, gestational hypertension, and preeclampsia (Sibai, 2008; Woolcock, 2008). According to Elovitz and coworkers (2013), microRNA assays may prove valuable as predictors of pregnancy-associated hypertension. This subject is discussed further in Chapter 40 (p. 747).

Prevention of Superimposed Preeclampsia

Trials of various substances to prevent preeclampsia in women with chronic hypertension have generally been disappointing. Low-dose aspirin has been evaluated most frequently. In the Network study by Caritis and associates (1998) cited above, the incidence of superimposed preeclampsia, fetal-growth restriction, or both was similar in women given low-dose aspirin or placebo. That said, Duley (2007) and Meads (2008) and their colleagues performed Cochrane reviews and found that low-dose aspirin was beneficial in some high-risk women. Minimal benefits were also found from a metaanalysis (Askie, 2007). To the contrary, however, the PARIS Collaborative Group (2007) reviewed individual data from 33,897 pregnant women enrolled in 33 randomized trials of low-dose aspirin and reported that women with chronic hypertension derived no benefits.

Spinnato and coworkers (2007) randomly assigned 311 women with chronic hypertension to antioxidant treatment with vitamins C and E or to a placebo. A similar number in both groups developed preeclampsia—17 versus 20 percent, respectively.

Placental Abruptio

There seems to be no doubt that chronic hypertension increases the risk two- to threefold for premature placental separation (American College of Obstetricians and Gynecologists, 2012). As discussed in Chapter 41 (p. 793), the overall risk is one in 200 to 300 pregnancies, and this is increased to 1 in 60 to 120 pregnancies in women with chronic hypertension (Ananth, 2007; Cruz, 2011; Madi, 2012; Tuuli, 2011). This risk is increased further if the woman smokes or if she develops superimposed preeclampsia. The risk is highest with severe hypertension, and Vigil-De Gracia and colleagues (2004) reported it to be 8.4 percent. Most abruptions are in women with worsening gestational hypertension or superimposed preeclampsia. From the Norwegian Birth Registry, supplemental folic acid slightly decreased the abruption incidence in women with chronic hypertension (Nilsen, 2008).

Perinatal Morbidity and Mortality

From the foregoing, it is not surprising that almost all adverse perinatal outcomes are increased in women with chronic hypertension. Some of those from a Network study are shown in Figure 50-2. The increasing incremental adverse effects of rising blood pressure levels are apparent. Interestingly, Bánhidý and colleagues (2011) have provided data suggesting that severe hypertension may be associated with fetal esophageal atresia or stenosis. As expected, for the entire group of women, those who developed preeclampsia had substantially increased adverse outcome rates compared with those without preeclampsia.

The stillbirth frequency is substantively greater in most reports (Chap. 35, p. 663). In the Nationwide Patient Sample study, the stillbirth rate was 15.1 per 1000 births (Bateman, 2012). This is similar to the frequency of 18 per 1000 from a Norwegian study (Ahmad, 2012). The rate was increased two- to threefold in the California database study by Yanit and associates (2012).

Low-birthweight infants are common and due to preterm delivery, fetal-growth restriction, or both. In the California

FIGURE 50-2 Perinatal outcomes in 759 women with midrange chronic hypertension enrolled in a Maternal-Fetal Medicine Units Network study (Ankumah, 2013).

study, a fourth of fetuses were delivered preterm (Yanit, 2012). This and other studies attest to the increased risk for fetal-growth restriction, and the incidence averages 20 percent. Zetterström and coworkers (2006) reported a 2.4-fold risk for fetal-growth restriction in 2754 chronically hypertensive Swedish women compared with the risk in normotensive women. Broekhuijsen and associates (2012) found a 1.3-fold increased risk for 1609 Dutch nulliparas with chronic hypertension compared with that in normotensive controls. Fetal-growth dysfunction is more likely in the chronically hypertensive women who develop superimposed preeclampsia. In one study, Chappell and colleagues (2008) reported an almost 50-percent incidence of growth-restricted fetuses born to women with superimposed preeclampsia compared with only 21 percent in women without preeclampsia. Because worsening hypertension frequently mandates preterm delivery, neonates born to these women have a correspondingly high rate of intensive-care nursery admission.

All of these aforementioned adverse perinatal effects of chronic hypertension contribute to the increased perinatal mortality rate, which is three- to fourfold higher in pregnancies complicated by chronic hypertension compared with those of normotensive women (American College of Obstetricians and Gynecologists, 2012). In the Network study shown in Figure 50-2, the perinatal death rate was 31 per 1000 with mild hypertension, 72 per 1000 with moderate disease, and 100 per 1000 in women with severe chronic hypertension. Again as expected, the highest rates are in women who develop superimposed preeclampsia, for whom the risk doubled from 4 to 8 percent. And, if diabetes coexists with chronic hypertension, then preterm delivery, fetal-growth restriction, and perinatal mortality rates are increased even more (Gonzalez-Gonzalez, 2008; Yanit, 2012).

MANAGEMENT DURING PREGNANCY

The diagnosis of chronic hypertension in pregnancy should be confirmed. For example, Brown and associates (2005) reported

“white-coat” hypertension in a third of 241 women diagnosed in early pregnancy. Within this third, pregnancy outcomes were good, and only 8 percent developed preeclampsia.

Management goals for chronic hypertension include reductions of adverse maternal or perinatal outcomes just discussed. Treatment is targeted to prevent moderate or severe hypertension and to delay or ameliorate pregnancy-aggravated hypertension. To some extent, these goals can be achieved pharmacologically. Blood-pressure self-monitoring is encouraged, but for accuracy, automated devices must be properly calibrated (Brown, 2004; Staessen, 2004). Personal health modification includes dietary counseling and reduction of behaviors such as tobacco, alcohol, cocaine, or other substance abuse (see Table 50-2).

■ Blood Pressure Control

Women with *severe hypertension* must be treated for maternal neuro-, cardio-, and renoprotection regardless of pregnancy status (American College of Obstetricians and Gynecologists, 2012). This includes women with prior adverse outcomes such as cerebrovascular events, myocardial infarction, and cardiac or renal dysfunction. We agree with the philosophy of beginning antihypertensive treatment in otherwise healthy pregnant women with persistent systolic pressures > 150 mm Hg or diastolic pressures of 95 to 100 mm Hg or greater (August, 2014; Working Group Report, 2000). With end-organ dysfunction, treatment of diastolic pressures \geq 90 mm Hg is reasonable to mitigate further organ damage.

There are only sparse data indicating salutary effects on pregnancy outcomes with simply lowering blood pressure. These studies are relatively small and have widely varying inclusion and outcome criteria. In a Cochrane review of 46 of these studies that included a total of 4282 women, Abalos and coworkers (2007) confirmed that the risk for severe hypertension was lowered with therapy. There were, however, no differences in the frequencies of superimposed preeclampsia, eclampsia, abruption, preterm birth, fetal-growth restriction, or perinatal or maternal mortality. These studies do attest to the apparent safety of antihypertensive therapy except for angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (Chap. 12, p. 247). As emphasized by the Working Group Report (2000), there is a need for further trials in chronically hypertensive women.

“Tight Control”

During the past decade, the concept of *tight control* of blood pressure has been espoused as a means of optimizing maternal and perinatal outcomes. Such control is compared with that of glycemic control for management of the pregnant diabetic. In one study, El Guindy and Nabhan (2008) randomly assigned 125 pregnant women with mild chronic hypertension or gestational hypertension to rigid versus less strict blood pressure control. More women in the latter group developed severe hypertension, they had more hospital admissions, and they were delivered of infants at a lower mean gestational age than the tight-control group. Other than these preliminary observations, there are limited data concerning this type of treatment.

■ Antihypertensive Drugs

As concluded by the American College of Obstetricians and Gynecologists (2012), treatment during pregnancy has included every drug class, but there still is limited information regarding safety and efficacy (Czeizel, 2011; Podymow, 2011). Although many studies indicate increased perinatal adverse effects in treated women, it is still not known whether this is due to cause or effect (Orbach, 2013). The following summary of antihypertensive drugs is abstracted from several sources, including the *2014 Physicians’ Desk Reference*. Many of these drugs are also discussed throughout Chapter 12 (p. 247) and have been recently reviewed by Umans and associates (2014).

Diuretics

Thiazide diuretics are sulfonamides, and these were the first drug group used to successfully treat chronic hypertension (Beyer, 1982). These agents and loop-acting diuretics such as furosemide are commonly used in nonpregnant hypertensives. In the short term, they provide sodium and water diuresis with volume depletion. But with time, there is *sodium escape*, and volume depletion is corrected. Some aspect of lowered peripheral vascular resistance likely contributes to their effectiveness in reducing long-term morbidity (Umans, 2014; Williams, 2001).

Thiazide drugs may be mildly diabetogenic, and expected volume expansion may be curtailed in pregnant women. Sibai and colleagues (1984) showed that plasma volume expanded only about 20 percent over time in hypertensive pregnant women who continued diuretic therapy compared with a 50-percent expansion in women who discontinued treatment. Although perinatal outcomes were similar in these women, such concerns have led to practices of withholding diuretics as first-line therapy, particularly after 20 weeks (Working Group Report, 2000). Even so, in a Cochrane review, Churchill and associates (2007) reported no differences in perinatal outcomes in 1836 nonhypertensive women randomly assigned to a thiazide diuretic or placebo for primary preeclampsia prevention. Overall, thiazide diuretics are considered safe in pregnancy (Briggs, 2011; Umans, 2014).

Adrenergic-Blocking Agents

This was the second class of effective antihypertensives. *Peripherally* acting β -adrenergic receptor blockers cause a generalized decrease in sympathetic tone. Examples are propranolol, metoprolol, and atenolol. Labetalol is a commonly used α/β -adrenergic blocker. Some adrenergic-blocking drugs act *centrally* by reducing sympathetic outflow to effect a generalized decreased vascular tone. Some of these are clonidine and α -methyldopa. The drugs most frequently used in pregnancy to treat hypertension are methyldopa or a β - or α/β -receptor blocking agent.

Vasodilators

Hydralazine relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (Chap. 40, p. 767). Oral hydralazine monotherapy for chronic hypertension is not generally used because of its weak antihypertensive effects and resultant tachycardia. It may be an effective adjunct for long-term use with other antihypertensives,

especially if there is chronic renal insufficiency. In the study by Su and coworkers (2013), vasodilator treatment of chronically hypertensive women was associated with a twofold increase in low-birthweight and growth-restricted neonates.

Calcium-Channel Blocking Agents

These drugs are divided into three subclasses based on their modification of calcium entry into cells and interference with binding sites on voltage-dependent calcium channels. Common agents include nifedipine—a dihydropyridine, and verapamil—a phenylalkyl amine derivative. These agents have negative inotropic effects and thus can worsen ventricular dysfunction and congestive heart failure. Theoretically, they may potentiate the actions of magnesium sulfate that is given for eclampsia neuroprophylaxis. There is minimal published experience with these agents during pregnancy (Abalos, 2007). That said, calcium-channel blockers appear to be safe for therapy for chronic hypertension (Briggs, 2011; Podymow, 2011; Umans, 2014).

The safety of acute peripartum nifedipine treatment has been questioned. The drug is used by some for rapid control of severe peripartum hypertension, and it is also widely used for tocolysis in preterm labor (Chap. 42, p. 853). Nifedipine for tocolysis should not be combined with intravenous β -agonists (Oei, 2006). Adverse outcomes reported in women given nifedipine for tocolysis or severe gestational hypertension include myocardial infarction and pulmonary edema (Abbas, 2006; Bal, 2004; Oei, 1999; Verhaert, 2004). Severe maternal hypotension with resultant fetal compromise necessitating cesarean delivery and fetal death have also been reported (Johnson, 2005; Kandysamy, 2005; van Veen, 2005).

Angiotensin-Converting Enzyme Inhibitors

These drugs inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. They can cause severe fetal malformations when given in the second and third trimesters. These include hypocalvaria and renal dysfunction (Chap. 12, p. 247). Some preliminary studies have also suggested teratogenic effects, and because of this, they are not recommended during pregnancy (Briggs, 2011; Podymow, 2011).

Angiotensin-receptor blockers act in a similar manner. But, instead of blocking the production of angiotensin-II, they inhibit binding to its receptor. They are presumed to have the same fetal effects as ACE inhibitors and thus are also contraindicated.

Antihypertensive Treatment in Pregnancy

As discussed, continuation of prepregnancy antihypertensive treatment when women become pregnant is debated. Although blood-pressure reduction is certainly beneficial to the mother long term, it at least theoretically can decrease uteroplacental perfusion. According to older observational reports, in general, most pregnancy outcomes in women with mild to moderate hypertension were good without treatment and unless superimposed preeclampsia developed (Chesley, 1978; Umans, 2014).

There are no large randomized trials to settle the questions surrounding empirical treatment. Abalos and associates (2007) performed a Cochrane database review of 46 small trials enrolling

TABLE 50-4. Comparison of Pregnancy Outcomes in Women with and without Antepartum Treatment for Mild to Moderate Chronic Hypertension

Outcome	Studies (Subjects)	RR (95% CI) ^a
Severe hypertension	19 (2409)	0.50 [0.41, 0.61]
Preeclampsia	22 (2702)	0.97 [0.83, 1.13]
SGA infants	9 (904)	1.38 [0.99, 1.92]
Perinatal mortality	26 (3081)	0.73 [0.50, 1.08]
Delivery < 37 weeks	14 (1992)	1.02 [0.89, 1.16]

^aPertains to those receiving treatment.

SGA = small-for-gestational age.

Includes only studies in which β -blocking drugs were given. Data from a Cochrane database review by Abalos, 2007.

a total of 4282 women. These studies varied widely in definitions of hypertension severity, use of placebos, gestational age at entry, and the type of drug(s) used. The salient results are shown in Table 50-4. These led the investigators to conclude again that treatment reliably lowered risk for severe hypertension during pregnancy.

This Cochrane review does raise concern for fetal-growth restriction with β -blocking drugs. It is not resolved, however, because diminished placental perfusion secondary to lowered maternal blood pressure is confounded by the fact that worsening blood pressure itself is associated with abnormal fetal growth. Some also posit that the drugs have a direct fetal action (Umans, 2014). In two of the larger randomized trials, however, the incidence of growth restriction was not altered in women randomly assigned to treatment (Gruppo di Studio Ipertensione in Gravidanza, 1998; Sibai, 1990a).

Severe Chronic Hypertension

Most data suggest that the prognosis for pregnancy outcome with chronic hypertension is dependent on the severity of disease antedating pregnancy. This may be related to findings that many women with severe hypertension have renal disease—as either cause or effect (Cunningham, 1990). One report by Sibai and coworkers (1986) described outcomes from 44 pregnancies in women whose blood pressure at 6 to 11 weeks was $\geq 170/110$ mm Hg. All were given oral treatment with α -methyldopa and hydralazine to maintain pressures $< 160/110$ mm Hg. If dangerous hypertension developed, then the woman was hospitalized and treated with parenteral hydralazine. Of the 44 pregnancies, superimposed preeclampsia developed in half, and all adverse perinatal outcomes were in this group. Moreover, all neonates of women in the latter group were delivered preterm, nearly 80 percent were also growth restricted, and they had a 48-percent perinatal mortality rate. Conversely, those women with severe chronic hypertension who did not develop superimposed preeclampsia had reasonably good outcomes. There were no perinatal deaths, and only 5 percent of fetuses were growth restricted.

Recommendations for Therapy in Pregnancy

The Working Group on High Blood Pressure in Pregnancy (2000) concluded that there were limited data from which to draw conclusions concerning any decision to treat mild chronic hypertension in pregnancy. As discussed on page 1005, the Group did recommend empirical therapy in women whose blood pressures exceed threshold levels of 150 to 160 mm Hg systolic or 100 to 110 mm Hg diastolic or in women with target-organ damage such as left ventricular hypertrophy or renal insufficiency. They also concluded that early treatment of hypertension would probably reduce subsequent hospitalization rates during pregnancy.

Some women will have persistently worrisome hypertension despite usual therapy (Samuel, 2011; Sibai, 1990a). In these women, primary attention is given to the likelihood of pregnancy-aggravated hypertension, with or without superimposed preeclampsia. Other possibilities include inaccurate blood-pressure measurements, suboptimal treatment, and antagonizing substances (Moser, 2006). Causes reported in non-pregnant cohorts were nonsteroidal antiinflammatory drugs including cyclooxygenase-2 inhibitors and alcohol consumption (Sowers, 2005; Xin, 2001).

Pregnancy-Agravated Hypertension or Superimposed Preeclampsia

As discussed, the incidence of superimposed preeclampsia for women with chronic hypertension varies depending on the study population and hypertension severity. A reasonable average is 20 to 30 percent. The incidence of superimposed preeclampsia may be underreported if the diagnosis is based solely on urine protein dipstick testing (Gangaram, 2005; Lai, 2006). Importantly, in approximately half of chronically hypertensive women, superimposed preeclampsia develops before 37 weeks (Chappell, 2008).

The diagnosis may be difficult to make, especially in women with hypertension who have underlying renal disease with chronic proteinuria (Cunningham, 1990). As discussed in Chapter 40 (p. 730), conditions that support the diagnosis of superimposed preeclampsia include worsening hypertension, new-onset proteinuria, neurological symptoms such as severe headaches and visual disturbances, generalized edema, oliguria, and certainly, convulsions or pulmonary edema. Supporting laboratory abnormalities are increasing serum creatinine levels, thrombocytopenia, serum hepatic transaminase elevations, or the triad of HELLP—hemolysis, elevated liver enzyme levels, low platelet count—syndrome. For women with chronic hypertension and superimposed preeclampsia with severe features, magnesium sulfate for maternal neuroprophylaxis is recommended (American College of Obstetricians and Gynecologists, 2013).

Some pregnant women with chronic hypertension have worsening hypertension with no other findings of superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, including fetal-growth restriction or decreased amniotic fluid volume, this likely represents the higher end of the normal blood-pressure

curve shown in Figure 50-1. In such women, if preeclampsia can be reasonably excluded, then it is reasonable to begin or to increase the dose of antihypertensive therapy.

Fetal Assessment

Women with well-controlled chronic hypertension and who have no complicating factors can generally be expected to have a good pregnancy outcome. Because even those with mild hypertension have an increased risk of superimposed preeclampsia and fetal-growth restriction, serial antepartum assessment of fetal well-being is recommended by many. That said, according to the American College of Obstetricians and Gynecologists (2012), with the exception of sonographic fetal-growth monitoring, there are no conclusive data to address either benefit or harm associated with various antepartum surveillance strategies.

Expectant Management

Given that half of these women develop superimposed preeclampsia before term, considerations for expectant management may be reasonable in some cases. In a study from Magee-Women's Hospital, 41 carefully selected women with a median gestational age of 31.6 weeks were expectantly managed (Samuel, 2011). Despite liberal criteria to mandate delivery, 17 percent developed either placental abruption or pulmonary edema. The latency period was extended by a mean of 9.7 days, and there were no perinatal deaths. These investigators recommended randomized trials to study expectant management.

Delivery

For chronically hypertensive women who have complications such as fetal-growth restriction or superimposed preeclampsia, the decision to deliver is made by clinical judgment. The route of delivery is dictated by obstetrical factors. Certainly, most women with superimposed severe preeclampsia are better delivered even when there is a markedly preterm pregnancy. These women are at increased risk for placental abruption, cerebral hemorrhage, and peripartum heart failure (Cunningham, 1986, 2005; Martin, 2005).

For women with mild to moderate chronic hypertension who continue to have an uncomplicated pregnancy, there are at least two options for timing of delivery (American College of Obstetricians and Gynecologists, 2012). The first is delivery at term, that is, ≥ 39 completed weeks. Another option is from consensus committee findings by Spong and associates (2011), which recommend consideration for delivery at 38 to 39 weeks, that is, ≥ 37 completed weeks. A trial of labor induction is preferable, and many of these women respond favorably and will be delivered vaginally (Alexander, 1999; Atkinson, 1995).

Intrapartum Consideration

For women with severe preeclampsia, peripartum management is the same as described in Chapter 40 (p. 761). Epidural analgesia for labor and delivery is optimal with the caveat that it is not given to treat hypertension (Lucas, 2001). That said, women with severe superimposed preeclampsia are more sensitive to the

acute hypotensive effects of epidural analgesia (Vricella, 2012). Magnesium sulfate neuroprophylaxis is initiated for prevention of eclampsia (Alexander, 2006). Severe hypertension—diastolic blood pressure ≥ 110 mm Hg or systolic pressure ≥ 160 mm Hg—is treated with either intravenous hydralazine or labetalol. Some prefer to treat women with a diastolic pressure of 100 to 105 mm Hg. Vigil-De Gracia and colleagues (2006) randomized 200 women to intravenous hydralazine or labetalol to acutely lower severe high blood pressure in pregnancy. Outcomes were similar except for significantly more maternal palpitations and tachycardia with hydralazine and significantly more neonatal hypotension and bradycardia with labetalol.

■ Postpartum Hypertension

In most respects, postpartum observation, prevention, and management of adverse complications are similar in women with severe chronic hypertension and in those with severe preeclampsia–eclampsia (Chap. 40, p. 767). For persistent severe hypertension, consideration is given for a cause such as pheochromocytoma or Cushing disease (Sibai, 2012). And because of chronic end-organ damage, certain complications are more common. These include cerebral or pulmonary edema, heart failure, renal dysfunction, or cerebral hemorrhage, especially within the first 48 hours after delivery (Martin, 2005; Sibai, 1990b). These frequently are preceded by sudden increases—“spikes”—of mean arterial blood pressure, especially the systolic component (Cunningham, 2000, 2005).

Following delivery, as maternal peripheral resistance increases, left ventricular workload also increases. This rise is further aggravated by appreciable and pathological amounts of interstitial fluid that are mobilized to be excreted as endothelial damage from preeclampsia resolves. In these women, sudden hypertension—either moderate or severe—exacerbates diastolic dysfunction, causes systolic dysfunction, and leads to pulmonary edema (Cunningham, 1986; Gandhi, 2001). Prompt hypertension control, along with furosemide-evoked diuresis, usually quickly resolves pulmonary edema. It is possible in many women to forestall this by the administration of intravenous furosemide to augment the normal postpartum diuresis. Daily weights are helpful in this regard. On average, a woman should weigh 15 pounds less immediately after delivery. Excessive extracellular fluid can be estimated by subtracting the postpartum weight from the predelivery weight—if not determined on hospital admission, the weight at the last prenatal visit provides a relatively accurate estimate. In one study, 20-mg oral furosemide given daily to postpartum women with severe preeclampsia aided blood-pressure control (Ascarelli, 2005).

■ Contraception

Women with chronic hypertension have special considerations for contraceptive and sterilization choices. These are discussed in detail throughout Chapters 38 and 39. These women are also at ultimate high risk for lifetime cardiovascular complications, especially when accompanied by diabetes, obesity, and the metabolic syndrome.

CYSTIC FIBROSIS	1022
CARBON MONOXIDE POISONING	1023

Acute and chronic pulmonary disorders are frequently encountered during pregnancy. Chronic asthma or an acute exacerbation is the most common and affects up to 4 percent of pregnant women. These disorders along with community-acquired pneumonia accounted for almost 10 percent of nonobstetrical hospitalizations in one managed care plan (Gazmararian, 2002). Pneumonia is also a frequent complication requiring readmission postpartum (Belfort, 2010). These and other pulmonary disorders are superimposed on several important pregnancy-induced changes of ventilatory physiology. For example, pregnant women, especially those in the last trimester, do not appear to tolerate severe acute pneumonitis as evidenced by the disparate number of maternal deaths during the 1918 and 1957 influenza pandemics.

The important and sometimes marked changes in the respiratory system induced by pregnancy are reviewed in Chapter 4 (p. 62), and values for associated tests can be found in the Appendix (p. 1292). Lung volumes and capacities that are measured directly to assess pulmonary pathophysiology may

be significantly altered. In turn, these change gas concentrations and acid-base values in blood. Some of the physiological alterations induced by pregnancy were summarized by Wise and associates (2006):

1. *Vital capacity* and *inspiratory capacity* increase by approximately 20 percent by late pregnancy.
2. *Expiratory reserve volume* decreases from 1300 mL to approximately 1100 mL.
3. *Tidal volume* increases approximately 40 percent as a result of respiratory stimulation by progesterone.
4. *Minute ventilation* increases 30 to 40 percent due to increased tidal volume. As a result, arterial PO_2 increases from 100 to 105 mm Hg.
5. Increasing metabolic demands cause a 30-percent increase in *carbon dioxide production*, but because of its concomitantly increased diffusion capacity along with hyperventilation, the arterial P_{CO_2} decreases from 40 to 32 mm Hg.
6. *Residual volume* decreases approximately 20 percent from 1500 mL to approximately 1200 mL.
7. *Chest wall compliance* is reduced by a third by the expanding uterus and increased abdominal pressure, which causes a 10- to 25-percent decrease in *functional residual capacity*—the sum of expiratory reserve and residual volumes.

The end result of these pregnancy-induced changes is substantially increased ventilation due to deeper but not more frequent breathing. These are thought to be stimulated by basal oxygen consumption as it increases incrementally from 20 to 40 mL/min in the second half of pregnancy.

ASTHMA

Asthma is seen frequently in young women and therefore often complicates pregnancy. Asthma prevalence increased steadily in many countries beginning in the mid-1970s but may have plateaued in the United States, with a prevalence

in adults of approximately 10 percent (Barnes, 2012; Centers for Disease Control and Prevention, 2010c). The estimated asthma prevalence during pregnancy ranges between 4 and 8 percent, and this appears to be increasing (Kwon, 2006; Namazy, 2005). Finally, evidence is accruing that fetal as well as neonatal environmental exposures may contribute to the origins of asthma in certain individuals (Harding, 2012; Henderson, 2012).

■ Pathophysiology

Asthma is a chronic inflammatory airway syndrome with a major hereditary component. Increased airway responsiveness and persistent subacute inflammation have been associated with genes on chromosomes 5q that include cytokine gene clusters, β -adrenergic and glucocorticoid receptor genes, and the T-cell antigen receptor gene (Barnes, 2012). Asthma is heterogeneous, and there inevitably is an *environmental allergic stimulant* such as influenza or cigarette smoke in susceptible individuals (Bel, 2013).

The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, vascular congestion, tenacious mucus, and mucosal edema. There is mucosal infiltration with eosinophils, mast cells, and T lymphocytes that causes airway inflammation and increased responsiveness to numerous stimuli including irritants, viral infections, aspirin, cold air, and exercise. Several inflammatory mediators produced by these and other cells include histamine, leukotrienes, prostaglandins, cytokines, and many others. IgE also plays a central role in pathophysiology (Strunk, 2006). *Because F-series prostaglandins and ergonovine exacerbate asthma, these commonly used obstetrical drugs should be avoided if possible.*

■ Clinical Course

Asthma findings range from mild wheezing to severe bronchoconstriction, which obstructs airways and decreases airflow. These reduce the forced expiratory volume in 1 second

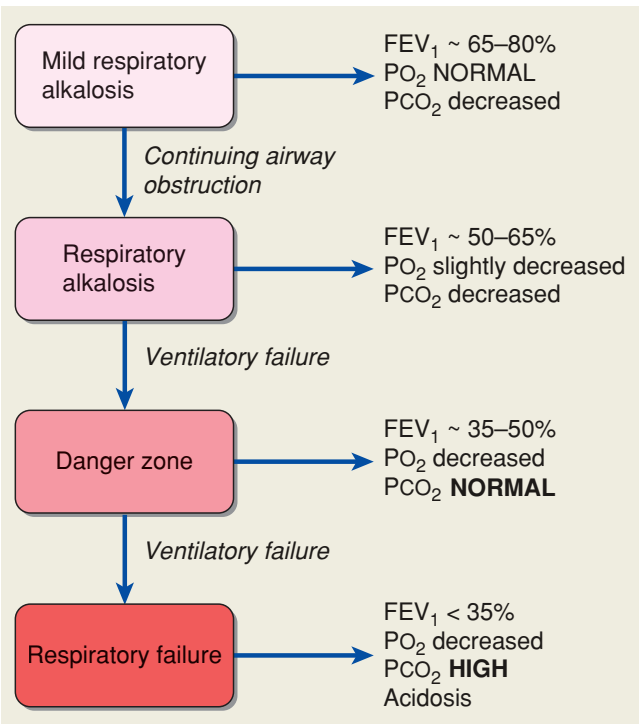

FIGURE 51-1 Clinical stages of asthma. FEV₁ = forced expiratory volume in 1 second.

(FEV₁)/forced vital capacity (FVC) ratio and the peak expiratory flow (PEF). The work of breathing progressively increases, and patients note chest tightness, wheezing, or breathlessness. Subsequent alterations in oxygenation primarily reflect ventilation–perfusion mismatching, because the distribution of airway narrowing is uneven.

Varied manifestations of asthma have led to a simple classification that considers severity as well as onset and duration of symptoms (Table 51-1). With persistent or worsening bronchial obstruction, stages progress as shown in Figure 51-1. Hypoxia initially is well augmented by hyperventilation, which

TABLE 51-1. Classification of Asthma Severity				
Component	Severity			
	Intermittent	Persistent		
		Mild	Moderate	Severe
Symptoms	≤ 2 day/wk	> 2 day/wk, not daily	Daily	Throughout day
Nocturnal awakenings	≤ 2x/mo	3–4x/mo	> 1/wk, not nightly	Often 7x/wk
Short-acting β-agonist for symptoms	≤ 2 day/wk	≥ 2 day/wk, but not > 1x/day	Daily	Several times daily
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal between exacerbations			
• FEV ₁	> 80% predicted	≥ 80% predicted	60–80% predicted	< 60% predicted
• FEV ₁ /FVC	Normal	Normal	Reduced 5%	Reduced > 5%

FEV = forced expiratory volume; FVC = forced vital capacity.
From National Heart, Lung, and Blood Institute, 2007.

maintains arterial PO_2 within a normal range while causing the PCO_2 to decrease with resultant respiratory alkalosis. As airway narrowing worsens, ventilation–perfusion defects increase, and arterial hypoxemia ensues. With severe obstruction, ventilation becomes impaired as fatigue causes early CO_2 retention. Because of hyperventilation, this may only be seen initially as an arterial PCO_2 returning to the normal range. With continuing obstruction, respiratory failure follows from fatigue.

Although these changes are generally reversible and well tolerated by the healthy nonpregnant individual, even early asthma stages may be dangerous for the pregnant woman and her fetus. This is because smaller functional residual capacity and increased pulmonary shunting render the woman more susceptible to hypoxia and hypoxemia.

Effects of Pregnancy on Asthma

There is no evidence that pregnancy has a predictable effect on underlying asthma. In their review of six prospective studies of more than 2000 pregnant women, Gluck and Gluck (2006) reported that approximately a third each improved, remained unchanged, or clearly worsened. Exacerbations are more common with severe disease (Ali, 2013). In a study by Schatz and associates (2003), baseline severity correlated with asthma morbidity during pregnancy. With mild disease, 13 percent of women had an exacerbation and 2.3 percent required admission; with moderate disease, these numbers were 26 and 7 percent; and for severe asthma, 52 and 27 percent. Others have reported similar observations (Charlton, 2013; Hendler, 2006; Murphy, 2005). Carroll and colleagues (2005) reported disparate morbidity in black compared with white women.

Some women have asthma exacerbations during labor and delivery. Up to 20 percent of women with mild or moderate asthma have been reported to have an intrapartum exacerbation (Schatz, 2003). Conversely, Wendel and associates (1996) reported exacerbations at the time of delivery in only 1 percent of women. Mabie and coworkers (1992) reported an 18-fold increased exacerbation risk following cesarean versus vaginal delivery.

Pregnancy Outcome

Women with asthma have had improved pregnancy outcomes during the past 20 years. From his review, Dombrowski (2006) concluded that, unless disease is severe, pregnancy outcomes are generally excellent. The incidence of spontaneous abortion in women with asthma may be slightly increased (Blais, 2013). Maternal and perinatal outcomes for nearly 30,000 pregnancies in asthmatic women are shown in Table 51-2. Findings are not consistent among these studies. For example, in some, but not all, incidences of preeclampsia, preterm labor, growth-restricted infants, and perinatal mortality are slightly increased (Murphy, 2011). Another report cited a small rise in the incidence of placental abruption and in preterm rupture of membranes (Getahun, 2006, 2007). But, in a European report of 37,585 pregnancies of women with asthma, the risks for most obstetrical complications were not increased (Tata, 2007). In the Canadian study in which inhaled-corticosteroid dosage was quantified, Cossette and coworkers (2013) found a nonsignificant trend between perinatal complications and increasing dosage. They concluded that low to moderate doses were not associated with perinatal risks and noted that more data were needed regarding higher doses.

Thus, there appears to be significantly increased morbidity linked to severe disease, poor control, or both. In the study by the Maternal-Fetal Medicine Units (MFMU) Network, delivery before 37 weeks' gestation was not increased among the 1687 pregnancies of asthmatics compared with those of 881 controls (Dombrowski, 2004a). But for women with severe asthma, the rate was increased approximately twofold. In a prospective evaluation of 656 asthmatic pregnant women and 1052 pregnant controls, Triche and coworkers (2004) found that women with moderate to severe asthma, regardless of treatment, are at increased risk of preeclampsia. Finally, the MFMU Network study suggests a direct relationship of baseline pregnancy forced expiratory volume at 1 second ($\text{FEV}_{1\text{s}}$) with birthweight and an inverse relationship with rates of gestational hypertension and preterm delivery (Schatz, 2006).

Life-threatening complications from status asthmaticus include muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale, and cardiac arrhythmias.

TABLE 51-2. Maternal and Perinatal Outcomes in Pregnancies Complicated by Asthma

Study	No.	Perinatal Outcomes (%)		
		Gestational Hypertension ^a	Growth Restriction	Preterm Delivery

Approximate average	29,733	~ 11	~ 11	~ 13

^aIncludes preeclampsia syndromes.

^bIncidence not significantly different compared with control group or general obstetrical population.

^cIncidence significantly greater than control group or general obstetrical population.

NS = not stated.

Maternal and perinatal mortality rates are substantively increased when mechanical ventilation is required.

Fetal Effects

With reasonable asthma control, perinatal outcomes are generally good. For example, in the MFMU Network study cited above, there were no significant adverse neonatal sequelae from asthma (Dombrowski, 2004a). The caveat is that severe asthma was uncommon in this closely monitored group. When respiratory alkalosis develops, both animal and human studies suggest that fetal hypoxemia develops well before the alkalosis compromises maternal oxygenation (Rolston, 1974). It is hypothesized that the fetus is jeopardized by decreased uterine blood flow, decreased maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve.

The fetal response to maternal hypoxemia is decreased umbilical blood flow, increased systemic and pulmonary vascular resistance, and decreased cardiac output. Observations by Bracken and colleagues (2003) confirm that the incidence of fetal-growth restriction increases with asthma severity. The realization that the fetus may be seriously compromised as asthma severity increases underscores the need for aggressive management. Monitoring the fetal response is, in effect, an indicator of maternal status.

Possible teratogenic or adverse fetal effects of drugs given to control asthma have been a concern. Fortunately, considerable data have accrued with no evidence that commonly used antiasthmatic drugs are harmful (Blais, 2007; Källén, 2007; Namazy, 2006). Thus, it is worrisome that Enriquez and coworkers (2006) reported a 13- to 54-percent patient-generated decrease in β -agonist and corticosteroid use between 5 and 13 weeks' gestation.

Clinical Evaluation

The subjective severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Although clinical examination can also be an inaccurate predictor, useful clinical signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory muscles. Signs of a potentially fatal attack include central cyanosis and altered consciousness.

Arterial blood gas analysis provides objective assessment of maternal oxygenation, ventilation, and acid-base status. With this information, the severity of an acute attack can be assessed (see Fig. 51-1). That said, in a prospective evaluation, Wendel and associates (1996) found that *routine* arterial blood gas analysis did not help to manage most pregnant women who required admission for asthma control. If used, the results must be interpreted in relation to normal values for pregnancy. For example, a $P_{CO_2} > 35$ mm Hg with a $pH < 7.35$ is consistent with hyperventilation and CO_2 retention in a pregnant woman.

Pulmonary function testing should be routine in the management of chronic and acute asthma. Sequential measurement of the FEV_1 or the *peak expiratory flow rate*—*PEFR*—are the best measures of severity. An FEV_1 less than 1 L, or less than 20 percent of predicted value, correlates with severe disease defined by hypoxia, poor response to therapy, and a high relapse rate. The

PEFR correlates well with the FEV_1 , and it can be measured reliably with inexpensive portable meters. Each woman determines her own baseline when asymptomatic—*personal best*—to compare with values when symptomatic. The PEFR does not change during the course of normal pregnancy (Brancazio, 1997).

Management of Chronic Asthma

The management guidelines of the Working Group on Asthma and Pregnancy include:

- 1. Patient education—general asthma management and its effect on pregnancy
- 2. Environmental precipitating factors—avoidance or control. Viral infections—including the common cold—are frequent triggering events (Murphy, 2013).
- 3. Objective assessment of pulmonary function and fetal well-being—monitor with PEFR or FEV_1
- 4. Pharmacological therapy—in appropriate combinations and doses to provide baseline control and treat exacerbations. Compliance may be a problem, and periodic medication reviews are helpful (Sawicki, 2012).

In general, women with moderate to severe asthma should measure and record either their FEV_1 or PEFR twice daily. The FEV_1 ideally is > 80 percent of predicted. For PEFR, predicted values range from 380 to 550 L/min. Each woman has her own baseline value, and therapeutic adjustments can be made using this (American College of Obstetricians and Gynecologists, 2012; Rey, 2007).

Treatment depends on disease severity. Although β -agonists help to abate bronchospasm, corticosteroids treat the inflammatory component. Regimens recommended for outpatient management are listed in Figure 51-2. For mild asthma, inhaled β -agonists as needed are usually sufficient. For persistent asthma, *inhaled corticosteroids* are administered every 3 to 4 hours. The goal is to reduce the use of β -agonists for symptomatic relief. A case-control study from Canada with a cohort of more than 15,600 nonpregnant women with asthma showed that inhaled corticosteroids reduced hospitalizations by 80 percent (Blais, 1998). And Wendel and colleagues (1996) achieved

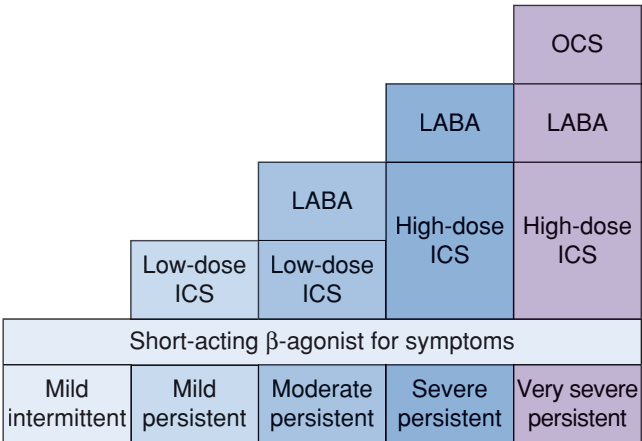

FIGURE 51-2 Stepwise approach to asthma treatment. ICS = inhaled corticosteroids; LABA = long-acting β -agonists; OCS = oral corticosteroids. (Modified from Barnes, 2012.)

a 55-percent reduction in readmissions for severe exacerbations in pregnant asthmatics given maintenance inhaled corticosteroids along with β -agonist therapy.

Theophylline is a methylxanthine, and its various salts are bronchodilators and possibly antiinflammatory agents. They have been used less frequently since inhaled corticosteroids became available. Some theophylline derivatives are considered useful for oral maintenance therapy if the initial response to inhaled corticosteroids and β -agonists is not optimal. Dombrowski and associates (2004b) conducted a randomized trial with nearly 400 pregnant women with moderate asthma. Oral theophylline was compared with inhaled beclomethasone for maintenance. In both groups, approximately 20 percent had exacerbations. Women taking theophylline had a significantly higher discontinuation rate because of side effects. Pregnancy outcomes were similar in the two groups.

Antileukotrienes inhibit leukotriene synthesis and include *zileuton*, *zafirlukast*, and *montelukast*. These drugs are given orally or by inhalation for prevention, but they are not effective for acute disease. For maintenance, they are used in conjunction with inhaled corticosteroids to allow minimal dosing. Approximately half of asthmatics will improve with these drugs (McFadden, 2005). They are not as effective as inhaled corticosteroids (Fanta, 2009). Finally, there is little experience with their use in pregnancy (Bakhireva, 2007).

Cromones include *cromolyn* and *nedocromil*, which inhibit mast cell degranulation. They are ineffective for acute asthma and are taken chronically for prevention. They are not as effective as inhaled corticosteroids and are used primarily to treat childhood asthma.

Management of Acute Asthma

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant asthmatic (Barnes, 2012). However, the threshold for hospitalization is significantly lowered. Intravenous hydration may help clear pulmonary secretions, and supplemental oxygen is given by mask. The therapeutic aim is to maintain the $\text{Po}_2 > 60$ mm Hg, and preferably normal, along with 95-percent oxygen saturation. Baseline pulmonary function testing includes FEV_1 or PEFR . Continuous pulse oximetry and electronic fetal monitoring, depending on gestational age, may provide useful information.

First-line therapy for acute asthma includes a *β -adrenergic agonist*, such as terbutaline, albuterol, isoetharine, epinephrine, isoproterenol, or metaproterenol, which is given subcutaneously, taken orally, or inhaled. These drugs bind to specific cell-surface receptors and activate adenylyl cyclase to increase intracellular cyclic AMP and modulate bronchial smooth muscle relaxation. Long-acting preparations are used for outpatient therapy.

If not previously given for maintenance, inhaled corticosteroids are commenced along with intensive β -agonist therapy. For severe exacerbations, magnesium sulfate may prove efficacious. *Corticosteroids should be given early to all patients with severe acute asthma.* Unless there is a timely response to bronchodilator and inhaled corticosteroid therapy, oral or parenteral corticosteroids are given (Lazarus, 2010). Intravenous methylprednisolone, 40 to 60 mg, every 6 hours for four doses

is commonly used. Equipotent doses of hydrocortisone by infusion or prednisone orally can be given instead. *Because their onset of action is several hours, corticosteroids are given initially along with β -agonists for acute asthma.*

Further management depends on the response to therapy. If initial therapy with β -agonists is associated with improvement of FEV_1 or PEFR to above 70 percent of baseline, then discharge can be considered. Some women may benefit from observation. Alternatively, for the woman with obvious respiratory distress, or if the FEV_1 or PEFR is < 70 percent of predicted after three doses of β -agonist, admission is likely advisable (Lazarus, 2010). Intensive therapy includes inhaled β -agonists, intravenous corticosteroids, and close observation for worsening respiratory distress or fatigue in breathing (Wendel, 1996). The woman is cared for in the delivery unit or an intermediate or intensive care unit (ICU) (Dombrowski, 2006; Zeeman, 2003).

Status Asthmaticus and Respiratory Failure

Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed status asthmaticus. Braman and Kaemmerlen (1990) have shown that management of nonpregnant patients with status asthmaticus in an intensive care setting results in a good outcome in most cases. Consideration should be given to early intubation when maternal respiratory status worsens despite aggressive treatment (see Fig. 51-1). Fatigue, carbon dioxide retention, and hypoxemia are indications for mechanical ventilation. Lo and colleagues (2013) have described a woman with status asthmaticus in whom cesarean delivery was necessary to effect ventilation. Andrews (2013) cautioned that such clinical situations are uncommon.

Labor and Delivery

For the laboring asthmatic, maintenance medications are continued through delivery. Stress-dose corticosteroids are administered to any woman given systemic corticosteroid therapy within the preceding 4 weeks. The usual dose is 100 mg of hydrocortisone given intravenously every 8 hours during labor and for 24 hours after delivery. The PEFR or FEV_1 should be determined on admission, and serial measurements are taken if symptoms develop.

Oxytocin or prostaglandins E_1 or E_2 are used for cervical ripening and induction. A nonhistamine-releasing narcotic such as fentanyl may be preferable to meperidine for labor, and epidural analgesia is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. Postpartum hemorrhage is treated with oxytocin or prostaglandin E_2 . *Prostaglandin $\text{F}_{2\alpha}$ or ergotamine derivatives are contraindicated because they may cause significant bronchospasm.*

ACUTE BRONCHITIS

Infection of the large airways is manifest by cough without pneumonitis. It is common in adults, especially in winter months. Infections are usually caused by viruses, and of these, influenza A and B, parainfluenza, respiratory syncytial,

coronavirus, adenovirus, and rhinovirus are frequent isolates (Wenzel, 2006). Bacterial agents causing community-acquired pneumonia are rarely implicated. The cough of acute bronchitis persists for 10 to 20 days (mean 18 days) and occasionally lasts for a month or longer. According to the 2006 guidelines of the American College of Chest Physicians, routine antibiotic treatment is not justified (Braman, 2006). Influenza bronchitis is managed as discussed below.

PNEUMONIA

According to Anand and Kollef (2009), current classification includes several types of pneumonia. *Community-acquired pneumonia (CAP)* is typically encountered in otherwise healthy young women, including during pregnancy. *Health-care-associated pneumonia (HCAP)* develops in patients in outpatient care facilities and more closely resembles *hospital-acquired pneumonia (HAP)*. Other types are *nursing home-acquired pneumonia (NHAO)* and *ventilator-associated pneumonia (VAP)*.

Community-acquired pneumonia in pregnant women is relatively common and is caused by several bacterial or viral pathogens (Brito, 2011; Sheffield, 2009). Gazmararian and coworkers (2002) reported that pneumonia accounts for 4.2 percent of antepartum admissions for nonobstetrical complications. Pneumonia is also a frequent indication for postpartum readmission (Belfort, 2010). During influenza season, admission rates for respiratory illnesses double compared with rates in the remaining months (Cox, 2006). Mortality from pneumonia is infrequent in young women, but during pregnancy severe pneumonitis with appreciable loss of ventilatory capacity is not as well tolerated (Rogers, 2010). This generalization seems to hold true regardless of the pneumonia etiology. Hypoxemia and acidosis are also poorly tolerated by the fetus and frequently stimulate preterm labor after midpregnancy. Because many cases of pneumonia follow viral upper respiratory illnesses, worsening or persistence of symptoms may represent developing pneumonia. *Any pregnant woman suspected of having pneumonia should undergo chest radiography.*

Bacterial Pneumonia

Many bacteria that cause community-acquired pneumonia, such as *Streptococcus pneumoniae*, are part of the normal resident flora (Bogaert, 2004). Some factors that perturb the symbiotic relationship between colonizing bacteria and mucosal phagocytic defenses include acquisition of a virulent strain or bacterial infections following a viral infection. Cigarette smoking and chronic bronchitis favor colonization with *S pneumoniae*, *Haemophilus influenzae*, and *Legionella* species. Other risk factors include asthma, binge drinking, and human immunodeficiency virus (HIV) infection (Goodnight, 2005; Sheffield, 2009).

Incidence and Causes

Pregnancy itself does not predispose to pneumonia. Jin and colleagues (2003) reported the antepartum hospitalization rate for pneumonia in Alberta, Canada, to be 1.5 per 1000 deliveries—almost identical to the rate of 1.47 per 1000 for nonpregnant

women. Likewise, Yost and associates (2000) reported an incidence of 1.5 per 1000 for pneumonia complicating 75,000 pregnancies cared for at Parkland Hospital. More than half of adult pneumonias are bacterial, and *S pneumoniae* is the most common cause. Lim and coworkers (2001) studied 267 nonpregnant inpatients with pneumonia and identified a causative agent in 75 percent—*S pneumoniae* in 37 percent; influenza A, 14 percent; *Chlamydia pneumoniae*, 10 percent; *H influenzae*, 5 percent; and *Mycoplasma pneumoniae* and *Legionella pneumophila*, 2 percent each. More recently, community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has emerged as the second most common pathogen in nonpregnant adults (Moran, 2013). These staphylococci may cause necrotizing pneumonia (Mandell, 2012; Rotas, 2007).

Diagnosis

Typical symptoms include cough, dyspnea, sputum production, and pleuritic chest pain. Mild upper respiratory symptoms and malaise usually precede these symptoms, and mild leukocytosis is usually present. Chest radiography is essential for diagnosis but does not accurately predict the etiology (Fig. 51-3). The responsible pathogen is identified in fewer than half of cases. According to the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS), tests to identify a specific agent are optional. Thus, sputum cultures, serological testing, cold agglutinin identification, and tests for bacterial antigens are not recommended. At Parkland Hospital, the one exception to this is rapid serological testing for influenza A and B (Sheffield, 2009).

Management

Although many otherwise healthy young adults can be safely treated as outpatients, at Parkland Hospital we hospitalize all pregnant women with radiographically proven pneumonia. For some, outpatient therapy or 23-hour observation is reasonable with optimal follow-up. Risk factors shown in Table 51-3 should prompt hospitalization.

With severe disease, admission to an ICU or intermediate care unit is advisable. Approximately 20 percent of pregnant

women admitted to Parkland Hospital for pneumonia require this level of care (Zeeman, 2003). Severe pneumonia is a relatively common cause of acute respiratory distress syndrome during pregnancy, and mechanical ventilation may become necessary. Indeed, of the 51 pregnant women who required mechanical ventilation in the review by Jenkins and coworkers (2003), 12 percent had pneumonia.

Antimicrobial treatment is empirical (Mandell, 2012). Because most adult pneumonias are caused by pneumococci, mycoplasma, or chlamydia, monotherapy initially is with

a macrolide—azithromycin, clarithromycin, or erythromycin. Yost and colleagues (2000) reported that erythromycin monotherapy, given intravenously and then orally, was effective in all but one of 99 pregnant women with uncomplicated pneumonia.

For women with severe disease according to criteria in Table 51-3, Mandell and associates (2007) summarized IDSA/ATS guidelines, which call for either: (1) a respiratory fluoroquinolone—levofloxacin, moxifloxacin, or gemifloxacin; or (2) a macrolide plus a β -lactam—high-dose amoxicillin or amoxicillin-clavulanate, which are preferred β -lactams. β -lactam alternatives include ceftriaxone, cefpodoxime, or cefuroxime. In areas in which there is “high-level” resistance of pneumococcal isolates to macrolides, these latter regimens are preferred. The teratogenicity risk of fluoroquinolones is low, and these should be given if indicated (Briggs, 2011). If community-acquired methicillin-resistant *S aureus* is suspected, then vancomycin or linezolid are added (Mandell, 2012; Sheffield, 2009). At this time, such therapy is empirical, and there are no tested regimens against CA-MRSA (Moran, 2013).

Clinical improvement is usually evident in 48 to 72 hours with resolution of fever in 2 to 4 days. Radiographic abnormalities may take up to 6 weeks to completely resolve (Torres, 2008). Worsening disease is a poor prognostic feature, and follow-up radiography is recommended if fever persists. Even with improvement, however, approximately 20 percent of women develop a pleural effusion. Pneumonia treatment is recommended for a minimum of 5 days. Treatment failure may occur in up to 15 percent of cases, and a wider antimicrobial regimen and more extensive diagnostic testing are warranted in these cases.

Pregnancy Outcome with Pneumonia

During the preantimicrobial era, as many as a third of pregnant women with pneumonia died (Finland, 1939). Although much improved, maternal and perinatal mortality rates both remain formidable. In five studies published after 1990, the maternal mortality rate was 0.8 percent of 632 women. Importantly, almost 7 percent of the women required intubation and mechanical ventilation.

Prematurely ruptured membranes and preterm delivery are frequent complications and have been reported in up to a third of cases (Getahun, 2007; Shariatzadeh, 2006). Likely related are older studies reporting a twofold increase in low-birthweight infants (Sheffield, 2009). In a more recent population-based study from Taiwan of nearly 219,000 births, there were significantly increased incidences of preterm and growth-restricted infants as well as preeclampsia and cesarean delivery (Chen, 2012).

Prevention

Pneumococcal vaccine is 60- to 70-percent protective against its 23 included serotypes. Its use has been shown to decrease emergence of drug-resistant pneumococci (Kyaw, 2006). The vaccine is not recommended for otherwise healthy pregnant women (American College of Obstetricians and Gynecologists, 2013). It is recommended for those who are immunocompromised, including those with HIV infection; significant smoking history; diabetes; cardiac, pulmonary, or renal disease; and

asplenia, such as with sickle-cell disease (Table 9-9, p. 185). Protection against pneumococcal infection in women with chronic diseases may be less efficacious than in healthy patients (Moberley, 2013).

■ Influenza Pneumonia

Clinical Presentation

Influenza A and B are RNA viruses that cause respiratory infection, including pneumonitis. Influenza pneumonia can be serious, and it is epidemic in the winter months. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages. Disease onset is 1 to 4 days following exposure (Longman, 2007). In most healthy adults, infection is self-limited.

Pneumonia is the most frequent complication of influenza, and it is difficult to distinguish from bacterial pneumonia. According to the Centers for Disease Control and Prevention (2010a), infected pregnant women are more likely to be hospitalized as well as admitted to an ICU. At Parkland Hospital during the 2003 to 2004 influenza season, pneumonia developed in 12 percent of pregnant women with influenza (Rogers, 2010). The 2009 influenza pandemic with the H1N1 strain was particularly severe. In a Maternal-Fetal Medicine Units Network study, 10 percent of pregnant or postpartum women admitted with H1N1 influenza were cared for in an ICU, and 11 percent of these ICU patients died (Varner, 2011). Risk factors included late pregnancy, smoking, and chronic hypertension. In California, 22 percent of H1N1-infected women required intensive care, and a third of these died.

Primary influenza pneumonitis is the most severe and is characterized by sparse sputum production and radiographic interstitial infiltrates. More commonly, secondary pneumonia develops from bacterial superinfection by streptococci or staphylococci after 2 to 3 days of initial clinical improvement. The Centers for Disease Control and Prevention (2007b) reported several cases in which CA-MRSA caused influenza-associated pneumonitis with a case-fatality rate of 25 percent. Other possible adverse effects of influenza A and B on pregnancy outcome are discussed in Chapter 64 (p. 1241).

Management

Supportive treatment with antipyretics and bed rest is recommended for uncomplicated influenza. Early antiviral treatment has been shown to be effective (Jamieson, 2011). As discussed, influenza hospitalizations for those with advanced pregnancy are increased compared with nonpregnant women (Dodds, 2007; Schanzer, 2007). Rapid resistance of influenza A (H3N2) strains to amantadine or rimantadine in 2005 prompted the Centers for Disease Control and Prevention (2006) to recommend against their use. Instead, neuraminidase inhibitors were given within 2 days of symptom onset for chemoprophylaxis and treatment of influenza A and B (Chap. 64, p. 1242). The drugs interfere with release of progeny virus from infected host cells and thus

prevent infection of new host cells (Moscona, 2005). Oseltamivir is given orally, 75 mg twice daily, or zanamivir is given by inhalation, 10 mg twice daily. Recommended treatment duration with either is 5 days. The drugs shorten the course of illness by 1 to 2 days, and they may reduce the risk for pneumonitis (Jamieson, 2011). Our practice is to treat all pregnant women with influenza whether or not pneumonitis is identified. There are few data regarding use of these agents in pregnant women, but the drugs were not teratogenic in animal studies and are considered low risk (Briggs, 2011).

Other concerns for viral resistance are for avian H5N1 and H7N9 strains isolated in Southeast Asia. These are candidate viruses for an influenza pandemic with a projected mortality rate that exceeds 50 percent (Beigi, 2007; World Health Organization, 2008). Currently, international efforts are being made to produce a vaccine effective against both strains.

Preventively, vaccination for influenza A is recommended and is discussed in detail in Chapter 64 (p. 1242). Prenatal vaccination also affords protection for a third of infants for at least 6 months (Zaman, 2008). During the 2012–2013 flu season, the Centers for Disease Control and Prevention (2013b) reported that only half of pregnant women received the vaccine.

■ Varicella Pneumonia

Infection with varicella-zoster virus—chicken pox—results in pneumonitis in 5 percent of pregnant women (Harger, 2002). Diagnosis and management are considered in Chapter 64 (p. 1240).

■ Fungal and Parasitic Pneumonia

Pneumocystis Pneumonia

Fungal and parasitic pulmonary infections are usually of greatest consequence in immunocompromised hosts, especially in women with acquired immunodeficiency syndrome (AIDS). Of these, lung infection with *Pneumocystis jirovecii*, formerly called *Pneumocystis carinii*, is a common complication in women with AIDS. The opportunistic fungus causes interstitial pneumonia characterized by dry cough, tachypnea, dyspnea, and diffuse radiographic infiltrates. Although this organism can be identified by sputum culture, bronchoscopy with lavage or biopsy may be necessary.

In a report from the AIDS Clinical Trials Centers, Stratton and colleagues (1992) described pneumocystis pneumonia as the most frequent HIV-related disorder in pregnant women. Ahmad and coworkers (2001) reviewed 22 cases during pregnancy and cited a 50-percent mortality rate. Treatment is with trimethoprim-sulfamethoxazole or the more toxic pentamidine (Walzer, 2005). Experience with dapsone or atovaquone is limited. In some cases, tracheal intubation and mechanical ventilation may be required.

As prophylaxis, several international health agencies recommend one double-strength trimethoprim-sulfamethoxazole tablet orally daily for certain HIV-infected pregnant women. These include women with CD4⁺ T-lymphocyte counts

< 200/ μ L, those whose CD4⁺ T lymphocytes constitute less than 14 percent, or if there is an AIDS-defining illness, particularly oropharyngeal candidiasis (Centers for Disease Control and Prevention, 2013a; Forna, 2006).

Fungal Pneumonia

Any of a number of fungi can cause pneumonia. In pregnancy, this is usually seen in women with HIV infection or who are otherwise immunocompromised. Infection is usually mild and self-limited. It is characterized initially by cough and fever, and dissemination is infrequent.

Histoplasmosis and *blastomycosis* do not appear to be more common or more severe during pregnancy. Data concerning *coccidioidomycosis* are conflicting (Bercovitch, 2011; Patel, 2013). In a case-control study from an endemic area, Rosenstein and coworkers (2001) reported that pregnancy was a significant risk factor for disseminated disease. In another study, however, Caldwell and coworkers (2000) identified 32 serologically confirmed cases during pregnancy and documented dissemination in only three cases. Arsura (1998) and Caldwell (2000) and their associates reported that pregnant women with symptomatic infection had a better overall prognosis if there was associated *erythema nodosum*. Crum and Ballon-Landa (2006) reviewed 80 cases of coccidioidomycosis complicating pregnancy. Almost all women diagnosed in the third trimester had disseminated disease. Although the overall maternal mortality rate was 40 percent, it was only 20 percent for 29 cases reported since 1973. Spinello (2007) and Bercovitch (2011), with their associates, have provided reviews of coccidioidomycosis in pregnancy.

Most cases of *cryptococcosis* reported during pregnancy have been reported to manifest as meningitis. Ely and colleagues (1998) described four otherwise healthy pregnant women with cryptococcal pneumonia. Diagnosis is difficult because clinical presentation is similar to that of other community-acquired pneumonias.

The 2007 IDSA/ATS guidelines recommend itraconazole as preferred therapy for disseminated fungal infections (Mandell, 2007). Pregnant women have also been given intravenous *amphotericin B* or *ketoconazole* (Hooper, 2007; Paranyuk, 2006). Amphotericin B has been used extensively in pregnancy with no embryo-fetal effects. Because of evidence that fluconazole, itraconazole, and ketoconazole may be embryotoxic in large doses in early pregnancy, Briggs and associates (2011) recommend that first-trimester use should be avoided if possible.

Three echinocandin derivatives—*caspofungin*, *micafungin*, and *anidulafungin*—are effective for invasive candidiasis (Medical Letter, 2006; Reboli, 2007). They are embryotoxic and teratogenic in laboratory animals and use in human pregnancies has not been reported (Briggs, 2011).

Severe Acute Respiratory Syndrome (SARS)

This coronaviral respiratory infection was first identified in China in 2002, but no new cases have been reported since 2005. It caused atypical pneumonitis with a case-fatality rate of approximately 10 percent (Dolin, 2012). SARS in pregnancy had

a case-fatality rate of up to 25 percent (Lam, 2004; Longman, 2007; Wong, 2004). Ng and coworkers (2006) reported that the placentas from 7 of 19 cases showed abnormal intervillous or subchorionic fibrin deposition in three, and extensive fetal thrombotic vasculopathy in two.

TUBERCULOSIS

Although tuberculosis is still a major worldwide concern, it is uncommon in the United States. The incidence of *active tuberculosis* in this country has plateaued since 2000 (Raviglione, 2012). More than half of active cases are in immigrants (Centers for Disease Control and Prevention, 2009b). Persons born in the United States have newly acquired infection, whereas foreign-born persons usually have reactivation of latent infection. In this country, tuberculosis is a disease of the elderly, the urban poor, minority groups—especially black Americans, and patients with HIV infection (Raviglione, 2012).

Infection is via inhalation of *Mycobacterium tuberculosis*, which incites a granulomatous pulmonary reaction. In more than 90 percent of patients, infection is contained and is dormant for long periods (Zumla, 2013). In some patients, especially those who are immunocompromised or who have other diseases, tuberculosis becomes reactivated to cause clinical disease. Manifestations usually include cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. Various infiltrative patterns are seen on chest radiograph, and there may be associated cavitation or mediastinal lymphadenopathy. Acid-fast bacilli are seen on stained smears of sputum in approximately two thirds of culture-positive patients. Forms of extrapulmonary tuberculosis include lymphadenitis, pleural, genitourinary, skeletal, meningeal, gastrointestinal, and miliary or disseminated (Raviglione, 2012).

Treatment

Cure rates with 6-month short-course *directly observed therapy*—DOT—approach 90 percent for new infections. Resistance to antituberculosis drugs was first manifest in the United States in the early 1990s following the epidemic from 1985 through 1992 (Centers for Disease Control and Prevention, 2007a). Strains of *multidrug-resistant tuberculosis (MDR-TB)* increased rapidly as tuberculosis incidence fell during the 1990s. Because of this, the Centers for Disease Control and Prevention (2003) now recommends a multidrug regimen for initial empirical treatment of patients with symptomatic tuberculosis. Isoniazid, rifampin, pyrazinamide, and ethambutol are given until susceptibility studies are performed. Other second-line drugs may need to be added. Drug susceptibility is performed on all first isolates.

In 2005, there was a worldwide emergence of *extensively drug-resistant tuberculosis*—*XDR-TB*. This is defined as resistance in vitro to at least the first-line drugs isoniazid and rifampin as well as to three or more of the six main classes of second-line drugs—aminoglycosides, polypeptides, fluoroquinolones, thioamides, cycloserine, and *para*-aminosalicylic acid (Centers for Disease Control and Prevention,

2009a). Like their predecessor MDR-TB, these extensively resistant strains predominate in foreign-born persons (Tino, 2007).

Tuberculosis and Pregnancy

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnant women. Sackoff and coworkers (2006) reported positive-tuberculin tests in half of 678 foreign-born women attending perinatal clinics in New York City. Almost 60 percent were newly diagnosed. Pillay and colleagues (2004) stress the prevalence of tuberculosis in HIV-positive pregnant women. Margono and coworkers (1994) reported that for two New York City hospitals, more than half of pregnant women with active tuberculosis were HIV positive. At Jackson Memorial Hospital in Miami, Schulte and associates (2002) reported that 21 percent of 207 HIV-infected pregnant women had a positive skin test result. Recall also that silent endometrial tuberculosis can cause tubal infertility (Levison, 2010).

Without antituberculosis therapy, active tuberculosis appears to have adverse effects on pregnancy (Anderson, 1997; Mnyani, 2011). Contemporaneous experiences are few, however, because antitubercular therapy has diminished the frequency of severe disease. Outcomes are dependent on the site of infection and timing of diagnosis in relation to delivery. Jana and colleagues (1994) from India and Figueroa-Damian and Arrendondo-Garcia (1998) from Mexico City reported that active pulmonary tuberculosis was associated with increased incidences of preterm delivery, low-birthweight and growth-restricted infants, and perinatal mortality. From her review, Efferen (2007) cited twofold increased rates of low-birthweight and preterm infants as well as preeclampsia. The perinatal mortality rate was increased almost tenfold. Adverse outcomes correlate with late diagnosis, incomplete or irregular treatment, and advanced pulmonary lesions. From Taiwan, 761 pregnant women diagnosed with tuberculosis had a higher incidence of low-birthweight and growth-restricted infants (Lin, 2010).

Extrapulmonary tuberculosis is less common. Jana and coworkers (1999) reported outcomes in 33 pregnant women with renal, intestinal, and skeletal tuberculosis, and a third had low-birthweight newborns. Llewelyn and associates (2000) reported that nine of 13 pregnant women with extrapulmonary disease had delayed diagnoses. Prevost and Fung Kee Fung (1999) reviewed 56 cases of tuberculous meningitis in which a third of mothers died. Spinal tuberculosis may cause paraplegia, but vertebral fusion may prevent it from becoming permanent (Badve, 2011; Nanda, 2002). Other presentations include widespread intraperitoneal tuberculosis simulating ovarian carcinomatosis and degenerating leiomyoma, and hyperemesis gravidarum from tubercular meningitis (Kutlu, 2007; Moore, 2008; Sherer, 2005).

Diagnosis

There are two types of tests to detect latent or active tuberculosis. One is the time-honored *tuberculin skin test (TST)*, and the others are *interferon-gamma release assays (IGRAs)*, which

TABLE 51-4. Groups at High Risk for Having Latent Tuberculosis Infection

Health-care workers
Contact with infectious person(s)
Foreign-born
HIV-infected
Working or living in homeless shelters
Alcoholics
Illicit drug use
Detainees and prisoners

HIV = human immunodeficiency virus.
From the Centers for Disease Control and Prevention, 2005a.

are becoming preferred (Horsburgh, 2011). IGRAs are blood tests that measure interferon-gamma release in response to antigens present in *M tuberculosis*, but not bacille Calmette-Guérin (BCG) vaccine (Ernst, 2007; Levison, 2010). The Centers for Disease Control and Prevention (2005b, 2010b) recommend either skin testing or IGRA testing of pregnant women who are in any of the high-risk groups shown in Table 51-4. For those who received BCG vaccination, IGRA testing is used (Mazurek, 2010).

For skin testing, the preferred antigen is purified protein derivative (PPD) of intermediate strength of 5 tuberculin units. If the intracutaneously applied test result is negative, no further evaluation is needed. A positive skin test result measures ≥ 5 mm in diameter and requires evaluation for active disease, including a chest radiograph (Centers for Disease Control and Prevention, 2005a, 2010b). It also may be interpreted according to risk factors proposed by the American Thoracic Society/Centers for Disease Control and Prevention (1990). For *very high-risk* patients—that is, those who are HIV-positive, those with abnormal chest radiography, or those who have a recent contact with an active case—5 mm or greater is considered a reason to treat. For those at *high risk*—foreign-born individuals, intravenous drug users who are HIV-negative, low-income populations, or those with medical conditions that increase the risk for tuberculosis—10 mm or greater is considered treatable. For persons with none of these risk factors, 15 mm or greater is defined as requiring treatment.

There are two IGRAs available: *QuantiFERON-TB Gold* and *T-SPOT.TB* tests are recommended by the Centers for Disease Control and Prevention (2005a,b) for the same indications as skin testing. These tests have not been evaluated as extensively as tuberculin skin testing. Lalvani (2007) reviewed them and found them to be useful in identifying patients with latent tuberculosis and at risk for progression to active disease. Kowada (2014) concluded that these tests are cost effective.

Essential laboratory methods for detection or verification of infection—both active and latent—include microscopy, culture, nucleic acid amplification assay, and drug-susceptibility testing (Centers for Disease Control and Prevention, 2009a, 2010b).

Treatment

Latent Infection. Different schemes are recommended for latent and active tuberculosis. In nonpregnant tuberculin-positive patients who are younger than 35 years and who have no evidence of active disease, isoniazid, 300 mg orally daily, is given for 9 months. Isoniazid has been used for decades, and it is considered safe in pregnancy (Briggs, 2011; Taylor, 2013). Compliance is a major problem, and Sackoff (2006) and Cruz (2005) and their associates reported a disappointing 10-percent treatment completion. One obvious disconnect is that care for tuberculosis is given in health systems different from prenatal care (Zenner, 2012). These observations are important because most recommend that isoniazid therapy be delayed until after delivery. Because of possibly increased isoniazid-induced hepatitis risk in postpartum women, some recommend withholding treatment until 3 to 6 months after delivery. That said, neither method is as effective as antepartum treatment to prevent active infection. Boggess and colleagues (2000) reported that only 42 percent of 167 tuberculin-positive asymptomatic women delivered at San Francisco General Hospital completed 6-month therapy that was not given until the first postpartum visit.

There are exceptions to delayed treatment in pregnancy. Known recent skin-test convertors are treated antepartum because the incidence of active infection is 5 percent in the first year (Zumla, 2013). Skin-test-positive women exposed to active infection are treated because the incidence of infection is 0.5 percent per year.

HIV-positive women are treated because they have an approximate 10-percent annual risk of active disease. Treatment of these women is of special concern if there is antiretroviral naïveté. In these circumstances, beginning concomitant therapy with antituberculosis and antiretroviral therapy can cause the *immune reconstitution inflammatory syndrome (IRIS)* with toxic drug effects (Török, 2011). Recent studies, however, support earlier administration of highly active antiretroviral therapy (HAART)—within 2 to 4 weeks—after beginning antituberculosis therapy (Blanc, 2011; Havlir, 2011; Karim, 2011).

Active Infection. Recommended initial treatment for active tuberculosis in pregnant patients is a four-drug regimen with isoniazid, rifampin, ethambutol, and pyrazinamide, along with pyridoxine. In the first 2-month phase, all four drugs are given—*bactericidal phase*. This is followed by a 4-month phase of isoniazid and rifampin—*continuation phase* (Raviglione, 2012; Zumla, 2013). Reports of MDR-TB during pregnancy are few, and Lessnau and Qarah (2003) and Shin and coworkers (2003) have reviewed treatment options. Breast feeding is not prohibited during antituberculous therapy.

As discussed above, beginning concomitant antituberculosis and antiretroviral therapy may cause the immune reconstitution inflammatory syndrome, and risks versus benefits are assessed. Also, for HIV-infected women, rifampin or rifabutin use may be contraindicated if certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors are being administered. If there is resistance to rifabutin or rifampin, then pyrazinamide therapy is given. Of the second-line regimens, the aminoglycosides—streptomycin, kanamycin, amikacin, and capreomycin—are ototoxic to the fetus and are contraindicated (Briggs, 2011).

Neonatal Tuberculosis. Tubercular bacilleemia can infect the placenta, but it is uncommon that the fetus becomes infected—*congenital tuberculosis*. The term also applies to newborns who are infected by aspiration of infected secretions at delivery. Each route of infection constitutes approximately half of the cases. A rare case of congenital tuberculosis caused by in vitro fertilization (IVF) was reported (Doudier, 2008). Neonatal tuberculosis simulates other congenital infections and manifests with hepatosplenomegaly, respiratory distress, fever, and lymphadenopathy (Smith, 2002).

Cantwell and associates (1994) reviewed 29 cases of congenital tuberculosis reported since 1980. Only 12 of the mothers had active infection, and tuberculosis was frequently demonstrated by postpartum endometrial biopsy. Adhikari and colleagues (1997) described 11 South African postpartum women whose endometrial biopsy was culture-positive. Six of their neonates had congenital tuberculosis.

Neonatal infection is unlikely if the mother with active disease has been treated before delivery or if her sputum culture is negative. Because the newborn is susceptible to tuberculosis, most authors recommend isolation from the mother suspected of having active disease. If untreated, the risk of disease in the infant born to a woman with active infection is 50 percent in the first year (Jacobs, 1988).

SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease of unknown etiology characterized by an accumulation of T lymphocytes and phagocytes within noncaseating granulomas (Baughman, 2012). Predisposition to the disease is genetically determined and characterized by an exaggerated response of helper T lymphocytes to environmental triggers (Moller, 2007; Spagnolo, 2007). Pulmonary involvement is most common, followed by skin, eyes, and lymph nodes. The prevalence of sarcoid in the United States is 20 to 60 per 100,000, with equal sex distribution, but it is 3 to 17 times more common for black compared with white persons (Baughman, 2012). Most patients are between 20 and 40 years. Clinical presentation varies, but more than half of patients have dyspnea and a dry cough without constitutional symptoms that develop insidiously over months. Disease onset is abrupt in about 25 percent of patients, and 10 to 20 percent are asymptomatic at discovery.

Pulmonary symptoms are dominant, and more than 90 percent of patients have an abnormal chest radiograph at some point (Lynch, 2007). *Interstitial pneumonitis* is the hallmark of pulmonary involvement. Approximately 50 percent of affected patients develop permanent radiological changes. *Lymphadenopathy*, especially of the mediastinum, is present in 75 to 90 percent of cases, and 25 percent have *uveitis*. A fourth have skin involvement, usually manifest as *erythema nodosum*. In women, sarcoid causes about 10 percent of cases of erythema nodosum (Acosta, 2013; Mert, 2007). Finally, any other organ system may be involved. Confirmation of the diagnosis is with biopsy, and because the lung may be the only obviously involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and it resolves without treatment in 50 percent of patients. Still, there is

diminished quality of life (de Vries, 2007). In the other 50 percent, permanent organ dysfunction, albeit mild and non-progressive, persists. About 10 percent die because of their disease.

Glucocorticoids are the most widely used treatment, and methotrexate is second-line medication. Permanent organ derangement is seldom reversed by their use (Paramothayan, 2002). Thus, the decision to treat is based on symptoms, physical findings, chest radiograph, and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period. If inflammation does not subside, then prednisone, 1 mg/kg, is given daily for 4 to 6 weeks (Baughman, 2012). For those with an inadequate response, cytotoxic agents or cytokine modulators may be indicated.

■ Sarcoidosis and Pregnancy

Because sarcoidosis is uncommon and is frequently benign, it is not often seen in pregnancy. De Regt (1987) described 14 cases in 20,000 pregnancies during a 12-year period—almost 1 in 1500. Although sarcoidosis seldom affects pregnancy adversely, serious complications such as meningitis, heart failure, and neurosarcoidosis have been described (Cardonick, 2000; Maisel, 1996; Seballos, 1994).

In general, perinatal outcomes are unaffected by sarcoidosis. Selroos (1990) reviewed 655 patients with sarcoidosis referred to the Mjölbolsta Hospital District in Finland. Of 252 women between 18 and 50 years, 15 percent had sarcoidosis during pregnancy or within 1 year postpartum. There was no evidence for disease progression in the 26 pregnancies in women with active disease. Three aborted spontaneously, and the other 23 women were delivered at term. In 18 pregnancies in 12 women with inactive disease, pregnancy outcomes were good. Agha and coworkers (1982) reported similar experiences with 35 pregnancies at the University of Michigan.

Active sarcoidosis is treated using the same guidelines as for the woman who is not pregnant. Severe disease warrants serial determination of pulmonary function. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone, 1 mg/kg orally per day.

■ CYSTIC FIBROSIS

One of the most common fatal genetic disorders in whites, cystic fibrosis is caused by one of more than 1500 mutations in a 230-kb gene on the long arm of chromosome 7 that encodes an amino acid polypeptide (Boucher, 2012). This peptide functions as a chloride channel and is termed the *cystic fibrosis transmembrane conductance regulator* (CFTR). There is a wide phenotypic variation, even among homozygotes for the common $\Delta F508$ mutation (Rowntree, 2003). This is discussed in greater detail in Chapter 14 (p. 295). Approximately 20 percent of affected individuals are diagnosed shortly after birth because of *meconium peritonitis* (Boucher, 2012). Currently, nearly 80 percent of females with cystic fibrosis now survive to adulthood, and their median survival is about 30 years (Gillet, 2002).

■ Pathophysiology

Mutations in the chloride channel cause altered epithelial cell membrane transport of electrolytes. This affects all organs that express CFTR—secretory cells, sinuses, lung, pancreas, liver, and reproductive tract. Disease severity depends on which two alleles are inherited, and homozygosity for $\Delta F508$ is one of the most severe (McKone, 2003).

Exocrine gland ductal obstruction develops from thick, viscid secretions (Rowe, 2005). In the lung, submucosal glandular ducts are affected. Eccrine sweat gland abnormalities are the basis for the diagnostic *sweat test*, characterized by elevated sodium, potassium, and chloride levels in sweat.

Lung involvement is commonplace and is frequently the cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction leads to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. For complex and not completely explicable reasons, chronic inflammation from *Pseudomonas aeruginosa* occurs in more than 90 percent of patients. *S aureus*, *H influenzae*, and *Burkholderia cepacia* are recovered in a minority (Rowe, 2005). Colonization with the last has been reported to signify a worse prognosis, especially in pregnancy (Gillet, 2002). Acute and chronic parenchymal inflammation ultimately causes extensive fibrosis, and along with airway obstruction, there is a ventilation–perfusion mismatch. Pulmonary insufficiency is the end result. Lung or heart–lung transplantation has a 5-year survival rate of 33 percent (Aurora, 1999). A few women have successfully undergone pregnancy following lung transplantation (Kruszka, 2002; Shaner, 2012).

■ Preconceptional Counseling

Women with cystic fibrosis are subfertile because of tenacious cervical mucus. Males have oligospermia or aspermia from vas deferens obstruction, and 98 percent are infertile (Ahmad, 2013). Despite this, the North American Cystic Fibrosis Foundation estimates that 4 percent of affected women become pregnant every year (Edenborough, 1995). The endometrium and tubes express some CFTR but are functionally normal, and the ovaries do not express the CFTR gene (Edenborough, 2001). Both intrauterine insemination and IVF have been used successfully in affected women (Rodgers, 2000). Several ethical considerations of undertaking pregnancy by these women were reviewed by Wexler and colleagues (2007). For male infertility, Sobczyńska-Tomaszewska and associates (2006) have emphasized the importance of molecular diagnosis.

■ Screening

The American College of Obstetricians and Gynecologists (2011) recommends that carrier screening be offered to at-risk couples. This is discussed in detail in Chapter 14 (p. 295). The Centers for Disease Control and Prevention also added cystic fibrosis to newborn screening programs (Comeau, 2007). This is discussed also in Chapter 32 (p. 632) and was the subject of a Cochrane Database review (Southern, 2009).

■ Pregnancy with Cystic Fibrosis

Pregnancy outcome is inversely related to severity of lung dysfunction. Severe chronic lung disease, hypoxia, and frequent

infections may prove deleterious. At least in the past, *cor pulmonale* was common, but even that does not preclude successful pregnancy (Cameron, 2005). In some women, *pancreatic dysfunction* may cause poor maternal nutrition. Normal pregnancy-induced insulin resistance frequently results in gestational diabetes after midpregnancy (Hardin, 2005; McMullen, 2006). In one study of 48 pregnancies, half had pancreatic insufficiency and a third required insulin (Thorpe-Beeson, 2013). Diabetes is most frequent with the $\Delta F508$ homozygous mutation (Giacobbe, 2012).

Cystic fibrosis per se is not affected by pregnancy (Schechter, 2013). Early reports of a deleterious effect on the course of cystic fibrosis were related to severe disease (Olson, 1997). An important factor to be considered in childbearing is the long-term prognosis for the mother. When matched with nonpregnant women by disease severity, recent reports indicate no deleterious effects on long-term survival (McMullen, 2006; Schechter, 2013).

Management

Prepregnancy counseling is imperative. Women who choose to become pregnant should have close surveillance for development of superimposed infection, diabetes, and heart failure. They are followed closely with serial pulmonary function testing, for management as well as for prognosis. When the FEV₁ is at least 70 percent, women usually tolerate pregnancy well. Emphasis is placed on postural drainage, bronchodilator therapy, and infection control.

β -Adrenergic bronchodilators help control airway constriction. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity (Boucher, 2012). Inhaled 7-percent saline has been shown to produce short- and long-term benefits (Donaldson, 2006; Elkins, 2006). Nutritional status is assessed and appropriate dietary counseling given. Pancreatic insufficiency is treated with replacement of oral pancreatic enzyme.

Infection is heralded by increasing cough and mucus production. Oral semisynthetic penicillins or cephalosporins usually suffice to treat staphylococcal infections. *Pseudomonas* infection is most problematic in adults. Inhaled tobramycin and colistin have been used successfully to control this organism (Boucher, 2012; Ratjen, 2003).

Immediate hospitalization and aggressive therapy are warranted for serious pulmonary infections. The threshold for hospitalization with other complications is low. For labor and delivery, epidural analgesia is recommended.

Pregnancy Outcome

When Cohen and coworkers (1980) conducted the first major survey of cystic fibrosis centers, severity was assessed by the *Schwachman-Kulezkycki* or *Taussig* scores based on radiological and clinical criteria. Although pregnancy outcomes were not disastrous, 18 percent of 129 women died within 2 years of giving birth. In a later review through 1991, Kent and Farquharson (1993) described similar outcomes in 215 pregnancies in 160 women.

More recent reports describe better outcomes, but there still are serious complications. Disease severity is now quantified

by pulmonary function studies, which are the best predictor of pregnancy and long-term maternal outcome. Edenborough and colleagues (2000) reported 69 pregnancies from 11 cystic fibrosis centers in the United Kingdom. If prepregnancy FEV₁ was < 60 percent of predicted, there was substantive risk for preterm delivery, respiratory complications, and death of the mother within a few years of childbirth. Thorpe-Beeson and associates (2013) reported similar findings.

Fitzsimmons and coworkers (1996) performed a case-control study of 258 women with cystic fibrosis who had a live birth. The 889 matched controls were women with cystic fibrosis who had not been pregnant. Pregnancy had no effect on worsening of any serious complications, and 8 percent in both groups had died by 2 years. Gillet and colleagues (2002) reported 75 pregnancies from the French Cystic Fibrosis Registry. Almost 20 percent of infants were delivered preterm, and 30 percent had growth restriction. The one maternal death was due to *Pseudomonas* sepsis in a woman whose prepregnancy FEV₁ was 60 percent. Long-term, however, 17 percent of women died and four infants had confirmed cystic fibrosis. Likewise, in the study by Thorpe-Beeson (2013) cited above, four of eight women whose FEV₁ was < 40 to 50 percent died from 2 to 8 years after delivery.

Lung Transplantation

Cystic fibrosis is a common antecedent disease leading to lung transplantation. Gyi and coworkers (2006) reviewed 10 pregnancies in such women and reported nine liveborn infants. Maternal outcomes were less favorable—three developed rejection during pregnancy, and all three had progressively declining pulmonary function and died of chronic rejection by 38 months after delivery.

CARBON MONOXIDE POISONING

Carbon monoxide is a ubiquitous gas, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be as high as 5 to 10 percent. Carbon monoxide is the most frequent cause of poisoning worldwide (Stoller, 2007). Toxic levels are often encountered in inadequately ventilated areas warmed by space heaters.

Carbon monoxide is particularly toxic because it is odorless and tasteless and has a high affinity for hemoglobin binding. Thus, it displaces oxygen and impedes its transfer with resultant hypoxia. Besides acute sequelae including death and anoxic encephalopathy, cognitive defects develop in as many as half of patients following loss of consciousness or in those with carbon monoxide levels > 25 percent (Weaver, 2002). Hypoxic brain damage has a predilection for the cerebral cortex and white matter and for the basal ganglia (Lo, 2007; Prockop, 2007).

Pregnancy and Carbon Monoxide Poisoning

Through several physiological alterations, the rate of endogenous carbon monoxide production almost doubles in normal pregnancy (Longo, 1977). Although the pregnant woman is not more susceptible to carbon monoxide poisoning, the fetus does

not tolerate excessive exposure. With chronic exposure, maternal symptoms usually appear when the carboxyhemoglobin concentration is 5 to 20 percent. Symptoms include headache, weakness, dizziness, physical and visual impairment, palpitations, and nausea and vomiting. With acute exposure, concentrations of 30 to 50 percent produce symptoms of impending cardiovascular collapse. Levels > 50 percent may be fatal for the mother.

Because hemoglobin F has an even higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother. This may be due to facilitated diffusion (Longo, 1977). Importantly, the half-life of carboxyhemoglobin is 2 hours in the mother but 7 hours in the fetus. Because carbon monoxide is bound so tightly to hemoglobin F, the fetus may be hypoxic even before maternal carbon monoxide levels are appreciably elevated. Several anomalies are associated with embryonic exposure, and anoxic encephalopathy is the primary sequela of later fetal exposure (Alehan, 2007; Aubard, 2000).

Treatment

For all victims, treatment of carbon monoxide poisoning is supportive along with immediate administration of 100-percent inspired oxygen. Indications for hyperbaric oxygen treatment in nonpregnant individuals are unclear (Kao, 2005). Weaver and associates (2002) reported that hyperbaric oxygen treatment minimized the incidence of cognitive defects in adults at both 6 weeks and 1 year compared with that with normobaric oxygen. Hyperbaric oxygen is generally recommended in pregnancy if there has been “significant” carbon monoxide exposure (Aubard, 2000; Ernst, 1998). The problem is how to define significant exposure. Although maternal carbon monoxide levels are not accurately predictive of those in the fetus, some clinicians recommend hyperbaric therapy if maternal levels exceed 15 to 20 percent. With fetal heart rate pattern evaluation, Towers and Corcoran (2009) described affected fetuses to have an elevated baseline, diminished variability, and absent accelerations and decelerations. Treatment of the affected newborn with hyperbaric oxygen is also controversial (Bar, 2007).

Elkharrat and colleagues (1991) reported successful hyperbaric treatments in 44 pregnant women. Silverman and Montano (1997) reported successful management of a woman whose abnormal neurological and cardiopulmonary findings abated in a parallel fashion with resolution of associated fetal heart rate variable decelerations. Greingor and coworkers (2001) used 2.5-atm hyperbaric 100-percent oxygen for 90 minutes in a 21-week pregnant woman who was delivered of a healthy infant at term. According to the Divers Alert Network—DAN (2013)—at Duke University, there are 700 chambers in North and Central America and the Caribbean. Consultation from DAN is available at 919-684-9111.

CHAPTER 52

Thromboembolic Disorders

PATHOPHYSIOLOGY 1028

THROMBOPHILIAS 1029

THROMBOPHILIA SCREENING 1034

DEEP-VEIN THROMBOSIS 1035

LABOR AND DELIVERY 1039

SUPERFICIAL VENOUS THROMBOPHLEBITIS 1040

PULMONARY EMBOLISM 1040

THROMBOPROPHYLAXIS 1044

The risk of venous thrombosis and pulmonary embolism in otherwise healthy women is considered highest during pregnancy and the puerperium. Indeed, in a recent study from the United Kingdom of nearly 1 million reproductive-aged women, the risks of venous thromboembolism for those during the third trimester and the first 6 weeks postpartum were calculated to be six and 22 times higher, respectively, than for nonpregnant women (Sultan, 2011). The incidence of all thromboembolic events averages approximately 1 per 1000 pregnancies, and about an equal number are identified antepartum and in the puerperium. In a study from Norway of more than 600,000 pregnancies, Jacobsen and colleagues (2008) reported that deep-vein thrombosis alone was more frequent antepartum, whereas pulmonary embolism was more common in the first 6 weeks postpartum.

Venous thromboembolism frequency during the puerperium has decreased remarkably as early ambulation has become more widely practiced. Even so, the thromboembolism rate has increased significantly during the past two decades (Callaghan, 2012). Although this increase may reflect the higher sensi-

tivities of newer diagnostic modalities, pulmonary embolism still remains a leading cause of maternal death in the United States (Table 1-3, p. 6) (O'Connor, 2011). Specifically, Berg and associates (2010) reported that approximately 10 percent of pregnancy-related maternal deaths in the United States between 1998 and 2005 were caused by thrombotic pulmonary embolism.

PATHOPHYSIOLOGY

Rudolf Virchow (1856) postulated that stasis, local trauma to the vessel wall, and hypercoagulability predisposed to venous thrombosis development. The risk for each of these increases during normal pregnancy. For example, compression of the pelvic veins and inferior vena cava by the enlarging uterus renders the lower extremity venous system particularly vulnerable to stasis. From their review, Marik and Plante (2008) cite a 50-percent reduction in venous flow velocity in the legs that lasts from the early third trimester until 6 weeks postpartum. This stasis is the most constant predisposing risk factor for venous thrombosis. Venous stasis and delivery may also contribute to endothelial cell injury. Last, as listed in the Appendix (p. 1288), marked increases in the synthesis of most clotting factors during pregnancy favor coagulation.

Risk factors for developing thromboembolism during pregnancy are shown in Table 52-1. The most important of these is a personal history of thrombosis. Indeed, 15 to 25 percent of all venous thromboembolism cases during pregnancy are recurrent events (American College of Obstetricians and Gynecologists, 2011). The magnitude of other risk factors was estimated by James and coworkers (2006) using data from the Agency for Healthcare Research and Quality of all hospital discharges during 2000 and 2001. They identified the diagnosis of venous thromboembolism in 7177 women during pregnancy and 7158 during the postpartum period. Calculated risks for

TABLE 52-1. Some Risk Factors Associated with an Increased Risk for Thromboembolism

Risk Factor ^a	Chapter Referral
Obstetrical	
Cesarean delivery	30
Diabetes	57
Hemorrhage and anemia	41
Hyperemesis	54
Immobility—prolonged bed rest	—
Multifetal gestation	45
Multiparity	—
Preeclampsia	40

Connective-tissue disease	59
Dehydration	54
Immobility—long-distance travel	8
Infection and inflammatory disease	37
Myeloproliferative disease	56
Nephrotic syndrome	53
Obesity	48
Oral contraceptive use	38
Orthopedic surgery	46
Paraplegia	60
Prior thromboembolism	52
Sickle-cell disease	56
Smoking	8
Thrombophilia	52

^aRisk factors are listed alphabetically.

thromboembolism were approximately doubled in women with multifetal gestation, anemia, hyperemesis, hemorrhage, and cesarean delivery. The risk was even greater in pregnancies complicated by postpartum infection. In a more recent nested case-control study of nearly 100,000 women with 10-year follow-up, Waldman and colleagues (2013) found that the risk

of venous thromboembolism was slightly higher in women with advanced maternal age and approximately doubled in women with great parity, a hypertensive disorder, cesarean delivery, or obesity. Risks were significantly greater among women who had a stillbirth or who underwent peripartum hysterectomy. At Parkland Hospital, the risk of postpartum thromboembolism most recently is approximately 1 in 5350 deliveries, with all of these risk factors confirmed.

The likelihood of developing a thrombosis during pregnancy is especially increased in women with certain genetic risk factors. Indeed—and likely related—after personal history of thrombosis, the next most important individual risk factor is thrombophilia. An estimated 20 to 50 percent of women who develop a venous thrombosis during pregnancy or postpartum have an identifiable underlying genetic disorder (American College of Obstetricians and Gynecologists, 2011).

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors in the coagulation cascade. Normal values for many of these proteins during pregnancy are found in the Appendix (p. 1288). Inherited or acquired deficiencies of these inhibitory proteins are collectively referred to as *thrombophilias*. These can lead to hypercoagulability and recurrent venous thromboembolism. Although these disorders are collectively present in about 15 percent of white European populations, they are responsible for approximately 50 percent of all thromboembolic events during pregnancy (Lockwood, 2002; Pierangeli, 2011). Some aspects of the more common inherited thrombophilias are summarized in [Table 52-2](#) and [Figure 52-1](#).

Inherited Thrombophilias

Patients with inherited thrombophilic disorders often have a family history of thrombosis. Inherited thrombophilias are also found in up to half of all patients who present with venous thromboembolism before the age of 45 years, particularly in those whose event occurred in the absence of well-recognized risk factors, such as surgery or immobilization,

TABLE 52-2. Inherited Thrombophilias and Their Association with Venous Thromboembolism (VTE) in Pregnancy

	Prevalence in General Population (%)	VTE Risk per Pregnancy (No History) (%)	VTE Risk per Pregnancy (Prior VTE) (%)	All VTE (%)
Factor V Leiden heterozygote	1–15	0.5–1.2	10	40
Factor V Leiden homozygote	< 1	4	17	2
Prothrombin gene heterozygote	2–5	< 0.5	> 10	17
Prothrombin gene homozygote	< 1	2–4	> 17	0.5
Factor V Leiden/prothrombin double heterozygote	0.01	4–5	> 20	1–3
Antithrombin III activity (< 60%)	0.02	3–7	40	1
Protein C activity (< 50%)	0.2–0.4	0.1–0.8	4–17	14
Protein S free antigen (< 55%)	0.03–0.13	0.1	0–22	3

Adapted from the American College of Obstetricians and Gynecologists, 2013.

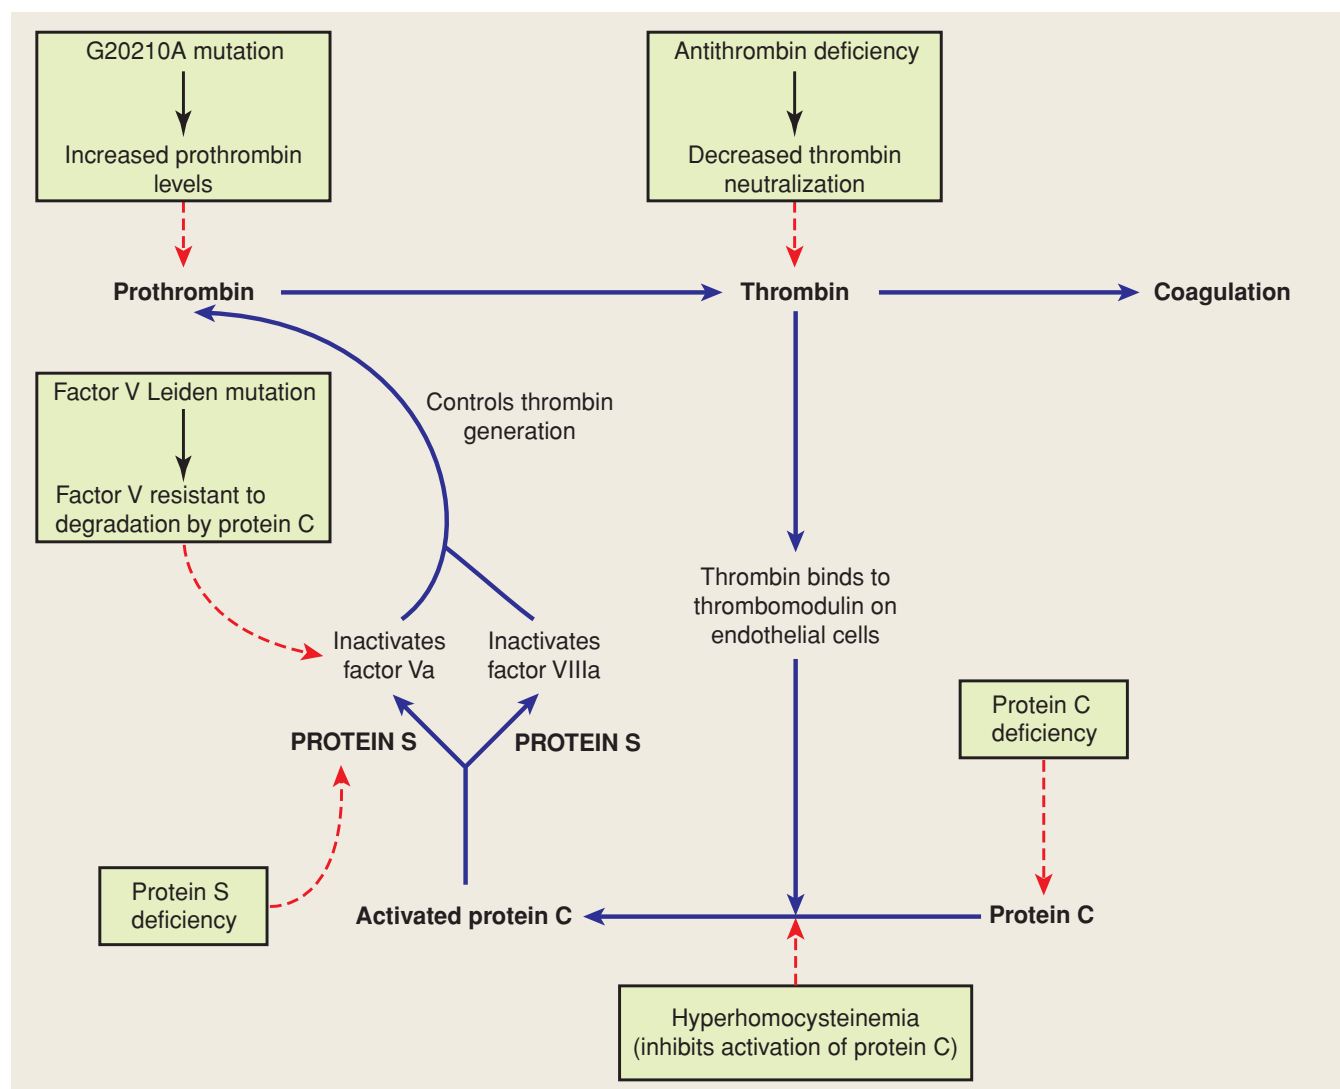

FIGURE 52-1 Overview of the inherited thrombophilias and their effect(s) on the coagulation cascade. (Adapted from Seligsohn, 2001.)

or with minimal provocation such as after a long-distance flight or after taking estrogens. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis (Anderson, 2011).

Antithrombin Deficiency

Synthesized in the liver, antithrombin is one of the most important inhibitors of thrombin in clot formation. Antithrombin functions as a natural anticoagulant by binding and inactivating thrombin and the activated coagulation factors IXa, Xa, XIa, and XIIa (Franchini, 2006). Of note, the rate of antithrombin interaction with its target proteases is accelerated by heparin (Anderson, 2011). Antithrombin deficiency may result from hundreds of different mutations that are almost always autosomal dominant. Type I deficiency is the result of reduced synthesis of biologically normal antithrombin, and type II deficiency is characterized by normal levels of antithrombin with reduced functional

activity (Anderson, 2011). Homozygous antithrombin deficiency is lethal (Katz, 2002).

Antithrombin deficiency is rare—it affects approximately 1 in 2000 to 5000 individuals, and it is the most thrombogenic of the heritable coagulopathies. Indeed, the thrombosis risk during pregnancy among antithrombin-deficient women without a personal or family history is 3 to 7 percent, and it is 11 to 40 percent with such a history (Lockwood, 2012). Specifically, those affected have approximately a 50-percent lifetime risk of venous thromboembolism.

Sabadell and associates (2010) studied the outcomes of 18 pregnancies complicated by antithrombin deficiency. Twelve of these were treated with low-molecular-weight heparin, and six were not treated because antithrombin deficiency had not yet been diagnosed. Three of the untreated patients suffered a thromboembolic episode compared with none in the treated group. Untreated women also had a 50-percent risk of stillbirth and fetal-growth restriction. By comparison, none of the treated women had a stillbirth, and approximately a fourth developed fetal-growth restriction. Seguin

and coworkers (1994) reviewed the outcomes of 23 newborns with antithrombin deficiency and described 11 cases of thrombosis and 10 deaths.

Given such risk, affected women are treated during pregnancy with heparin regardless of whether they have had a prior thrombosis. When anticoagulation is necessarily withheld, such as during surgery or delivery, Paidas and colleagues (2013) found that treatment with recombinant human antithrombin protected against venous thromboembolism development in 21 patients with hereditary antithrombin deficiency. Sharpe and associates (2011) described successful use of antithrombin concentrate infusions plus therapeutic anticoagulation in a pregnant woman with antithrombin deficiency who developed a thrombosis during the third trimester despite therapeutic doses of low-molecular-weight heparin.

Protein C Deficiency

When thrombin is bound to thrombomodulin on endothelial cells of small vessels, its procoagulant activities are neutralized. This binding also activates protein C, a natural anticoagulant that in the presence of protein S controls thrombin generation, in part, by inactivating factors Va and VIIIa (see Fig. 52-1). Activated protein C also inhibits the synthesis of plasminogen-activator inhibitor 1 (p. 1032).

Protein C activity is largely unchanged in pregnancy (Appendix, p. 1288). Based on their study of 440 healthy women, however, Said and associates (2010b) found that protein C activity increases modestly but significantly throughout the first half of pregnancy. These investigators speculated that this increase may play a role in maintaining early pregnancy through both anticoagulant and inflammatory regulatory pathways.

More than 100 different autosomal dominant mutations for the protein C gene have been described. The prevalence of protein C deficiency is 2 to 3 per 1000, but many of these individuals do not have a thrombosis history because the phenotypic expression is highly variable (Anderson, 2011). These prevalence estimates correspond with functional activity threshold values of 50 to 60 percent, which are used by most laboratories and which are associated with a six- to 12-fold increased risk for venous thromboembolism (Lockwood, 2012).

Protein S Deficiency

This circulating anticoagulant is activated by protein C, which enhances its capacity to inactivate factors Va and VIIIa (see Fig. 52-1). Protein S deficiency may be caused by more than 100 different mutations, with an aggregate prevalence of approximately 2 per 1000 (Lockwood, 2012). Protein S deficiency may be measured by antigenically determined free, functional, and total S levels. All three decline substantively during normal gestation, thus the diagnosis in pregnant women—as well as in those taking certain oral contraceptives—is difficult (Archer, 1999). If screening during pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at less than 30 percent and less than 24 percent, respectively. Among those with a positive family history, the venous thromboembolism risk in pregnancy

has been reported to be 6 to 7 percent (American College of Obstetricians and Gynecologists, 2013).

Conard and coworkers (1990) described thrombosis in 5 of 29 pregnant women with protein S deficiency. One woman had a cerebral vein thrombosis. Similarly, Burneo and colleagues (2002) reported maternal cerebral vein thrombosis at 14 weeks' gestation. Neonatal homozygous protein C or S deficiency is usually associated with a severe clinical phenotype known as purpura fulminans. This is characterized by extensive thromboses in the microcirculation soon after birth leading to skin necrosis (Salonvaara, 2004).

Activated Protein C Resistance—Factor V Leiden Mutation

The most prevalent of the known thrombophilia syndromes, this condition is characterized by resistance of plasma to the anticoagulant effects of activated protein C. A number of mutations have been described, but the most common is the factor V Leiden mutation, which was named after the city in which it was described. This missense mutation in the factor V gene results from a substitution of glutamine for arginine at position 506 in the factor V polypeptide, which gains resistance to degradation by activated protein C. The unimpeded abnormal factor V protein retains its procoagulant activity and predisposes to thrombosis (see Fig. 52-1).

Heterozygous inheritance for factor V Leiden is the most common heritable thrombophilia. It is found in 3 to 15 percent of select European populations and 3 percent of African Americans, but it is virtually absent in African blacks and Asians (Lockwood, 2012). As shown in Table 52-2, women who are heterozygous for factor V Leiden account for approximately 40 percent of venous thromboembolism cases during pregnancy. However, the actual risk among pregnant women who are heterozygous and who do not have a personal history or a first-degree relative with a thrombotic episode before age 50 years is 5 to 12 per 1000. In contrast, this risk increases to at least 10 percent among women with a personal or family history. Pregnant women who are homozygous without a personal or family history have a 1- to 4-percent risk for venous thromboembolism, whereas those with such a history have an approximately 17-percent risk (American College of Obstetricians and Gynecologists, 2013).

As described later (p. 1034), diagnosis during pregnancy is performed by DNA analysis for the mutant factor V gene. This is because bioassay is confounded by the fact that resistance is normally increased after early pregnancy because of alterations in other coagulation proteins (Walker, 1997). Of note, activated protein C resistance can also be caused by antiphospholipid syndrome, which is described later (p. 1033) and also detailed in Chapter 59 (p. 1173) (Eldor, 2001; Saenz, 2011).

To assess the prognostic significance of maternal factor V Leiden mutation during pregnancy, Kjellberg and colleagues (2010) compared the outcomes of 491 carriers with 1055 controls. All three of the thromboembolic events occurred among the carriers. But, there were no differences in preterm birth, birthweight, or hypertensive complications between the two groups. Similarly, Hammerová and coworkers (2011) found

that adverse pregnancy events were not increased among women with heterozygous mutations. In a meticulously executed prospective observational study of approximately 5000 women conducted by the Maternal-Fetal Medicine Units Network, Dizon-Townson and associates (2005) found that the heterozygous mutant gene incidence was 2.7 percent. Of three pulmonary emboli and one deep-vein thrombosis cases—a rate of 0.8 per 1000 pregnancies—none were among these carriers. There was no increased risk of preeclampsia, placental abruption, fetal-growth restriction, or pregnancy loss in heterozygous women. The investigators concluded that universal prenatal screening for the Leiden mutation and prophylaxis for carriers without a prior venous thromboembolism is not indicated. Finally, Clark and colleagues (2002) concluded that such routine prenatal screening was not cost effective.

Prothrombin G20210A Mutation

This missense mutation in the prothrombin gene leads to excessive accumulation of prothrombin, which then may be converted to thrombin. As with factor V Leiden, a personal history or a family history of venous thromboembolism in a first-degree relative before age 50 years increases the risk of venous thromboembolism during pregnancy (see Table 52-2). For a heterozygous carrier with such a history, the risk exceeds 10 percent. Without such a history, heterozygous carriers of the mutation have less than a 1-percent risk of venous thromboembolism during pregnancy (American College of Obstetricians and Gynecologists, 2013).

Homozygous patients or those who coinherit a G20210A mutation with a factor V Leiden mutation have an even greater thromboembolism risk. Stefano and associates (1999) performed a retrospective cohort study of 624 nonpregnant patients with one prior episode of deep-vein thrombosis. They found that those doubly heterozygous individuals had a 2.6-fold increased risk of recurrence relative to those with the heterozygous Leiden mutation alone. They concluded that carriers with both mutations are candidates for lifelong anticoagulation after a first thrombotic episode.

In a secondary analysis of the Maternal-Fetal Medicine Units Network study described earlier, Silver and coworkers (2010) tested nearly 4200 women for the prothrombin G20210A mutation. A total of 157—or 3.8 percent—of the women carried the mutation, and only one of these was homozygous. Carriers had similar rates of pregnancy loss, preeclampsia, growth restriction, and placental abruption compared with noncarriers. The three thromboembolic events occurred in women who tested negative for the mutation.

Hyperhomocysteinemia

The most common cause of elevated homocysteine is the C667T thermolabile mutation of the enzyme 5, 10-methylene-tetrahydrofolate reductase (MTHFR). Inheritance is autosomal recessive. Elevated homocysteine levels may also result from deficiency of one of several enzymes involved in methionine metabolism and from correctible nutritional deficiencies of folic acid, vitamin B₆, or vitamin B₁₂ (Hague, 2003; McDonald, 2001). During normal pregnancy, mean homo-

cysteine plasma concentrations are decreased (López-Quesada, 2003; McDonald, 2001). Thus, to make a diagnosis during pregnancy, Lockwood (2002) recommends a fasting threshold of > 12 μmol/L to define hyperhomocysteinemia.

Although hyperhomocysteinemia was previously reported to be a modest risk factor for venous thromboembolism, more recent data indicate that an elevated homocysteine level is actually a weak risk factor (American College of Obstetricians and Gynecologists, 2013). In an interesting metaanalysis, den Heijer and colleagues (2005) found that international studies of MTHFR polymorphisms were collectively associated with slightly increased significant risks for thrombosis—odds ratios 1.15 to 1.6. In contrast, studies conducted in North America collectively demonstrated no such association. The authors speculated that folic acid supplementation could explain the difference. Recall that folic acid serves as a cofactor in the remethylation reaction of homocysteine to methionine. Similarly, the American College of Chest Physicians concluded that the lack of an association with thromboembolism could reflect the physiological reductions in homocysteine levels associated with pregnancy and the effects of widespread prenatal folic acid supplementation (Bates, 2012).

In a follow-up study of 167 women who developed a venous thromboembolism during pregnancy and 128 controls, Kovac and associates (2010) found no difference in the prevalence of MTHFR C677T homozygosity between the two groups. The American College of Obstetricians and Gynecologists (2013) has concluded that there is insufficient evidence to support assessment of MTHFR polymorphisms or measurement of fasting homocysteine levels in the evaluation for venous thromboembolism.

Other Thrombophilia Mutations

A number of potentially thrombophilic polymorphisms are being discovered at an ever-increasing rate. Unfortunately, information regarding the prognostic significance of such newly discovered mutations is limited. For example, protein Z is a vitamin K-dependent protein that serves as a cofactor in factor Xa inactivation. Studies in nonpregnant patients have found that low protein Z levels are associated with an increased thromboembolism risk (Santacroce, 2006). Similarly, plasminogen activator inhibitor type 1 (PAI-1) is an important regulator of fibrinolysis. Certain polymorphisms in the gene promoter have been associated with small increased venous thromboembolism risks. These thrombophilias and others, including alternative mutations in the factor V gene and activity-enhancing mutations in various clotting factor genes, appear to exert little independent risk for venous thromboembolism. And although they may exacerbate risk among patients when coinherited with other thrombophilias, the American College of Obstetricians and Gynecologists (2013) has concluded that there is insufficient evidence to recommend screening.

As an interesting aside, Galanaud and coworkers (2010) hypothesized that a paternal thrombophilia could increase the risk of a maternal thromboembolism. Specifically, these investigators found that a paternal thrombophilia—the PROCRC 6936G allele—affects the endothelial protein C receptor. This receptor is expressed by villous trophoblast and thus is exposed to maternal blood. Although this research is preliminary, it

could help explain the pathogenesis of recurrent idiopathic thromboses in pregnant women.

■ Acquired Thrombophilias

Some examples of acquired hypercoagulable states include antiphospholipid syndrome (Chap. 59, p. 1173), heparin-induced thrombocytopenia (p. 1040), and cancer (Chap. 63, p. 1219).

Antiphospholipid Antibodies

These autoantibodies are detected in approximately 2 percent of patients who have nontraumatic venous thrombosis. The antibodies are directed against cardiolipin(s) or against phospholipid-binding proteins such as β_2 -glycoprotein I. They are commonly—but not always—found in patients with systemic lupus erythematosus and are described in detail in Chapter 59 (p. 1169). Women with moderate-to-high levels of these antibodies may have antiphospholipid syndrome, which, as summarized by the American College of Obstetricians and Gynecologists (2012), is defined by a number of clinical features. In addition to vascular thromboses, these include: (1) at least one otherwise unexplained fetal death at or beyond 10 weeks; (2) at least one preterm birth before 34 weeks because of eclampsia, severe preeclampsia, or placental insufficiency; or (3) at least three unexplained consecutive spontaneous abortions before 10 weeks.

In these women, thromboembolism—either venous or arterial—most commonly involves the lower extremities. Importantly, the syndrome should also be considered in women with thromboses in unusual sites, such as the portal, mesenteric, splenic, subclavian, axillary, and cerebral veins. Antiphospholipid antibodies predispose to arterial thromboses, which may also occur in relatively unusual locations, such as the retinal, subclavian, brachial, or digital arteries. The thrombotic mechanisms associated with antiphospholipid syndrome have recently been reviewed by Giannakopoulos and Krilis (2013).

The thrombosis risk increases significantly during pregnancy in women with antiphospholipid syndrome. Indeed, up to 25 percent of thrombotic events in women with antiphospholipid syndrome occur during pregnancy or in the puerperium. Looking at this a different way, women with antiphospholipid syndrome have a 5- to 12-percent risk of thrombosis during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2012).

■ Thrombophilias and Pregnancy Complications

Attention has been directed toward possible relationships between inherited thrombophilias and pregnancy complications other than thromboses. Summarized in [Table 52-3](#) are

TABLE 52-3. Obstetrical Complications Associated with Thrombophilias

Type of Thrombophilia	Early Loss	Recurrent First-Trimester Loss	Nonrecurrent Second-Trimester Loss	Late Loss	Preeclampsia	Placental Abruptio	Fetal-Growth Restriction
Factor V Leiden (homozygous)	2.71 (1.32–5.58)	— ^a	— ^a	1.98 (0.40–9.69)	1.87 (0.44–7.88)	8.43 (0.41–171.20)	4.64 (0.19–115.68)

From Bates, 2012.

the findings of 25 studies systematically reviewed by Robertson and associates (2005). These were incorporated into the most recent recommendations of the American College of Chest Physicians (Bates, 2012). Importantly, the considerable heterogeneity and wide confidence intervals illustrate the uncertainty of these associations.

More recent investigations continue to underscore the heterogeneity of results. For example, Kahn and coworkers (2009) found no increased risk for early-onset or severe preeclampsia in women with factor V Leiden mutation, prothrombin G20210A mutation, MTHFR C677T polymorphism, or hyperhomocysteinemia. Said and associates (2010a) prospectively screened more than 2000 healthy nulliparous women for factor V Leiden, prothrombin gene mutation, MTHFR C677T, MTHFR A1298C, and thrombomodulin polymorphism. Women who carried the prothrombin gene mutation had a 3.6-fold increased risk of adverse pregnancy outcome, including severe preeclampsia, fetal-growth restriction, placental abruption, or stillbirth. But, none of the other polymorphisms conferred an increased risk of these adverse outcomes. Moreover, this group of investigators found no association between the PAI-1 4G/5G polymorphism and adverse pregnancy outcome (Said, 2012). Similarly, based on their prospective study of 750 pregnancies complicated by stillbirth, Korteweg and colleagues (2010) concluded that routine thrombophilia testing after fetal death is inadvisable.

Because of uncertainties associated with the magnitude of risk as well as any benefits of prophylaxis given to prevent pregnancy complications in women with heritable thrombophilias, it remains unproven that screening is in the best interest of these women. The American College of Obstetricians and Gynecologists (2013) has concluded that a definitive causal link cannot be made between inherited thrombophilias and adverse pregnancy outcomes. Similarly, the American College of Chest Physicians recently concluded that it was unclear whether screening for inherited thrombophilias is prudent in women with pregnancy complications (Bates, 2012). In contrast, and as

shown in Table 52-3 and detailed in Chapter 59 (p. 1174), the association between antiphospholipid syndrome and adverse pregnancy outcomes—including fetal loss, recurrent pregnancy loss, and preeclampsia—is much stronger.

Thrombophilia Screening

Given the high incidence of thrombophilia in the population and the low incidence of venous thromboembolism, universal screening during pregnancy is not cost effective (Carbone, 2010). Thus, a selective screening strategy is required. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that thrombophilia screening be considered in the following clinical circumstances: (1) a personal history of venous thromboembolism that was associated with a nonrecurrent risk factor such as fractures, surgery, and/or prolonged immobilization; and (2) a first-degree relative (parent or sibling) with a history of high-risk thrombophilia or venous thromboembolism before age 50 years in the absence of other risk factors.

As described earlier, the American College of Obstetricians and Gynecologists (2013) has concluded that testing for inherited thrombophilias in women who have experienced recurrent fetal loss or placental abruption is not recommended because there is insufficient clinical evidence that antepartum heparin prophylaxis prevents recurrence. Similarly, testing is not recommended for women with a history of fetal-growth restriction or preeclampsia. The American College of Chest Physicians also recommends against screening women with prior pregnancy complications (Bates, 2012). As discussed in Chapter 59, however, screening for antiphospholipid antibodies may be appropriate in women who have experienced a fetal loss.

Screening Tests

Methods of screening for the more common inherited thrombophilias are shown in Table 52-4. Whenever possible, laboratory testing should be performed at least 6 weeks after the

TABLE 52-4. Inherited Thrombophilia Testing

Thrombophilia	Testing Method	Is Testing Reliable During Pregnancy?	Is Testing Reliable During Acute Thrombosis?	Is Testing Reliable with Anticoagulation?
Factor V Leiden mutation	Activated protein C resistance assay (second generation)	Yes	Yes	No
	If abnormal: DNA analysis	Yes	Yes	Yes
Prothrombin gene mutation G20210A	DNA analysis	Yes	Yes	Yes
Protein C deficiency	Protein C activity (< 60%)	Yes	No	No
Protein S deficiency	Functional assay (< 55%)	No ^a	No	No
Antithrombin deficiency	Antithrombin activity (< 60%)	Yes	No	No

^aIn nonpregnant patients, protein S deficiency should be assessed initially by performing a functional assay. A value < 55 percent should be followed with measurement of free protein S levels. A free protein S antigen value < 55 percent is consistent with protein S deficiency. If screening in pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at < 30 percent and < 24 percent, respectively.

Adapted from the American College of Obstetricians and Gynecologists, 2013.

thrombotic event, while the patient is not pregnant, and when she is not receiving anticoagulation or hormonal therapy. Because of the lack of association between methylenetetrahydrofolate reductase (MTHFR) gene mutations—the most common cause of hyperhomocysteinemia—and adverse pregnancy outcomes, screening with fasting homocysteine levels or MTHFR mutation analyses is not recommended (American College of Obstetricians and Gynecologists, 2013).

DEEP-VEIN THROMBOSIS

Clinical Presentation

During pregnancy, most venous thromboses are confined to the deep veins of the lower extremity. Approximately 70 percent of cases are located in the iliofemoral veins without involvement of the calf veins. Isolated iliac vein and calf vein thromboses occur in approximately 17 and 6 percent of cases, respectively (Chan, 2010).

The signs and symptoms vary greatly and depend on the degree of occlusion and the intensity of the inflammatory response. Most cases during pregnancy are left sided. Ginsberg and coworkers (1992) reported that 58 of 60 antepartum women—97 percent—had left leg thromboses. Blanco-Molina and coworkers (2007) reported left-leg involvement in 78 percent. Our experiences at Parkland Hospital are similar—approximately 90 percent of lower extremity thromboses

involved the left leg. Greer (2003) hypothesizes that this results from compression of the left iliac vein by the right iliac and ovarian artery, both of which cross the vein only on the left side. Yet, as described in Chapter 53 (p. 1051), the ureter is compressed more on the right side!

Classic thrombosis involving the lower extremity is abrupt in onset, and there is pain and edema of the leg and thigh. The thrombus typically involves much of the deep-venous system to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations. Conversely, there may be appreciable clot, yet little pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing or to Achilles tendon stretching—*Homan's sign*—may be caused by a strained muscle or contusion. Between 30 and 60 percent of women with a confirmed lower-extremity acute deep-vein thrombosis have an asymptomatic pulmonary embolism (p. 1041).

Diagnosis

Clinical diagnosis of deep-vein thrombosis is difficult, and thus other methods are imperative for confirmation. In one study of pregnant women, the clinical diagnosis was confirmed in only 10 percent (Hull, 1990). Shown in Figure 52-2 is one diagnostic algorithm recommended by the American College of Chest Physicians that can be used for evaluation of pregnant women (Guyatt, 2012). With a few modifications, we follow a similar evaluation at Parkland Hospital.

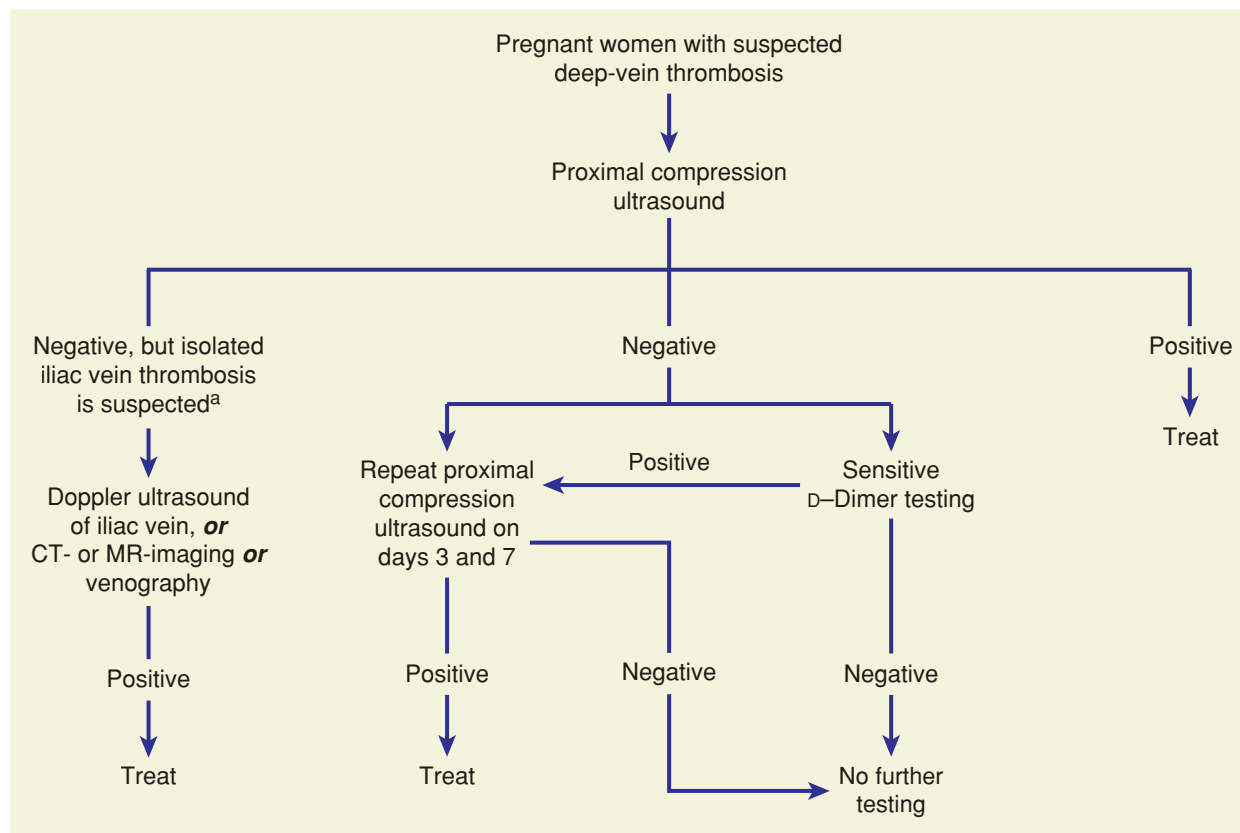

FIGURE 52-2 Algorithm for evaluation of suspected deep-vein thrombosis in pregnancy. CT = computed tomography; MR = magnetic resonance. (Adapted from the American College of Chest Physicians, Guyatt, 2012.) ^aSigns and symptoms include swelling of the entire leg, with or without flank, buttock, or back pain.

Compression Ultrasonography

In pregnant women with suspected deep-vein thrombosis, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend compression ultrasonography of the proximal veins as the initial diagnostic test. According to the American College of Chest Physicians, this noninvasive technique is currently the most-used first-line test to detect deep-vein thrombosis (Guyatt, 2012). The diagnosis is based on the noncompressibility and typical echoarchitecture of a thrombosed vein.

For *nonpregnant* patients with suspected thrombosis, the safety of withholding anticoagulation has been established for those who have normal serial compression examinations over a week (Birdwell, 1998; Heijboer, 1993). Specifically, isolated calf thromboses that extend into the proximal veins in about a fourth of patients will do so within 1 to 2 weeks of presentation. Moreover, these are usually detected by serial ultrasonographic compression.

In *pregnant* women, the important caveat is that normal findings with venous ultrasonography results do not always exclude a pulmonary embolism. This is because the thrombosis may have already embolized or because it arose from iliac or other deep-pelvic veins, which are less accessible to ultrasound evaluation (Goldhaber, 2004). Thrombosis associated with pulmonary embolism during pregnancy frequently originates in the iliac veins. Although serial investigations are recommended by many, Le Gal and colleagues (2012) recently studied the use of nonserial proximal and distal compression ultrasonography in 226 pregnant and postpartum women with suspected deep-vein thrombosis. Deep-vein thrombosis was diagnosed in 10 percent. Of the 177 women without a deep-vein thrombosis and who were not anticoagulated, two had an objectively confirmed thrombosis diagnosed within three months. Thus, these preliminary data suggest that a negative single complete compression ultrasonography study may safely exclude the diagnosis of deep-vein thrombosis in most pregnant women.

Magnetic Resonance Imaging

This imaging technique allows excellent delineation of anatomical detail above the inguinal ligament. Thus, in many cases, magnetic resonance (MR) imaging is immensely useful for diagnosis of iliofemoral and pelvic vein thrombosis. The venous system can also be reconstructed using MR venography as discussed in Chapter 46 (Fig. 46-5, p. 936). Erdman and associates (1990) reported that MR imaging was 100-percent sensitive and 90-percent specific for detection of venographically proven deep-vein thrombosis in nonpregnant patients. Importantly, almost half of those without deep-vein thrombosis were found to have nonthrombotic conditions that included cellulitis, myositis, edema, hematomas, and superficial phlebitis.

Khalil and coworkers (2012) used magnetic resonance venography to study the natural history of pelvic vein thrombosis after vaginal delivery. Among the 30 *asymptomatic* patients who were all within four days of delivery, 30 percent had a definitive thrombosis in either the iliac or ovarian veins, and another 37 percent had a suspected thrombosis.

Our experience with hundreds of postpartum MR scans does not support these findings. Thus, although the clinical significance of their findings is uncertain, it seems clear that some degree of pelvic vein intraluminal filling defect may be a normal finding.

D-Dimer Screening Tests

These specific fibrin degradation products are generated when fibrinolysin degrades fibrin, as occurs in thromboembolism (Chap. 41, p. 809). Their measurement is frequently incorporated into diagnostic algorithms for venous thromboembolism in nonpregnant patients (Kelly, 2002; Wells, 2003). Screening with the D-dimer test in pregnancy, however, is problematic for a number of reasons. As shown in the Appendix (p. 1288), depending on assay sensitivity, D-dimer serum levels increase with gestational age along with substantively elevated plasma fibrinogen concentrations (McCrae, 2014). Levels are also affected by multifetal gestation and cesarean delivery (Morikawa, 2011). In a serial study of 50 healthy women, Kline and colleagues (2005) found that D-dimer levels increased progressively during pregnancy. Also, 22 percent of women in midpregnancy and no women in the third trimester had a D-dimer concentration below 0.50 mg/L—a conventional threshold used to exclude thromboembolism. D-Dimer concentrations can also be elevated in certain pregnancy complications such as placental abruption, preeclampsia, and sepsis syndrome. For these reasons, their use during pregnancy remains uncertain, but a negative D-dimer test should be considered reassuring (Lockwood, 2012; Marik, 2008).

Venography

Invasive contrast venography is the gold standard to exclude lower extremity deep-vein thrombosis (Chunilal, 2001). It has a negative-predictive value of 98 percent, and as discussed in Chapter 46 (p. 932), fetal radiation exposure without shielding is approximately 3 mGy (Nijkeuter, 2006). That said, venography is associated with significant complications, including thrombosis, and it is time consuming and cumbersome. Because of this, noninvasive methods are used primarily to confirm the diagnosis, and venography is seldom used today.

Management

Optimal management of venous thromboembolism during pregnancy has not undergone major clinical study to provide evidence-based practices. There is, however, consensus for treatment with anticoagulation and limited activity. If thrombophilia testing is performed, it is done before anticoagulation because heparin induces a decline in antithrombin levels, and warfarin decreases protein C and S concentrations (Lockwood, 2002).

Anticoagulation is initiated with either unfractionated or low-molecular-weight heparin. Although either type is acceptable, most recommend one of the low-molecular-weight heparins. In its recently revised guidelines, for example, the American College of Chest Physicians suggests preferential use of low-molecular-weight heparin during pregnancy because of better bioavailability, longer plasma half-life, more predictable dose response, reduced risks of osteoporosis and thrombocytopenia, and less frequent dosing (Bates, 2012).

During pregnancy, heparin therapy is continued, and for postpartum women, anticoagulation is begun simultaneously with warfarin. Recall that pulmonary embolism develops in as many as 60 percent of patients with untreated venous thrombosis, and anticoagulation decreases this risk to less than 5 percent. In nonpregnant patients, the mortality rate is approximately 1 percent (Douketis, 1998; Pollack, 2011).

Over several days, leg pain dissipates. After symptoms have abated, graded ambulation should be started. Elastic stockings are fitted, and anticoagulation is continued. Recovery to this stage usually takes 7 to 10 days. Graduated compression stockings should be continued for 2 years after the diagnosis to reduce the incidence of postthrombotic syndrome (Brandjes, 1997). This syndrome can include chronic leg paresthesias or pain, intractable edema, skin changes, and leg ulcers.

■ Unfractionated Heparin

This agent should be considered for the initial treatment of thromboembolism and in situations in which delivery, surgery, or thrombolysis may be necessary (p. 1039) (American College of Obstetricians and Gynecologists, 2011).

Unfractionated heparin (UFH) can be administered by one of two alternatives: (1) initial intravenous therapy followed by adjusted-dose subcutaneous UFH given every 12 hours; or (2) twice-daily, adjusted dose subcutaneous UFH with doses adjusted to prolong the activated partial thromboplastin time (aPTT) into the therapeutic range 6 hours postinjection (Bates, 2012). As shown in [Table 52-5](#), the therapeutic dose for subcutaneous UFH is usually 10,000 units or more every 12 hours.

For intravenous therapy, there are a number of acceptable protocols. In general, UFH is initiated with a bolus intravenous dose of 70 to 100 U/kg, about 5000 to 10,000 U, followed by continuous intravenous infusions beginning at 1000 U/hr or 15 to 20 U/kg/hr, titrated to achieve an aPTT of 1.5 to 2.5 times control values (Brown, 2010). Intravenous anticoagulation should be maintained for at least 5 to 7 days, after which treatment is converted to subcutaneous heparin to maintain the aPTT to at least 1.5 to 2.5 times control throughout the dosing interval. For women with antiphospholipid syndrome, aPTT does not accurately assess heparin anticoagulation, and thus anti-factor Xa levels are preferred.

TABLE 52-5. Anticoagulation Regimen Definitions

Anticoagulation Regimen	Definition
Prophylactic LMWH*	Enoxaparin, 40 mg SC once daily Dalteparin, 5,000 units SC once daily Tinzaparin, 4,500 units SC once daily
Therapeutic LMWH†	Enoxaparin, 1 mg/kg every 12 hours Dalteparin, 200 units/kg once daily Tinzaparin, 175 units/kg once daily Dalteparin, 100 units/kg every 12 hours May target an anti-Xa level in the therapeutic range of 0.6–1.0 units/mL for twice daily regimen; slightly higher doses may be needed for a once-daily regimen.
Minidose prophylactic UFH	UFH, 5,000 units SC every 12 hours
Prophylactic UFH	UFH, 5,000–10,000 units SC every 12 hours UFH, 5,000–7,500 units SC every 12 hours in first trimester UFH, 7,500–10,000 units SC every 12 hours in the second trimester UFH, 10,000 units SC every 12 hours in the third trimester, unless the aPTT is elevated
Therapeutic UFH†	UFH, 10,000 units or more SC every 12 hours in doses adjusted to target aPTT in the therapeutic range (1.5–2.5) 6 hours after injection
Postpartum anticoagulation	Prophylactic LMWH/UFH for 4–6 weeks or vitamin K antagonists for 4–6 weeks with a target INR of 2.0–3.0, with initial UFH or LMWH therapy overlap until the INR is 2.0 or more for 2 days
Surveillance	Clinical vigilance and appropriate objective investigation of women with symptoms suspicious of deep vein thrombosis or pulmonary embolism

Abbreviations: aPTT, activated partial thromboplastin time; INR, international normalized ratio; LMWH, low molecular weight heparin; SC, subcutaneously; UFH, unfractionated heparin.

*Although at extremes of body weight, modification of dose may be required.

†Also referred to as weight adjusted, full treatment dose.

From Inherited thrombophilias in pregnancy. Practice Bulletin No. 138. American College of Obstetricians and Gynecologists. Obstet Gynecol 2013;122:706–17.

The duration of full anticoagulation varies, and there are no studies that have defined the optimal duration for pregnancy-related thromboembolism. In nonpregnant patients with venous thromboembolism, evidence supports a minimum treatment duration of 3 months (Kearon, 2012). For pregnant patients, the American College of Chest Physicians recommends anticoagulation throughout pregnancy and postpartum for a minimum total duration of 3 months (Bates, 2012). Lockwood (2012) recommends that full anticoagulation be continued for at least 20 weeks followed by prophylactic doses if the woman is still pregnant. Prophylactic doses of subcutaneous unfractionated heparin can range from 5000 to 10,000 units every 12 hours titrated to maintain an anti-factor Xa level of 0.1 to 0.2 units, measured 6 hours after the last injection. If the venous thromboembolism occurs during the postpartum period, Lockwood (2012) recommends a minimum of 6 months of anticoagulation treatment.

■ Low-Molecular-Weight Heparin

This is a family of derivatives of unfractionated heparin, and their molecular weights average 4000 to 5000 daltons compared with 12,000 to 16,000 daltons for conventional heparin. None of these heparins cross the placenta, and all exert their anticoagulant activity by activating antithrombin. The primary difference is their relative inhibitory activity against factor Xa and thrombin (Garcia, 2008). Specifically, unfractionated heparin has equivalent activity against factor Xa and thrombin, but low-molecular-weight heparins (LMWH) have greater activity against factor Xa than thrombin. They also have a more predictable anticoagulant response and fewer bleeding complications than unfractionated heparin because of their better bioavailability, longer half-life, dose-independent clearance, and decreased interference with platelets (Tapson, 2008). These LMWH compounds are cleared by the kidneys and must be used cautiously when there is renal dysfunction.

A number of studies have shown that venous thromboembolism is treated effectively with LMWH (Quinlan, 2004; Tapson, 2008). Using serial venograms, Breddin and associates (2001) observed that these compounds were more effective than UFH in reducing thrombus size without increasing mortality rates or major bleeding complications. Several different treatment regimens using adjusted-dose LMWH for treatment of acute venous thromboembolism are recommended by the American College of Obstetricians and Gynecologists (2011) and are listed in Table 52-5.

Pharmacokinetics in Pregnancy

Low-molecular-weight heparins available for use in pregnancy include enoxaparin, tinzaparin, and dalteparin. Enoxaparin (Lovenox) pharmacokinetics were studied by Rodie and coworkers (2002) in 36 women with venous thromboembolism during pregnancy or immediately postpartum. The dose was approximately 1 mg/kg given twice daily based on early pregnancy weight. Treatment was monitored by peak anti-factor Xa activity 3 hours postinjection, with a target therapeutic range

of 0.4–1.0 U/mL. In 33 women, enoxaparin provided satisfactory anticoagulation. In the other three women, dose reduction was necessary. None developed recurrent thromboembolism or bleeding complications. Smith and colleagues (2004) reported similar results with tinzaparin (Innohep) given as a once-daily 50 U/kg dose. They found that a dosage of 75 to 175 U/kg/day was necessary to achieve peak anti-factor Xa levels of 0.1 to 1.0 U/mL.

Dalteparin (Fragmin) pharmacokinetics were studied by Barbour (2004) and Jacobsen (2003) and their associates in longitudinal studies of 13 and 20 pregnant women, respectively. Both groups of investigators concluded that conventional starting doses of dalteparin—100 U/kg every 12 hours—were likely insufficient to maintain full anticoagulation and that slightly higher doses than that shown in Table 52-5 may be required. As an aside, several groups of investigators have found in preliminary studies that dalteparin use is associated with shorter labors (Ekman-Ordeberg, 2010; Isma, 2010). If these observations are verified, then the mechanism of action may involve increased cytokine secretion as in vitro studies suggest.

Dosing and Monitoring

Standard prophylactic and therapeutic dosages recommended by the American College of Obstetricians and Gynecologists (2011) for various LMWHs are listed in Table 52-5. Whether such dosages require adjustments during the course of pregnancy is controversial (Cutts, 2013). Some suggest periodic measurement of anti-factor Xa levels 4 to 6 hours after an injection with dose adjustment to maintain a therapeutic level. According to Bates and coworkers (2012), large studies using clinical end points that demonstrate an optimal therapeutic range or that show dose adjustments increase therapy safety or efficacy are lacking. Moreover, assay measurement accuracy and reliability are uncertain; correlations with bleeding and recurrence risks are lacking; and assay costs are high. Accordingly, the American College of Chest Physicians has concluded that routine monitoring with anti-Xa levels is difficult to justify.

Safety in Pregnancy

Early reviews by Sanson (1999) and Lepercq (2001), each with their colleagues, concluded that low-molecular-weight heparins were safe and effective. Despite this, in 2002, the manufacturer of Lovenox warned that its use in pregnancy had been associated with congenital anomalies and an increased risk of hemorrhage. After its own extensive review, the American College of Obstetricians and Gynecologists (2002) concluded that these risks were rare, that their incidence was not higher than expected, and that no cause-and-effect relationship had been established. It further concluded that enoxaparin and dalteparin could be given safely during pregnancy, and subsequent reports have continued to confirm their safety (Andersen, 2010; Bates, 2012; Deruelle, 2007; Galambosi, 2012).

Nelson-Piercy and coworkers (2011) assessed the safety profile of tinzaparin through a comprehensive study of 1267 pregnant women treated at 28 participating hospitals in

North America and Europe. There were no maternal deaths or complications from regional analgesia. Although thrombocytopenia developed in 1.8 percent, there were no cases of heparin-induced thrombocytopenia (p. 1040). The allergy incidence was 1.3 percent. Osteoporotic fractures in three women (0.2 percent) were judged to be related to tinzaparin (p. 1038). A total of 43 women (3.4 percent) required medical intervention for bleeding. Of the 15 stillbirths, four were judged as possibly being related to tinzaparin use. But, none of the neonatal deaths or congenital abnormalities was attributed to tinzaparin. The authors concluded that tinzaparin during pregnancy was safe for mother and fetus.

Like unfractionated heparin, LMWHs are safe during breast feeding. Although there may be detectable levels of these drugs in breast milk, the bioavailability when ingested orally is poor, and there is no anticoagulant effect in the infant (Lim, 2010).

Caveats are that LMWHs should be avoided in women with renal failure (Krivak, 2007). Moreover, when given within 2 hours of cesarean delivery, these agents increase the risk of wound hematoma (van Wijk, 2002). Lee and Goodwin (2006) described development of a massive subchorionic hematoma associated with enoxaparin use. Forsnes and associates (2009) reported a woman who developed a spontaneous thoracolumbar epidural hematoma that required surgical drainage.

■ Labor and Delivery

Women receiving either therapeutic or prophylactic anticoagulation should be converted from LMWH to the shorter half-life UFH in the last month of pregnancy or sooner if delivery appears imminent. The purpose of conversion to UFH has less to do with any risk of maternal bleeding at the time of delivery, but rather with neuraxial blockade complicated by an epidural or spinal hematoma (Chap. 25, p. 516). The American College of Chest Physicians recommends that women scheduled for a planned delivery who are receiving twice-daily adjusted-dose subcutaneous UFH or LMWH discontinue their heparin 24 hours before labor induction or cesarean delivery. Patients receiving once-daily LMWH should take only 50 percent of their normal dose on the morning of the day before delivery (Bates, 2012). The American College of Obstetricians and Gynecologists (2013) advises that adjusted-dose subcutaneous LMWH or UFH can be discontinued 24 to 36 hours before an induction of labor or scheduled cesarean delivery. The American Society of Regional Anesthesia and Pain Medicine advises withholding neuraxial blockade for 10 to 12 hours after the last prophylactic dose of LMWH or 24 hours after the last therapeutic dose (Horlocker, 2010).

If a woman begins labor while taking UFH, clearance can be verified by an aPTT. Reversal of heparin with protamine sulfate is rarely required and is not indicated with a prophylactic dose of heparin (p. 1044). For women in whom anticoagulation therapy has temporarily been discontinued, pneumatic compression devices are recommended (American College of Obstetricians and Gynecologists, 2011).

■ Anticoagulation with Warfarin Compounds

Warfarin derivatives are generally contraindicated because they readily cross the placenta and may cause fetal death and malformations from hemorrhages (Chap. 12, p. 252). Like UFH and LMWH, however, they do not accumulate in breast milk and do not induce an anticoagulant effect in the infant and are thus safe during breast feeding.

Postpartum venous thrombosis is usually treated with intravenous heparin and oral warfarin initiated simultaneously. The initial dose of warfarin is usually 5 to 10 mg for the first 2 days. Subsequent doses are titrated to achieve an international normalized ratio (INR) of 2 to 3. To avoid paradoxical thrombosis and skin necrosis from the early anti-protein C effect of warfarin, these women are maintained on therapeutic doses of UFH or LMWH for 5 days and until the INR is in a therapeutic range (2.0–3.0) for 2 consecutive days (American College of Obstetricians and Gynecologists, 2013; Stewart, 2010). Warfarin skin necrosis has been described in a postpartum patient with protein S deficiency (Cheng, 1997).

Treatment in the puerperium may require larger doses of anticoagulant. Brooks and colleagues (2002) compared anticoagulation in postpartum women with that of age-matched nonpregnant controls. The former required a significantly larger median total dose of warfarin—45 versus 24 mg—and a longer time—7 versus 4 days—to achieve the target INR. Moreover, the mean maintenance dose was slightly higher in postpartum women compared with that in the control group—4.9 versus 4.3 mg.

■ Newer Agents

Several oral anticoagulants have recently become available. These inhibit thrombin—dabigatran, or factor Xa—rivaroxaban and apixaban. Preliminary studies in nonpregnant patients have been very promising (Cohen, 2013; Schulman, 2013). In one study of nearly 2500 nonpregnant subjects, anticoagulation with apixaban significantly reduced the risk of recurrent venous thromboembolism without increasing major bleeding complications (Agnelli, 2013). Currently, there are no studies of these newer agents during pregnancy, and thus the human reproductive risks are unknown (Bates, 2012).

■ Complications of Anticoagulation

Three significant complications associated with anticoagulation are hemorrhage, thrombocytopenia, and osteoporosis. The latter two are unique to heparin, and their risk may be reduced with low-molecular-weight heparins. The most serious complication is hemorrhage, which is more likely if there has been recent surgery or lacerations. Troublesome bleeding also is more likely if the heparin dosage is excessive. Unfortunately, management schemes using laboratory testing to identify when a heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Heparin-Induced Thrombocytopenia

There are two types—the most common is a nonimmune, benign, reversible thrombocytopenia that develops within the first few days of therapy and resolves in approximately 5 days without therapy cessation. The second is the severe form of heparin-induced thrombocytopenia (HIT), which results from an immune reaction involving IgG antibodies directed against complexes of platelet factor 4 and heparin. When severe, HIT paradoxically causes thrombosis, which is the most common presentation.

The incidence of HIT is approximately 3 to 5 percent in nonpregnant individuals. Interestingly, however, Fausett and coworkers (2001) reported no cases among 244 heparin-treated pregnant women compared with 10 among 244 nonpregnant patients. Accordingly, the American College of Chest Physicians estimates that the incidence of HIT in obstetrical patients is less than 0.1 percent (Linkins, 2012). In the latest guidelines, moreover, the American College of Chest Physicians recommends against platelet count monitoring when the risk of HIT is considered to be less than 1 percent. In others, they suggest monitoring every 2 or 3 days from day 4 until day 14 (Linkins, 2012). Kelton and colleagues (2013) have recently provided a scholarly review of HIT.

Management

When HIT is diagnosed, heparin therapy is stopped and alternative anticoagulation initiated. LMWH may not be entirely safe because it has some cross reactivity with unfractionated heparin. The American College of Chest Physicians recommends danaparoid—a sulfated glycosaminoglycan heparinoid (Bates, 2012; Linkins, 2012). In a review of nearly 50 pregnant women with either HIT or a skin rash, Lindhoff-Last and associates (2005) concluded that danaparoid—available only from Canada—was a reasonable alternative. However, they reported two fatal maternal hemorrhages and three fetal deaths. Magnani (2010) reviewed 30 case reports of pregnant women treated with danaparoid. Although it was effective, two patients died related to bleeding, three patients suffered nonfatal major bleeds, and three women developed thromboembolic events unresponsive to danaparoid.

Other agents are fondaparinux and argatroban (Kelton, 2013; Linkins, 2012). Argatroban is a direct thrombin inhibitor available in this country to treat HIT (Chapman, 2008; Tapson, 2008). Fondaparinux is a pentasaccharide factor Xa inhibitor that is also used for HIT (Kelton, 2013). Successful use in pregnancy has been reported (Knol, 2010; Mazzolai, 2006). Tanimura and coworkers (2012) successfully used argatroban, and later fondaparinux, to manage HIT in a pregnant woman with hereditary antithrombin deficiency. Interestingly, heparin-dependent antibodies do not invariably reappear with subsequent heparin use (Warkentin, 2001).

Heparin-Induced Osteoporosis

Bone loss may develop with long-term heparin administration—usually 6 months or longer—and is more prevalent in cigarette smokers (Chap. 58, p. 1159). UFH can cause osteopenia, and this is less likely with LMWH (Deruelle, 2007). Women treated with any heparin should be encouraged to take a daily 1500-mg

calcium supplement (Cunningham, 2005; Lockwood, 2012). In one study, Rodger and colleagues (2007) found that long-term use for a mean of 212 days with dalteparin was not associated with a significant decrease in bone mineral density.

Anticoagulation and Abortion

The treatment of deep-vein thrombosis with heparin does not preclude pregnancy termination by careful curettage. After the products are removed without trauma to the reproductive tract, full-dose heparin can be restarted in several hours.

Anticoagulation and Delivery

The effects of heparin on blood loss at delivery depend on several variables: (1) dose, route, and timing of administration; (2) number and depth of incisions and lacerations; (3) intensity of postpartum myometrial contractions; and (4) presence of other coagulation defects. Blood loss should not be greatly increased with vaginal delivery if the episiotomy—if any—is modest in depth, there are no lacerations, and the uterus promptly contracts. Unfortunately, such ideal circumstances do not always prevail. For example, Mueller and Lebherz (1969) described 10 women with antepartum thrombophlebitis treated with heparin. Three women who continued to receive heparin during labor and delivery bled remarkably and developed large hematomas. Thus, heparin therapy generally is stopped during labor and delivery. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend restarting UFH or LMWH no sooner than 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. It is our practice, however, to wait at least 24 hours if there are significant lacerations or following a major surgical procedure.

Slow intravenous administration of protamine sulfate generally reverses the effect of heparin promptly and effectively. It should not be given in excess of the amount needed to neutralize the heparin, because it also has an anticoagulant effect. Serious bleeding may occur when heparin in usual therapeutic doses is administered to a woman who has undergone cesarean delivery within the previous 24 to 48 hours.

SUPERFICIAL VENOUS THROMBOPHLEBITIS

Thrombosis limited strictly to the superficial veins of the saphenous system is treated with analgesia, elastic support, heat, and rest. If it does not soon subside or if deep-vein involvement is suspected, appropriate diagnostic measures are performed. Heparin is given if deep-vein involvement is confirmed. Superficial thrombophlebitis is typically seen in association with varicosities or as a sequela to an indwelling intravenous catheter.

PULMONARY EMBOLISM

Although it causes approximately 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. The incidence averages

1 in 7000 pregnancies. There is an almost equal prevalence for antepartum and postpartum embolism, but those developing postpartum have a higher mortality rate. According to Marik and Plante (2008), 70 percent of women presenting with a pulmonary embolism have associated clinical evidence of deep-vein thrombosis. And recall that between 30 and 60 percent of women with a deep-vein thrombosis will have a coexisting silent pulmonary embolism.

Clinical Presentation

Findings from the international cooperative pulmonary embolism registry were reported by Goldhaber and colleagues (1999). During a 2-year period, almost 2500 nonpregnant patients with a proven pulmonary embolism were enrolled. Symptoms included dyspnea in 82 percent, chest pain in 49 percent, cough in 20 percent, syncope in 14 percent, and hemoptysis in 7 percent. Pollack and coworkers (2011) presented results from a similar study of 1880 nonpregnant patients who presented to an emergency room and were found to have a proven pulmonary embolism. Half had dyspnea at rest, 40 percent had pleuritic chest pain, 27 percent had dyspnea with exertion, and 25 percent had coughing. Other predominant clinical findings typically included tachypnea, apprehension, and tachycardia. In some cases, there was an accentuated pulmonic closure sound, rales, and/or friction rub.

Right axis deviation and T-wave inversion in the anterior chest leads may be evident on the electrocardiogram. In at least half, chest radiography is normal. But, there is atelectasis, an

infiltrate, or an effusion each in 14 percent of nonpregnant patients (Pollack, 2011). There also may be loss of vascular markings in the lung region supplied by the obstructed artery. Although most women are hypoxemic, a normal arterial blood gas analysis does not exclude pulmonary embolism. Approximately a third of young patients have PO_2 values > 80 mm Hg. In contrast, the alveolar-arterial oxygen tension difference is a more useful indicator of disease. More than 86 percent of patients with acute pulmonary embolism will have an alveolar-arterial difference of > 20 mm Hg (Lockwood, 2012). Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis may be deceptively nonspecific.

Massive Pulmonary Embolism

This is defined as embolism causing hemodynamic instability (Tapson, 2008). Acute mechanical obstruction of the pulmonary vasculature causes increased vascular resistance and pulmonary hypertension followed by acute right ventricular dilatation. In otherwise healthy patients, significant pulmonary hypertension does not develop until 60 to 75 percent of the pulmonary vascular tree is occluded (Guyton, 1954). Moreover, circulatory collapse requires 75- to 80-percent obstruction. This is depicted schematically in Figure 52-3 and emphasizes that most acutely symptomatic emboli are large and likely a saddle embolism. These are suspected when the pulmonary artery pressure is substantively increased as estimated by echocardiography.

FIGURE 52-3 Schematic of pulmonary arterial circulation. Note that the cross-sectional area of the pulmonary trunk and the combined pulmonary arteries is 9 cm². A large saddle embolism could occlude 50 to 90 percent of the pulmonary tree, causing hemodynamic instability. As the arteries give off distal branches, the total surface area rapidly increases, that is, 13 cm² for the combined five lobar arteries, 36 cm² for the combined 19 segmental arteries, and more than 800 cm² for the total 65 subsegmental arterial branches. Thus, hemodynamic instability is less likely with emboli past the lobar arteries. (Data from Singhal, 1973.)

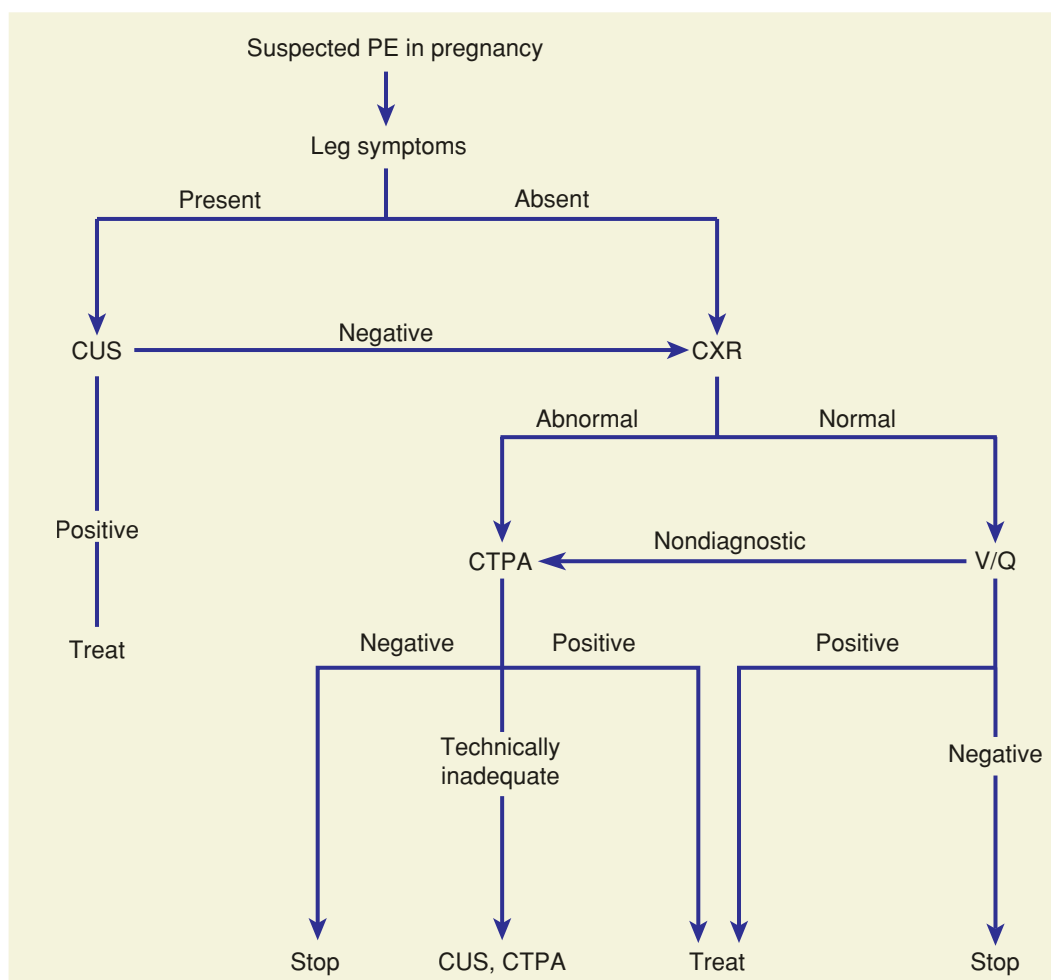

FIGURE 52-4 The American Thoracic Society and Society of Thoracic Radiology diagnostic algorithm for suspected pulmonary embolism during pregnancy. CTPA = computed tomographic pulmonary angiography; CUS = compression ultrasonography; CXR = chest x-ray; PE = pulmonary embolism; V/Q = ventilation/perfusion scintigraphy. (Redrawn from Leung, 2011, with permission.)

If there is evidence of right ventricular dysfunction, the mortality rate approaches 25 percent, compared with 1 percent without such dysfunction (Kinane, 2008). It is important in these cases to infuse crystalloids carefully and to support blood pressure with vasopressors. Oxygen treatment, endotracheal intubation, and mechanical ventilation are completed preparatory to thrombolysis, filter placement, or embolectomy (Tapson, 2008).

■ Diagnosis

In most cases, recognition of a pulmonary embolism requires a high index of suspicion that prompts objective evaluation. In 2011, the American Thoracic Society and the Society of Thoracic Radiology developed an algorithm—shown in [Figure 52-4](#)—for the diagnosis of pulmonary embolism during pregnancy (Leung, 2011). In addition to compression ultrasonography, which was previously discussed (p. 1036), the algorithm includes computed-tomographic pulmonary angiography (CTPA) and ventilation-perfusion scintigraphy.

Computed-Tomographic Pulmonary Angiography

Multidetector computed tomography with pulmonary angiography is currently the most commonly employed technique used for pulmonary embolism diagnosis in nonpregnant patients (Bourjeily, 2012; Pollack, 2011). The technique is described further in Chapter 46 (p. 934), and an imaging example is shown in [Figure 52-5](#).

There is some controversy regarding the best imaging method to be used in pregnancy. The American College of Radiology has concluded CTPA to be the most accurate. With a normal chest radiograph, however, the perfusion scan alone with radioisotopes is similarly accurate, and the ventilation scan can be omitted. And because pregnant women frequently have an accompanying normal chest radiograph, the British Society of Haemostasis and Thrombosis recommends the perfusion scan as the initial preferred procedure (Cutts, 2013). Finally, the estimated breast dose of 10 to 70 mGy attributable to CTPA far exceeds that of approximately 0.5 mGy with lung scintigraphy (Cutts, 2013; Revel, 2011).

In a prospective study of 102 consecutive nonpregnant patients with suspected pulmonary embolism who underwent

FIGURE 52-5 Axial image of the chest from a four-channel multidetector spiral computed tomographic scan performed after administration of intravenous contrast. There is enhancement of the pulmonary artery with a large thrombus on the right (arrow) consistent with pulmonary embolism. (Image contributed by Dr. Michael Landay.)

CTPA, Kavanagh and coworkers (2004) found that during a mean surveillance period of 9 months, only one patient had a false-negative scan. Bourjeily and colleagues (2012) performed a similar follow-up study of 318 pregnant women who had a negative CTPA performed for a suspected pulmonary embolism. All were seen 3 months following their initial presentation or at 6 weeks postpartum. None of these women were subsequently diagnosed with a venous thromboembolism.

Although CTPA has many advantages, we have found that the better resolution allows detection of previously inaccessible smaller distal emboli that have uncertain clinical significance. Similar observations have been reported by Anderson (2007) and Hall (2009) and all their associates. Others have found that the hyperdynamic circulation and increased plasma volume associated with pregnancy lead to a higher number of non-diagnostic studies compared with nonpregnant patients (Ridge, 2011; Scarsbrook, 2006).

Ventilation-Perfusion Scintigraphy—Lung Scan

This technique is used less commonly in the United States. It involves a small dose of radiotracer such as intravenously administered technetium-99m-macroaggregated albumin. As shown in Table 52-6, there is negligible fetal radiation exposure. The scan may not provide a definite diagnosis because many other conditions—for example, pneumonia or local bronchospasm—can cause perfusion defects. Ventilation scans with inhaled xenon-133 or technetium-99m were added to perfusion scans to detect abnormal areas of ventilation in areas with normal perfusion such as with pneumonia or hypoventilation. The method is not precise, and although ventilation scanning increased the probability of an accurate diagnosis with large perfusion defects and ventilation mismatches, normal V/Q scan findings do not exclude pulmonary embolism.

TABLE 52-6. Estimated Mean Fetal Radiation Dosimetry from Ventilation-Perfusion (V/Q) Lung Scanning Compared with 4-Channel Multidetector Spiral Computed Tomography (CT) Scanning

Pregnancy Duration	V/Q Scintigraphy		Spiral CT Scanning	
	mGy	mrem	mGy	mrem
Early	0.46	46	0.04	4
First trimester	0.46	46	0.04	4
Second trimester	0.57	57	0.11	11
Third trimester ^a	0.45	45	0.31	31

^aIn late pregnancy, the maximum exposure with spiral CT scanning may exceed the estimated mean by a factor of 5 to 7 due to increased proximity of the fetus to the primary beam.

Data courtesy of Dr. Jon Anderson.

Chan and coworkers (2002) found that a fourth of V/Q scans in pregnant women were nondiagnostic. In these instances, CTPA is preferred.

Revel and colleagues (2011) retrospectively compared the performance of lung scintigraphy and CTPA in 137 pregnant women with suspected pulmonary embolism. They found that the two modalities had comparable performance, and no significant differences between the proportions of positive, negative, or indeterminate results were found. Specifically, the proportion of indeterminate results for both was approximately 20 percent. By way of comparison, about a fourth of the nonpregnant population has indeterminate studies. The investigators attributed this difference to the younger age of the pregnant patients.

Magnetic Resonance Angiography

Although this technique has a high sensitivity for detection of central pulmonary emboli, the sensitivity for detection of subsegmental emboli is less precise (Scarsbrook, 2006). In a study of 141 nonpregnant patients with suspected pulmonary embolism, Oudkerk and associates (2002) performed magnetic resonance angiography (MRA) before conventional angiography. Approximately a third of patients were found to have an embolus. And, the sensitivity of MRA for isolated subsegmental, segmental, and central or lobar pulmonary embolism was 40, 84, and 100 percent, respectively. There are no reports specifically involving MRA during pregnancy.

Intravascular Pulmonary Angiography

This requires catheterization of the right side of the heart and is considered the reference test for pulmonary embolism. With newer generation multidetector CT scanners, however, the role of invasive pulmonary angiography has been questioned (Kuriakose, 2010). Other detractors are that it is time consuming, uncomfortable, and associated with dye-induced allergy and renal failure. Indeed, the procedure-related mortality rate is approximately 1 in 200 (Stein,

1992). It is reserved for confirmation when less invasive tests are equivocal.

Management

Immediate treatment for pulmonary embolism is full anticoagulation similar to that for deep-vein thrombosis as discussed on page 1036. A number of complementary procedures may be indicated.

Vena Caval Filters

The woman who has very recently suffered a pulmonary embolism and who must undergo cesarean delivery presents a particularly serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In these, placement of a vena caval filter should be considered before surgery (Marik, 2008). Although an uncommon occurrence, we have had good outcomes at Parkland Hospital with placement of a short-term filter. Routine filter placement has no added advantage to heparin given alone (Decousus, 1998). In the very infrequent circumstances in which heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs, or when embolism develops from these sites despite heparin treatment, a vena caval filter may be indicated. Such filters can also be used with massive emboli in patients who are not candidates for thrombolysis (Deshpande, 2002). The device may be inserted through either the jugular or femoral vein and can be inserted during labor (Jamjute, 2006).

Retrievable filters may be used as short-term protection against embolism. These may be removed before they become endothelialized, or they can be left in place permanently (Tapson, 2008). Liu and colleagues (2012) describe the successful use of retrievable filters placed on the day of cesarean delivery in 15 women with deep-vein thrombosis and then removed 1 to 2 weeks later.

Thrombolysis

Compared with heparin, thrombolytic agents provide more rapid lysis of pulmonary clots and improvement of pulmonary hypertension (Tapson, 2008). Konstantinides and coworkers (2002) studied 256 nonpregnant patients receiving heparin for an acute submassive pulmonary embolism. They also were assigned randomly to a placebo or the recombinant tissue plasminogen activator alteplase. Those given the placebo had a threefold increased risk of death or treatment escalation compared with those given alteplase. Agnelli and associates (2002) performed a metaanalysis of nine randomized trials involving 461 nonpregnant patients. They reported that the risk of recurrence or death was significantly lower in patients given thrombolytic agents and heparin compared with those given heparin alone—10 versus 17 percent. Importantly, however, there were five—2 percent—fatal bleeding episodes in the thrombolysis group and none in the heparin-only group.

There are a few cases reports of thrombolysis during pregnancy. In their review, Leonhardt and colleagues (2006) identified 28 reports of thrombolytic therapy using tissue

plasminogen activator during pregnancy. Ten of these cases were for thromboembolism. Complication rates were similar compared with reports from nonpregnant patients, and the authors concluded that such therapy should not be withheld during pregnancy if indicated. More recent reports of the successful use of thrombolysis for massive pulmonary embolism in five pregnant patients support this conclusion (Fasullo, 2011; Holden, 2011; Lonjaret, 2011). Our anecdotal experiences with these drugs also have been favorable. Tissue plasminogen activator does not cross the placenta.

Embolectomy

Surgical embolectomy is uncommonly indicated with use of thrombolysis and filters. Published experience with emergency embolectomy during pregnancy is limited to case reports such as those by Funakoshi (2004) and Taniguchi (2008) and their coworkers. Based on their review, Ahearn and associates (2002) found that although the operative risk to the mother is reasonable, the stillbirth rate is 20 to 40 percent.

THROMBOPROPHYLAXIS

Most recommendations regarding thromboprophylaxis during pregnancy stem from consensus guidelines, and thus not are all congruent. Okoroh and colleagues (2012) performed a systematic review of evidence-based guidelines for thromboprophylaxis published between 2000 and 2011. From the nine separate guidelines, they concluded that “there is a lack of overall agreement about which groups of women should be offered thromboprophylaxis during or after pregnancy or offered testing for thrombophilias.” The confusion that has ensued has provided fertile ground for the plaintiff bar to plow. Cleary-Goldman and associates (2007) surveyed 151 fellows of the American College of Obstetricians and Gynecologists and reported that intervention without a firm indication is common. Table 52-7 and 52-8 list several consensus recommendations for thromboprophylaxis. In some cases, more than one option is listed, thus illustrating the confusion that currently reigns.

In general, and as shown in Table 52-8, either antepartum surveillance or heparin prophylaxis is recommended for women without a recurrent risk factor, including no known thrombophilia. The study by Tengborn and coworkers (1989), however, suggested that such management may not be effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease and were not tested for thrombophilias. Despite heparin prophylaxis, which was usually 5000 U twice daily, three of 20—or 15 percent—of women developed antepartum recurrence compared with eight of 67—or 12 percent—of women not given heparin.

Brill-Edwards and colleagues (2000) prospectively studied 125 pregnant women with a single prior venous thromboembolism. Antepartum heparin was not given, but anticoagulant therapy was given for 4 to 6 weeks postpartum. A total of six women had a recurrent venous thrombosis—three antepartum and three postpartum. There were no recurrences in the 44 women without a known thrombophilia or whose prior thrombosis was associated with a temporary risk factor.

TABLE 52-7. American College of Chest Physicians Recommendations for Thromboprophylaxis Following Cesarean Delivery

Major Risk Factors	Minor Risk Factors
Immobility (strict antepartum bed rest for ≥ 1 week) Postpartum hemorrhage ≥ 1 L with surgery Previous venous thromboembolism Thrombophilia Antithrombin deficiency Factor V Leiden (homozygous or heterozygous) Prothrombin G20210A (homozygous or heterozygous) Medical conditions Systemic lupus erythematosus Heart disease Sickle-cell disease Blood transfusion Postpartum infection Concurrent malignancy	Body mass index > 30 kg/m ² Multifetal pregnancy Postpartum hemorrhage > 1 L Smoking > 10 cigarettes/day Fetal-growth restriction (gestational age + sex-adjusted birthweight < 25 th percentile) Thrombophilia Protein C deficiency Protein S deficiency Preeclampsia

If no risk factors, recommend early mobilization.
 If one major or two minor risk factors, recommend prophylactic low-molecular-weight heparin or mechanical prophylaxis (elastic stockings or intermittent pneumatic compression) in those with contraindications to anticoagulants while in the hospital.
 If at higher risk, recommend low-molecular weight heparin plus mechanical prophylaxis.
 If significant risk factors persist following delivery, prophylaxis should be extended for up to 6 weeks postpartum.
 Adapted from Bates, 2012.

These findings imply that prophylactic heparin may not be required for these two groups of women. In contrast, women with a prior thrombosis in association with a thrombophilia or in the absence of a temporary risk factor generally should be given both antepartum and postpartum prophylaxis (see Table 52-8).

De Stefano and coworkers (2006) studied 1104 women who had a first-episode venous thromboembolism before the age of 40 years. After excluding those with antiphospholipid antibodies, 88 women were identified who subsequently had a total of 155 pregnancies and who were not given antithrombotic prophylaxis. There were 19 women—22 percent—who had a subsequent pregnancy- or puerperium-related venous thromboembolism. Of 20 women whose original thrombosis was associated with a transient risk factor—not including pregnancy or oral contraceptive use—there were no recurrences during pregnancy, but two during the puerperium. Like the findings by Brill-Edwards and associates (2000), these data suggest that for women with a prior venous thromboembolism, antithrombotic prophylaxis during pregnancy could be tailored according to the circumstances of the original event. It is emphasized that more data are needed.

Our practice at Parkland Hospital for many years for women with a history of prior thromboembolism was to administer subcutaneous unfractionated heparin, 5000 to 7500 units two to three times daily. With this regimen, the recurrence of documented deep-vein thrombosis embolization was rare. Beginning approximately 10 years ago, we have successfully used 40 mg enoxaparin given subcutaneously daily.

Cesarean Delivery

For many years in the United States, thromboprophylaxis for women undergoing cesarean delivery was not widely employed. In a survey of 157 members of the Society for Maternal-Fetal Medicine, for example, Casele and Grobman (2007) found that only 8 percent of respondents routinely used thromboprophylaxis—defined as compression boots, stockings, or heparin—for women undergoing cesarean delivery. Friedman and colleagues (2013) found that the rate of postcesarean prophylaxis increased from 8 percent in 2003 to 41 percent in 2010. The risk for deep-vein thrombosis and especially for fatal thromboembolism is increased manyfold in women following cesarean compared with vaginal delivery. When considering that a third of women giving birth in the United States yearly undergo cesarean delivery, it is easily understandable that pulmonary embolism is a major cause of maternal mortality (Chap. 1, p. 5).

For these reasons, the American College of Obstetricians and Gynecologists (2011) recently has recommended placement of pneumatic compression devices before cesarean delivery for all women not already receiving thromboprophylaxis. For patients undergoing cesarean delivery with additional risk factors for thromboembolism, both pneumatic compression devices and unfractionated or low-molecular-weight heparin may be recommended. Cesarean delivery in an emergency setting should not be delayed because of the time necessary to implement thromboprophylaxis. The American College of Chest Physicians recommends the risk-adjusted approach to thromboprophylaxis shown in Table 52-7 (Bates, 2012).

TABLE 52-8. Some Recommendations for Thromboprophylaxis during Pregnancy

Clinical Scenario	Pregnancy		Postpartum	
	ACOG ^a	ACCP ^b	ACOG ^a	ACCP ^b
Prior single VTE				
Risk factor no longer present	Surveillance only	Surveillance only	Postpartum anticoagulation ^c "Surveillance only acknowledged by some experts."	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Pregnancy- or estrogen-related or no known association (idiopathic) and not receiving long-term therapy	Prophylactic UFH or LMWH or "Surveillance only acknowledged by some experts"	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation ^c	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Receiving long-term warfarin	NSS	Adjusted-dose LMWH or 75% of a therapeutic dose of LMWH	NSS	Resume long-term anticoagulation
Associated with a high-risk thrombophilia ^d and not receiving long-term anticoagulation or an affected first-degree relative	Prophylactic, intermediate-, or adjusted-dose LMWH or UFH	NSS	Postpartum anticoagulation ^c or intermediate- or adjusted-dose LMWH or UFH × 6 weeks ^c	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Associated with a low-risk thrombophilia ^e and not receiving treatment	Prophylactic or intermediate-dose LMWH or UFH or surveillance only	NSS	Postpartum anticoagulation ^c or intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Two or more prior VTEs with or without thrombophilia				
Not receiving long-term therapy	Prophylactic or therapeutic-dose UFH or LMWH	NSS	Postpartum anticoagulation ^c or therapeutic-dose LMWH or UFH × 6 weeks	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Receiving long-term anticoagulation	Therapeutic-dose LMWH or UFH	Adjusted-dose LMWH or 75% of a therapeutic dose of LMWH	Resumption of long-term anticoagulation	Resumption of long-term anticoagulation
No prior VTE				
High-risk thrombophilia ^d	Surveillance only or prophylactic or intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH	Postpartum anticoagulation ^c	Intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE and homozygous factor V Leiden or prothrombin 20210A mutation	NSS	Prophylactic or intermediate-dose LMWH	NSS	Prophylactic or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks

TABLE 52-8. Continued

Clinical Scenario	Pregnancy		Postpartum	
	ACOG ^a	ACCP ^b	ACOG ^a	ACCP ^b
Negative family history VTE and homozygous factor V Leiden or prothrombin 20210A mutation	Surveillance only or prophylactic LMWH or UFH	Surveillance only	Postpartum anticoagulation ^c	Prophylactic- or intermediate-dose LMWH or warfarin target INR 2.0–3.0 × 6 weeks
Positive family history VTE and low-risk thrombophilias ^e	Surveillance only	Surveillance only	Postpartum anticoagulation ^c or intermediate-dose LMWH or UFH	Prophylactic or intermediate-dose LMWH or in women <u>not</u> protein C or S deficient, warfarin target INR 2.0–3.0
Low-risk thrombophilia ^e	Surveillance only	Surveillance only if no family history	Surveillance only; postpartum anticoagulation with additional risk factors ^f	Surveillance only if no family history
Antiphospholipid antibodies				
History of VTE	Prophylactic anticoagulation with UFH or LMWH (?plus low-dose aspirin)	NSS	Prophylactic anticoagulation ^c ; referral to specialist ^g	NSS
No prior VTE	Surveillance only or prophylactic LMWH or UFH or prophylactic LMWH or UFH plus low-dose aspirin if prior recurrent pregnancy loss or stillbirth	Prophylactic- or intermediate-dose UFH or prophylactic-dose LMWH, both given with 75–100 mg/day aspirin ^h	Prophylactic heparin plus low-dose aspirin × 6 weeks if prior recurrent pregnancy loss or stillbirth ^g	NSS

^aAmerican College of Obstetricians and Gynecologists, 2012, 2013.

^bAmerican College of Chest Physicians (Bates, 2012).

^cPostpartum treatment levels should be ≥ antepartum treatment.

^dAntithrombin deficiency; doubly heterozygous or homozygous for prothrombin 20210A and factor V Leiden.

^eHeterozygous factor V Leiden or prothrombin 20210A; protein S or C deficiency.

^fFirst-degree relative with VTE at < 50 years; other major thrombotic risk factors, e.g., obesity, prolonged immobility.

^gWomen with antiphospholipid syndrome should not use estrogen-containing contraceptives.

^hTreatment is recommended if the diagnosis of antiphospholipid syndrome is based on three or more prior pregnancy losses. LMWH = low-molecular-weight heparin; NSS = not specifically stated; UFH = unfractionated heparin; VTE = venous thromboembolism.

Prophylactic, intermediate-, and adjusted-dose regimens are listed in Table 52-5 (p. 1037).

■ Prolonged Antepartum Bed Rest

There are no recommendations concerning thromboprophylaxis for women placed on bed rest for a number of obstetrical indications. This danger is possibly mitigated because strict bed rest is seldom indicated or enforced. In the survey cited above

by Casele and Grobman (2007), 25 percent of maternal-fetal medicine specialists routinely use some form of thromboprophylaxis for women on bed rest > 72 hours. It seems reasonable to consider such measures if additional risk factors are identified, for example, obesity or diabetes.

CHAPTER 53

Renal and Urinary Tract Disorders

PREGNANCY-INDUCED URINARY TRACT CHANGES . . .	1051
URINARY TRACT INFECTIONS	1052
NEPHROLITHIASIS	1056
PREGNANCY AFTER RENAL TRANSPLANTATION	1057
POLYCYSTIC KIDNEY DISEASE	1058
GLOMERULAR DISEASES	1058
CHRONIC RENAL DISEASE	1060
ACUTE KIDNEY INJURY	1063
LOWER URINARY TRACT LESIONS	1064

Renal and urinary tract disorders are commonly encountered in pregnancy. Some precede pregnancy—one example being nephrolithiasis. In some women, pregnancy-induced changes may predispose to development or worsening of urinary tract disorders—an example is the markedly increased risk for pyelonephritis. Finally, there may be renal pathology unique to pregnancy such as preeclampsia. With good prenatal care, however, most women with these disorders will likely have no long-term sequelae.

PREGNANCY-INDUCED URINARY TRACT CHANGES

Significant changes in both structure and function that take place in the urinary tract during normal pregnancy are discussed in Chapter 4 (p. 63). The kidneys become larger, and as shown in [Figure 53-1](#), dilatation of the renal calyces and ureters can be striking. Some dilatation develops before 14 weeks and likely is due to progesterone-induced relaxation of the muscularis. More marked dilatation is apparent beginning in midpregnancy because of ureteral compression, especially on the right side (Faúndes, 1998). There is also some *vesicoureteral reflux*

during pregnancy. An important consequence of these physiological changes is an increased risk of upper urinary infection, and occasionally erroneous interpretation of studies done to evaluate obstruction.

Evidence of functional renal hypertrophy becomes apparent very soon after conception. Glomeruli are larger, although cell numbers do not increase (Streven, 2003). Pregnancy-induced intrarenal vasodilatation—both afferent and efferent resistance decreases—leads to increased effective renal plasma flow and glomerular filtration (Helal, 2012; Hussein, 2014). By 12 weeks' gestation, the glomerular filtration rate is already increased 20 percent above nonpregnant values (Hladunewich, 2004). Ultimately, plasma flow and glomerular filtration increase by 40 and 65 percent, respectively. Consequently, serum concentrations of creatinine and urea decrease substantively across pregnancy, and values within a nonpregnant normal range may be abnormal for pregnancy (Appendix, p. 1289). Other alterations include those related to maintaining normal acid-base homeostasis, osmoregulation, and fluid and electrolyte retention.

Assessment of Renal Function During Pregnancy

The *urinalysis* is essentially unchanged during pregnancy, except for occasional glucosuria. Although *protein excretion* normally is increased, it seldom reaches levels that are detected by usual screening methods. As discussed in Chapter 4 (p. 65), Higby and colleagues (1994) reported 24-hour protein excretion to be 115 mg with a 95-percent confidence level of 260 mg/day. There were no significant differences by trimester. Albumin constitutes only a small part of total protein excretion and ranges from 5 to 30 mg/day. From their review, Airolidi and Weinstein (2007) concluded that proteinuria must exceed 300 mg/day to be considered abnormal. Many consider 500 mg/day to be important with gestational hypertension. Quantification

FIGURE 53-1 The 50th, 75th, and 90th percentiles for maternal renal caliceal diameters measured using sonography in 1395 pregnant women from 4 to 42 weeks. (Redrawn from Faúndes, 1998.)

of urinary albumin-to-creatinine ratio (ACR) in a spot urine sample—ideally from a first-morning void—is helpful in estimating a 24-hour albumin excretion rate (AER), in which ACR (mg/g) approximates AER (mg/24 h). Some laboratories measure total proteins instead of albumin.

Stehman-Breen and associates (2002) found that 3 percent of 4589 nulliparas had *idiopathic hematuria*, defined as 1+ or greater blood on urine dipstick when screened before 20 weeks. They also reported that these women had a twofold risk of developing preeclampsia. In another study of 1000 women screened during pregnancy, Brown and coworkers (2005) reported a 15-percent incidence of dipstick hematuria. Most women had trace levels of hematuria, and the false-positive rate was 40 percent.

If the serum creatinine level in pregnancy persistently exceeds 0.9 mg/dL (75 μ mol/L), then intrinsic renal disease should be suspected. In these cases, some determine the creatinine clearance as an estimate of the glomerular filtration rate. *Sonography* provides imaging of renal size, relative consistency, and elements of obstruction (see Fig. 53-1). Full-sequence *intravenous pyelography* is not done routinely, but injection of contrast media with one or two abdominal radiographs may be indicated by the clinical situation (Chap. 46, p. 931). The usual clinical indications for *cystoscopy* are followed. There is an approximate 5-percent complication rate of *ureteroscopy* done for stone removal during pregnancy (Johnson, 2012; Semins, 2009). Magnetic resonance (MR) imaging of renal masses has been shown to have excellent results (Putra, 2009).

Although *renal biopsy* is relatively safely performed during pregnancy, it usually is postponed unless results may change therapy. From a review of 243 biopsies in pregnant women, the incidence of complications was 7 percent—this compares with 1 percent in postpartum women (Piccoli, 2013).

FIGURE 53-2 Increased glomerular filtration rate in early pregnancy in normal women, those stable after unilateral nephrectomy, and those with a successful renal transplant. (Data from Newcastle-upon-Tyne, 1974–2006, courtesy of Dr. John Davison.)

Lindheimer and colleagues (2007a) recommend its consideration for rapid deterioration of renal function with no obvious cause or for symptomatic nephrotic syndrome. We and others have found biopsy helpful in selected cases to direct management (Chen, 2001; Piccoli, 2013). Strevens and associates (2003) performed renal biopsy in 12 *normal* pregnant volunteers and reported that five had slight to moderate glomerular endotheliosis. In contrast, all 27 women with proteinuric hypertension had endotheliosis, and in all but one, it was moderate to severe.

Pregnancy after Unilateral Nephrectomy

After removal of one kidney, and if the remaining kidney is normal, there is hypertrophy of renal function. In addition, with pregnancy, the surviving kidney undergoes further hypertrophy of function (Fig. 53-2). Because of this, women with one normal kidney most often have no difficulty in pregnancy (Baylis, 1991). Thorough functional evaluation of the remaining kidney is essential. Finally, there are no long-term adverse consequences of kidney donation done before pregnancy (Ibrahim, 2009).

URINARY TRACT INFECTIONS

These are the most common bacterial infections during pregnancy. Although *asymptomatic bacteriuria* is the most common, symptomatic infection includes *cystitis*, or it may involve the renal calyces, pelvis, and parenchyma—*pyelonephritis*.

Organisms that cause urinary infections are those from the normal perineal flora. Approximately 90 percent of *Escherichia coli* strains that cause nonobstructive pyelonephritis have *adhesins* such as P- and S-fimbriae. These are cell-surface protein structures that enhance bacterial adherence and thereby, virulence (Foxman, 2010; Hooton, 2012). These adhesins promote binding to vaginal and uroepithelial cells through expression of the *PapG* gene that encodes the

P-fimbriae tip and by production of toxins and other virulence factors (Spurbeck, 2011).

Data suggest that pregnant women have more severe sequelae from urosepsis. The T-helper cell—Th1/Th2 ratio—reversal of normal pregnancy is discussed in Chapter 4 (p. 56). There are also various perturbations of cytokine expression that have been reported (Chaemsaihong, 2013). And maternal deaths have been attributed to *E coli* bearing Dr⁺ and P adhesins (Sledzińska, 2011). But even if pregnancy itself does not enhance these virulence factors, urinary stasis, vesicoureteral reflux, and diabetes predispose to symptomatic upper urinary infections (Czaja, 2009; Twickler, 1994).

In the puerperium, there are several risk factors that predispose a woman to urinary infections. Bladder sensitivity to intravesical fluid tension is often decreased as a consequence of labor trauma or conduction analgesia (Chap. 36, p. 676). Sensation of bladder distention can also be diminished by discomfort caused by an episiotomy, periurethral lacerations, or vaginal wall hematomas. Normal postpartum diuresis may worsen bladder overdistention, and catheterization to relieve retention commonly leads to urinary infection. Postpartum pyelonephritis is treated in the same manner as antepartum renal infections (McDonnold, 2012).

■ Asymptomatic Bacteriuria

This refers to persistent, actively multiplying bacteria within the urinary tract in asymptomatic women. Its prevalence in nonpregnant women is 5 to 6 percent and depends on parity, race, and socioeconomic status (Hooton, 2000). The highest incidence is in African-American multiparas with sickle-cell trait, and the lowest incidence is in affluent white women of low parity. Asymptomatic infection is also more common in diabetics (Schneeberger, 2014). Because in most women there is recurrent or persistent bacteriuria, it frequently is discovered during prenatal care. The incidence during pregnancy is similar to that in nonpregnant women and varies from 2 to 7 percent.

Bacteriuria is typically present at the first prenatal visit. An initial positive urine culture result prompts treatment, after which, fewer than 1 percent of women develop a urinary tract infection (Whalley, 1967). A clean-voided specimen containing more than 100,000 organisms/mL is diagnostic. It may be prudent to treat when lower concentrations are identified, because pyelonephritis develops in some women despite colony counts of only 20,000 to 50,000 organisms/mL (Lucas, 1993).

Significance

If asymptomatic bacteriuria is not treated, approximately 25 percent of infected women will develop symptomatic infection during pregnancy. Eradication of bacteriuria with antimicrobial agents prevents most of these. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), as well as a U.S. Preventive Services Task Force (2008), recommend screening for bacteriuria at the first prenatal visit (Chap. 9, p. 174). Standard urine cultures may not be cost effective when the prevalence is low. However, less expensive screening tests such as the leukocyte esterase-nitrite dipstick are when the prevalence is 2 percent or less (Rouse,

1995). Because of a high prevalence—5 to 8 percent—at Parkland Hospital, culture screening is done in most women. Susceptibility determination is not necessary because initial treatment is empirical (Hooton, 2012). Also, a dipstick culture technique has excellent positive- and negative-predictive values (Mignini, 2009). With this, a special agar-coated dipstick is first placed into urine and then also serves as the culture plate.

In some, but not all studies, covert bacteriuria has been associated with preterm or low-birthweight infants (Kass, 1962). It is even more controversial whether eradication of bacteriuria decreases these complications. Evaluating a cohort of 25,746 mother-infant pairs, Schieve and coworkers (1994) reported urinary tract infection to be associated with increased risks for low-birthweight infants, preterm delivery, pregnancy-associated hypertension, and anemia. These findings vary from those of Gilstrap and colleagues (1981b) and Whalley (1967). In most studies, asymptomatic infection is not evaluated separately from acute renal infection (Banhid, 2007). A Cochrane database review by Vasquez and Abalos (2011) found that benefits of treatment for asymptomatic bacteria are limited to the reduction of the incidence of pyelonephritis.

Treatment

Bacteriuria responds to empirical treatment with any of several antimicrobial regimens listed in Table 53-1. Although selection can be based on in vitro susceptibilities, in our extensive

TABLE 53-1. Oral Antimicrobial Agents Used for Treatment of Pregnant Women with Asymptomatic Bacteriuria

Single-dose treatment

Amoxicillin, 3 g
Ampicillin, 2 g
Cephalosporin, 2 g
Nitrofurantoin, 200 mg
Trimethoprim-sulfamethoxazole, 320/1600 mg

3-day course

Amoxicillin, 500 mg three times daily
Ampicillin, 250 mg four times daily
Cephalosporin, 250 mg four times daily
Ciprofloxacin, 250 mg twice daily
Levofloxacin, 250 or 500 mg daily
Nitrofurantoin, 50 to 100 mg four times daily or 100 mg twice daily
Trimethoprim-sulfamethoxazole, 160/800 mg two times daily

Other

Nitrofurantoin, 100 mg four times daily for 10 days
Nitrofurantoin, 100 mg twice daily for 5 to 7 days
Nitrofurantoin, 100 mg at bedtime for 10 days

Treatment failures

Nitrofurantoin, 100 mg four times daily for 21 days

Suppression for bacterial persistence or recurrence

Nitrofurantoin, 100 mg at bedtime for pregnancy remainder

experience, empirical oral treatment for 10 days with nitrofurantoin macrocrystals, 100 mg at bedtime, is usually effective. Lumbiganon and associates (2009) reported satisfactory results with a 7-day oral course of nitrofurantoin, 100 mg given twice daily. Single-dose antimicrobial therapy has also been used with success for bacteriuria. The important caveat is that, regardless of regimen given, the recurrence rate is approximately 30 percent. This may indicate covert upper tract infection and the need for longer therapy.

Periodic surveillance is necessary to prevent recurrent urinary infections (Schneeberger, 2012). For recurrent bacteriuria, we have had success with nitrofurantoin, 100 mg orally at bedtime for 21 days (Lucas, 1994). For women with persistent or frequent bacteriuria recurrences, suppressive therapy for the remainder of pregnancy can be given. We routinely use nitrofurantoin, 100 mg orally at bedtime. This drug may rarely cause an acute pulmonary reaction that dissipates on its withdrawal (Bogges, 1996).

■ Cystitis and Urethritis

Lower urinary infection during pregnancy may develop without antecedent covert bacteriuria (Harris, 1981). Cystitis is characterized by dysuria, urgency, and frequency, but with few associated systemic findings. Pyuria and bacteriuria are usually found. Microscopic hematuria is common, and occasionally there is gross hematuria from hemorrhagic cystitis (Fakhoury, 1994). Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Almost 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower tract infection (Gilstrap, 1981a).

Women with cystitis respond readily to any of several regimens. Most of the three-day regimens listed in Table 53-1 are usually 90-percent effective (Fihn, 2003). Single-dose therapy is less effective, and if it is used, concomitant pyelonephritis must be confidently excluded.

Lower urinary tract symptoms with pyuria accompanied by a sterile urine culture may be from urethritis caused by *Chlamydia trachomatis*. Mucopurulent cervicitis usually coexists, and azithromycin therapy is effective. (Chap. 65, p. 1270)

■ Acute Pyelonephritis

Renal infection is the most common serious medical complication of pregnancy. In a study of the 2006 Nationwide Inpatient Sample by Jolley and coworkers (2012), there were nearly 29,000 hospitalizations for acute pyelonephritis. Rates were highest for adolescents at 17.5 per 1000 and for Hispanic women at 10.1 per 1000. In another study of more than 70,000 pregnancies in a managed care organization, Gazmararian and colleagues (2002) reported that 3.5 percent of antepartum admissions were for urinary infections. The potential seriousness is underscored by the observations of Snyder and associates (2013) that pyelonephritis was the leading cause of septic shock during pregnancy. And in a 2-year audit of admissions to the Parkland Hospital Obstetrical Intensive Care Unit, 12 percent of antepartum admissions were for sepsis syndrome caused by pyelonephritis (Zeeman, 2003). There is also concern that urosepsis may be

related to an increased incidence of cerebral palsy in preterm infants (Jacobsson, 2002). Fortunately, there appear to be no serious long-term maternal sequelae (Raz, 2003).

Clinical Findings

Renal infection develops more frequently in the second trimester, and nulliparity and young age are associated risk factors (Hill, 2005). Pyelonephritis is unilateral and right-sided in more than half of cases, and it is bilateral in a fourth. There is usually a rather abrupt onset with fever, shaking chills, and aching pain in one or both lumbar regions. Anorexia, nausea, and vomiting may worsen dehydration. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The urinary sediment contains many leukocytes, frequently in clumps, and numerous bacteria. Bacteremia is demonstrated in 15 to 20 percent of these women. *E coli* is isolated from urine or blood in 70 to 80 percent of infections, *Klebsiella pneumoniae* in 3 to 5 percent, *Enterobacter* or *Proteus* species in 3 to 5 percent, and gram-positive organisms, including group B *Streptococcus* and *S aureus*, in up to 10 percent of cases (Hill, 2005; Wing, 2000). The differential diagnosis includes, among others, labor, chorioamnionitis, appendicitis, placental abruption, or infarcted leiomyoma. Evidence of the sepsis syndrome is common, and this is discussed in detail in Chapter 47 (p. 946).

Plasma creatinine is monitored because early studies reported that 20 percent of pregnant women developed renal dysfunction. More recent findings, however, show this to be only 5 percent if aggressive fluid resuscitation is provided (Hill, 2005). Follow-up studies have demonstrated that this endotoxin-induced damage is reversible in the long term. Varying degrees of respiratory insufficiency from endotoxin-induced alveolar injury are manifest in up to 10 percent of women and may result in frank pulmonary edema (Cunningham, 1987; Sheffield, 2005; Snyder, 2013). In some cases, pulmonary injury may be so severe that it causes *acute respiratory distress syndrome (ARDS)* (Fig. 53-3).

Uterine activity from endotoxin is common and is related to fever severity (Graham, 1993). In the study by Millar and coworkers (2003), women with pyelonephritis averaged 5 contractions per hour at admission, and this decreased to 2 per hour within 6 hours of intravenous fluid and antimicrobial administration. As discussed in Chapter 47 (p. 942), β -agonist therapy for tocolysis increases the likelihood of respiratory insufficiency from permeability edema because of the sodium- and fluid-retaining properties of those agents (Lamont, 2000). The incidence of pulmonary edema in women with pyelonephritis who were given β -agonists was reported to be 8 percent—a fourfold increase over that expected (Towers, 1991).

Endotoxin-induced *hemolysis* is common, and approximately a third of patients with pyelonephritis develop anemia (Cox, 1991). With recovery, hemoglobin regeneration is normal because acute infection does not affect erythropoietin production (Cavenee, 1994).

Management

One scheme for management of acute pyelonephritis is shown in Table 53-2. Although we routinely obtain urine and blood

FIGURE 53-3 A series of anterior-posterior projection chest radiographs of improving acute respiratory distress syndrome (ARDS) in a second-trimester pregnant woman with severe pyelonephritis. **A.** An extensive infiltrative process and complete obliteration of the diaphragm (white arrows) is seen. **B.** Improved aeration of lung fields bilaterally is noted as pleural disease resolves (arrows). **C.** Markedly improved visualization of the lungs fields with residual platelike atelectasis and normal appearance of the diaphragm.

cultures, prospective trials show them to be of limited clinical utility (Wing, 2000). *Intravenous hydration to ensure adequate urinary output is the cornerstone of treatment.* Antimicrobials are also begun promptly with the caveat that they may initially worsen endotoxemia from bacterial lysis. Ongoing surveillance for worsening of sepsis syndrome is monitored by serial determinations of urinary output, blood pressure, pulse, temperature, and oxygen saturation. High fever should be lowered with a cooling blanket or acetaminophen. This is especially important in early pregnancy because of possible teratogenic effects of hyperthermia (Chap. 14, p. 284).

Antimicrobial therapy usually is empirical, and ampicillin plus gentamicin; cefazolin or ceftriaxone; or an extended-spectrum antibiotic were all 95-percent effective in randomized trials (Sanchez-Ramos, 1995; Wing, 1998, 2000). Fewer than half of *E coli* strains are sensitive to ampicillin in vitro, but cephalosporins and gentamicin generally have excellent activity.

TABLE 53-2. Management of the Pregnant Woman with Acute Pyelonephritis

Hospitalize patient
Obtain urine and blood cultures
Evaluate hemogram, serum creatinine, and electrolytes
Monitor vital signs frequently, including urinary output—consider indwelling catheter
Establish urinary output ≥ 50 mL/hr with intravenous crystalloid solution
Administer intravenous antimicrobial therapy (see text)
Obtain chest radiograph if there is dyspnea or tachypnea
Repeat hematology and chemistry studies in 48 hours
Change to oral antimicrobials when afebrile
Discharge when afebrile 24 hours, consider antimicrobial therapy for 7 to 10 days
Repeat urine culture 1 to 2 weeks after antimicrobial therapy completed

Modified from Lucas, 1994; Sheffield, 2005.

Serum creatinine is monitored if nephrotoxic drugs are given. Initial treatment at Parkland Hospital is ampicillin plus gentamicin. Some recommend suitable substitutes if bacterial studies show in vitro resistance. With any of the regimens discussed, response is usually prompt, and 95 percent of women are afebrile by 72 hours (Hill, 2005; Sheffield, 2005; Wing, 2000). After discharge, most recommend oral therapy for a total of 7 to 14 days (Hooton, 2012).

Persistent Infection. Generally, intravenous hydration and antimicrobial therapy are followed by stepwise defervescence of approximately 1°F per day. With persistent spiking fever or lack of clinical improvement by 48 to 72 hours, urinary tract obstruction or another complication or both are considered. Renal sonography is recommended to search for obstruction manifest by abnormal ureteral or pyelocaliceal dilatation (Seidman, 1998). Although most women with continuing infection have no evidence of obstruction, some are found to have calculi. Although renal sonography will detect hydronephrosis, stones are not always seen in pregnancy (Butler, 2000; Maikranz, 1987). If stones are strongly suspected despite a nondiagnostic sonographic examination, a plain abdominal radiograph will identify nearly 90 percent. Another option is the modified *one-shot intravenous pyelogram*—a single radiograph obtained 30 minutes after contrast injection—which usually provides adequate imaging (Butler, 2000).

In some women, MR imaging may disclose the cause of persistent infection (Spencer, 2004). Even without urinary obstruction, persistent infection can be due to an intrarenal or perinephric abscess or phlegmon (Cox, 1988; Rafi, 2012). Obstruction relief is important, and one method is cystoscopic placement of a double-J ureteral stent (Rodriguez, 1988). Because these stents are usually left in place until after delivery, they frequently become encrusted and require replacement. We have found that percutaneous nephrostomy is preferable because the stents are more easily replaced. Finally, surgical removal of stones may be required in some women (p. 1057).

Outpatient Management of Pyelonephritis. Outpatient management is an option for nonpregnant women with uncomplicated pyelonephritis (Hooton, 2012). Wing and

associates (1999) have described outpatient management in 92 pregnant women who were first given in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart. At this point, one third of the group was considered suitable for outpatient therapy, and these women were randomized either to discharge and oral antimicrobials or to continued hospitalization with intravenous therapy. A third of the outpatient management group was unable to adhere to the treatment regimen and was admitted. These findings suggest that outpatient management is applicable to very few pregnant women.

Surveillance

Recurrent infection—either covert or symptomatic—is common and develops in 30 to 40 percent of women following completion of treatment for pyelonephritis (Cunningham, 1973). Unless other measures are taken to ensure urine sterility, nitrofurantoin, 100 mg orally at bedtime given for the remainder of the pregnancy, reduces bacteriuria recurrence (Van Dorsten, 1987).

Reflux Nephropathy

Vesicoureteral reflux in early childhood can cause recurrent urinary tract infections, and thus, subsequent chronic interstitial nephritis was attributed to *chronic pyelonephritis*. Moreover, it was also found that high-pressure sterile reflux impaired normal renal growth. Combined, this leads to patchy interstitial scarring, tubular atrophy, and loss of nephron mass and is termed *reflux nephropathy*. In adults, long-term complications include hypertension, which may be severe if there is demonstrable renal damage (Diamond, 2012; Köhler, 2003).

Perhaps half of women with reflux nephropathy were treated during childhood for renal infections. Of these, many also had surgical correction of reflux as children, and these commonly have bacteriuria when pregnant (Mor, 2003). In the other half of women with reflux nephropathy, there is no clear history of recurrent cystitis, acute pyelonephritis, or obstructive disease (Diamond, 2012). Reports describing 939 pregnancies in 379 women with reflux nephropathy indicate that impaired renal function and bilateral renal scarring were associated with increased maternal complications (El-Khatib, 1994; Jungers, 1996; Köhler, 2003). Chronic renal disease and pregnancy outcome is discussed further on page 1061.

NEPHROLITHIASIS

Kidney stones develop in 7 percent of women during their lifetime with an average age of onset in the third decade (Asplin, 2012). Calcium salts make up approximately 80 percent of stones, and up to half of affected women have polygenic *familial idiopathic hypercalciuria* (Worcester, 2010). Hyperparathyroidism should be excluded. Although calcium oxalate stones in young nonpregnant women are most common, most stones in pregnancy—65 to 75 percent—are calcium phosphate or hydroxyapatite (Ross, 2008; Tan, 2013). Patients who have a stone typically form another stone every 2 to 3 years.

Contrary to past teachings, a low-calcium diet *promotes* stone formation. Prevention of recurrences with hydration and a diet low in sodium and protein is currently recommended (Asplin, 2012). Thiazide diuretics also diminish stone formation. In general, obstruction, infection, intractable pain, and heavy bleeding are indications for stone removal. Removal by a flexible basket via cystoscopy, although used less often than in the past, is still a reasonable consideration for pregnant women. In nonpregnant patients, stone destruction by *lithotripsy* is preferred to surgical therapy in most cases. There is limited information on the use of these procedures during pregnancy, and they are not generally recommended.

Stone Disease During Pregnancy

The incidence of stone disease complicating pregnancy has been reported with widespread variability. At the low end, Butler and colleagues (2000) found the incidence to be 0.3 admissions per 1000 pregnancies in more than 186,000 deliveries at Parkland Hospital. In an Israeli population-based study, the incidence in nearly 220,000 pregnancies was 0.8 per 1000 (Rosenberg, 2011). In a population-based study from Washington state, Swartz and coworkers (2007) reported an incidence of 1.7 per 1000 pregnancies. Bladder stones are rare, but recurrent infection and labor obstructed by stones have been reported (Ait Benkaddour, 2006; Ruan, 2011).

Data are conflicting whether women with kidney stones have an increased risk for low-birthweight and preterm infants. The case-control study by Swartz and colleagues (2007) of 2239 women with nephrolithiasis reported excessive preterm delivery—10.6 versus 6.4 percent—compared with normal controls. The more recent nationwide population-based case-control study from Taiwan also reported 20- to 40-percent increases in low-birthweight and preterm births (Chung, 2013). To the contrary, a case-control study from Hungary reported that pregnancy outcomes, including preterm delivery, were similar in women with stones and normal controls (Banhidy, 2007). Comparable conclusions were drawn from the Israeli population-based study noted earlier (Rosenberg, 2011).

Diagnosis

There is some evidence that pregnant women may have fewer symptoms with stone passage because of urinary tract dilatation (Hendricks, 1991; Tan, 2013). That said, more than 90 percent of pregnant women with nephrolithiasis present with pain. Gross hematuria is less common than in nonpregnant women and was reported to be a presenting symptom in 23 percent of women described by Butler and associates (2000). In another study, however, Lewis and coworkers (2003) found that only 2 percent had hematuria. Sonography is usually selected to visualize stones, but as discussed above, many are not detected because hydronephrosis may obscure findings (McAleer, 2004). If there is abnormal dilatation without stone visualization, then the one-shot pyelogram may be useful. Transabdominal color Doppler sonography to detect presence or absence of ureteral “jets” of urine into the bladder has been used to exclude obstruction (Asrat, 1998).

Helical computed tomography (CT) scanning is the imaging method of choice for nonpregnant individuals, however, it is avoided during pregnancy if possible (Brown, 2010). If it is used, the slices can be tailored as needed (Chap. 46, p. 934). For pregnant women, White and colleagues (2007) recommend unenhanced helical CT and cite an average fetal radiation dose to be 7 mGy. These exigencies have led some to recommend MR imaging as the second-line test following nondiagnostic sonography (Masselli, 2013).

Management

Treatment depends on symptoms and gestational age (Semins, 2013). Intravenous hydration and analgesics are given. In half of women with symptomatic stones, infection will be identified, and this is treated vigorously. Although calculi infrequently cause symptomatic obstruction during pregnancy, persistent pyelonephritis should prompt a search for obstruction due to nephrolithiasis.

Approximately 65 to 80 percent of symptomatic women will have improvement with conservative therapy, and the stone usually passes spontaneously (Tan, 2013). Others require an invasive procedure such as ureteral stenting, ureteroscopy, percutaneous nephrostomy, transurethral laser lithotripsy, or basket extraction (Butler, 2000; Semins, 2010). The need for fluoroscopy limits the utility of percutaneous nephrolithotomy (Toth, 2005). In the case-control study cited above by Swartz and associates (2007), there were 623 procedures performed in 2239 symptomatic pregnant women, but less than 2 percent required surgical exploration.

As noted earlier, extracorporeal shock-wave lithotripsy is contraindicated in pregnancy. Watterson and coworkers (2002) described successful transurethral holmium:YAG laser lithotripsy in nine of 10 women. Semins and Matlaga (2010) found that ureteroscopic removal is also safe in pregnancy.

PREGNANCY AFTER RENAL TRANSPLANTATION

In 2013, there were approximately 97,000 registrants on the waiting list for renal transplantations through the Organ Procurement and Transplantation Network—OPTN (2013). The 1-year graft survival rate is 95 percent for grafts from living donors and 89 percent from deceased donors (Carpenter, 2008). Survival rates approximately doubled between 1988 and 1996, due in large part to the introduction of cyclosporine and muromonab-CD3 (OKT3 monoclonal antibody) to prevent and treat organ rejection. Since then, mycophenolate mofetil and tacrolimus have further reduced acute rejection episodes, however, the former is considered teratogenic (Briggs, 2011). In the report from the National Transplant Pregnancy Registry, 23 percent of fetuses exposed to mycophenolate had birth defects (Coscia, 2010). Importantly, resumption of renal function after transplantation promptly restores fertility in reproductive-aged women (Hladunewich, 2011; Lessan-Pezeshki, 2004). More than half of transplant recipients reported that they were not counseled regarding contraception (French, 2013).

Pregnancy Outcomes

Coscia and coworkers (2010) reviewed the outcomes of 2000 pregnancies in transplant recipients as reported to the National

Transplantation Pregnancy Registry. Most were treated with cyclosporine and tacrolimus, and approximately 75 percent of pregnancies resulted in a live birth. Similar outcomes were described for the Australian and New Zealand Transplant Registry by Wyld and associates (2013). Bramham and colleagues (2013) identified 105 pregnancies in renal transplant recipients and the United Kingdom Obstetric Surveillance System (UKOSS). Excluding nine abortions, there was only one perinatal death and 97 living children. Half were delivered before 37 weeks' gestation, but only 9 percent before 32 weeks. Half were born weighing < 2500 g, and a fourth were growth restricted. Importantly, the incidence of fetal malformations was not increased, except in those who took mycophenolate mofetil (Coscia, 2010). Twin pregnancy has also been described following renal transplantation (Gizzo, 2014).

The incidence of preeclampsia is high in all transplant recipients (Brosens, 2013). In the UK National Cohort Study reported by Bramham and associates (2013), the incidence of preeclampsia was 22 percent. From their review, Josephson and McKay (2011) cite an incidence of a third of pregnancies but question the validity of this frequency. Importantly, in some cases, rejection is difficult to distinguish from preeclampsia. That said, the incidence of rejection episodes approximates only 2 percent (Bramham, 2013). Viral infections—especially polyomavirus hominis 1, also called BK virus, infections—are frequent. Also, gestational diabetes is found in approximately 5 percent. Both are likely related to immunosuppression therapy. Similar outcomes have been reported by several other investigators (Al Duraihimi, 2008; Cruz Lemini, 2007; Ghafari, 2008; Gutierrez, 2005).

Lindheimer (2007a) and Josephson (2011) and their coworkers recommend that women who have undergone transplantation satisfy several requisites before attempting pregnancy. First, women should be in good general health for at least 1 to 2 years after transplantation. Also, there should be stable renal function without severe renal insufficiency—serum creatinine < 2 mg/dL and preferably < 1.5 mg/dL—and < 500 mg/day proteinuria. Evidence for graft rejection should be absent for 6 months, and pyelocalyceal distention by urography should not be apparent. Moreover, hypertension should be absent or well controlled. And last, no teratogenic drugs are being given, and drug therapy is reduced to maintenance levels.

Cyclosporine or tacrolimus is given routinely to renal transplantation recipients (Jain, 2004). Cyclosporine blood levels decline during pregnancy, although this was not reported to be associated with rejection episodes (Thomas, 1997). Unfortunately, these agents are nephrotoxic and also may cause renal hypertension. In fact, they likely contribute substantively to chronic renal disease that develops in 10 to 20 percent of patients with nonrenal solid-organ transplantation (Goes, 2007).

Concern persists regarding the possible late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the children of the offspring. In addition, cyclosporine is secreted in breast milk, and in at least one instance, it produced therapeutic serum levels in the nursing child (Moretti, 2003).

Finally, although pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival, Sturgiss and

Davison (1995) found no evidence for this in a case-control study of 34 allograft recipients followed for a mean of 15 years.

Management

Close surveillance is necessary. Covert bacteriuria is treated, and if it is recurrent, suppressive treatment is given for the remainder of the pregnancy. Serial hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Some recommend measurement of serum cyclosporine levels. Gestational diabetes is more common if corticosteroids are taken, and overt diabetes must be excluded with glucose tolerance testing done at approximately 26 weeks' gestation. Surveillance for opportunistic infections from herpesvirus, cytomegalovirus, and toxoplasmosis is important because these infections are common. Some recommend surveillance for BK virus in women known to be infected (Josephson, 2011). Treatment is problematic.

Renal function is monitored, and as shown in Figure 53-2, the glomerular filtration rate usually increases 20 to 25 percent. If a significant rise in the serum creatinine level is detected, then its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity, preeclampsia, infection, and urinary tract obstruction. Evidence of pyelonephritis or graft rejection should prompt admission for aggressive management. Imaging studies and kidney biopsy may be indicated. The woman is carefully monitored for development or worsening of underlying hypertension, and especially superimposed preeclampsia. Management of hypertension during pregnancy is the same as for patients without a transplant.

Because of increased incidences of fetal-growth restriction and preterm delivery, vigilant fetal surveillance is indicated (Chaps. 42, p. 842 and 44, p. 880). Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney obstructs labor. In all women with a renal transplant, the cesarean delivery rate exceeds 60 percent (Bramham, 2013; Rocha, 2013).

POLYCYSTIC KIDNEY DISEASE

This usually autosomally dominant systemic disease primarily affects the kidneys. Its basic pathophysiology is one of a *ciliopathy* (Hildebrandt, 2011). The disease is found in 1 in 800 live births and causes approximately 5 to 10 percent of end-stage renal disease in the United States (Bargman, 2012). Although genetically heterogeneous, almost 85 percent of cases are due to *PKD1* gene mutations on chromosome 16, and the other 15 percent to *PKD2* mutations on chromosome 4 (Salant, 2012). Prenatal diagnosis is available if the mutation has been identified in a family member or if linkage has been established in the family.

Renal complications are more common in men than in women, and symptoms usually appear in the third or fourth decade. Flank pain, hematuria, proteinuria, abdominal masses, and associated calculi and infection are common findings. Hypertension develops in 75 percent, and progression to renal failure is a major problem. Superimposed acute renal failure may also develop from infection or obstruction from ureteral angulation by cyst displacement.

Other organs are commonly involved. Hepatic involvement is more common and more aggressive in women than in men

(Chapman, 2003). Asymptomatic *hepatic cysts* coexist in a third of patients with polycystic kidneys. Approximately 10 percent of patients with polycystic kidney disease die from rupture of an associated *intracranial berry aneurysm*. Up to a fourth of patients have *cardiac valvular lesions*, with mitral valve prolapse and mitral, aortic, and tricuspid valvular incompetence.

Pregnancy Outcomes

The prognosis for pregnancy in women with polycystic kidney disease depends on the degree of associated hypertension and renal insufficiency. Urinary tract infections are common. Chapman and coworkers (1994) compared pregnancy outcomes in 235 affected women who had 605 pregnancies with those of 108 unaffected family members who had 244 pregnancies. Composite perinatal complication rates were similar—33 versus 26 percent—but hypertension, including preeclampsia, was more common in women with polycystic kidneys. Pregnancy does not seem to accelerate the natural disease course (Lindheimer, 2007b).

GLOMERULAR DISEASES

The glomerulus and its capillaries are subject to numerous and various conditions and agents that can lead to acute and chronic diseases. Glomerular damage can be caused by several agents such as toxins or infections or from systemic disorders such as hypertension or diabetes. It may also be idiopathic. When there is capillary inflammation, the process is termed *glomerulonephritis*, and in many of these cases, an autoimmune process is involved. Glomerular disease or glomerulonephritis may result from a single stimulus such as that following group A streptococcal infections. However, it may be a manifestation of a multisystem disease such as systemic lupus erythematosus or diabetes (Sethi, 2012).

Persistent glomerulonephritis eventually leads to renal functional decline. Progression is variable and often does not become apparent until chronic renal insufficiency is diagnosed as discussed on page 1060. Lewis and Neilsen (2012) group glomerular injuries into six syndromes based on clinical patterns (Table 53-3). Some underlying disorders—examples include infections, vasculitides, and diabetes—can result in one clinical pattern in different individuals. Finally, within each of these categories, there are disorders encountered in young women, and thus, these may antedate or first manifest during pregnancy.

Acute Nephritic Syndromes

Acute glomerulonephritis may result from any of several causes (see Table 53-3). The clinical presentation usually includes hypertension, hematuria, red-cell casts, pyuria, and proteinuria. Varying degrees of renal insufficiency and salt and water retention result in edema, hypertension, and circulatory congestion (Lewis, 2012). The prognosis and treatment of nephritic syndromes depends on their etiology. Some recede spontaneously or with treatment. However, in some patients, *rapidly progressive glomerulonephritis* leads to end-stage renal failure, whereas in others, *chronic glomerulonephritis* develops with slowly progressive renal disease.

TABLE 53-3. Patterns of Clinical Glomerulonephritis

Acute Nephritic Syndromes: poststreptococcal, infective endocarditis, SLE, antiglomerular basement membrane disease, IgA nephropathy, ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia, membranoproliferative and mesangioproliferative glomerulonephritis

Pulmonary-Renal Syndromes: Goodpasture, ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia

Nephrotic Syndromes: minimal change disease, focal segmental glomerulosclerosis, membranous glomerulonephritis, diabetes, amyloidosis, others

Basement Membrane Syndromes: anti-GBM disease, others

Glomerular Vascular Syndromes: atherosclerosis, chronic hypertension, sickle-cell disease, thrombotic microangiopathies, antiphospholipid antibody syndrome, ANCA vasculitis, others

Infectious Disease-Associated Syndromes: poststreptococcal, infective endocarditis, HIV, HBV, HCV, syphilis, others

ANCA = antineutrophilic cytoplasmic antibodies; anti-GBM = anti-glomerular basement membrane; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; IgA = immunoglobulin A; SLE = systemic lupus erythematosus.

Adapted from Lewis, 2012.

The prototype is *acute poststreptococcal glomerulonephritis*, which is historically interesting because it was confused with eclampsia until the mid-1800s. *IgA nephropathy*, also known as *Berger disease*, is the most common form of acute glomerulonephritis worldwide (Wyatt, 2013). The isolated form occurs sporadically, and it may be related to *Henoch-Schönlein purpura* as the systemic form (Donadio, 2002). Isolated nephritis may be due to antiglomerular basement membrane (GBM) antibodies. These may also involve the lungs to manifest as a pulmonary-renal syndrome with alveolar hemorrhage, which is termed *Goodpasture syndrome* (Bazari, 2012; Vasilou, 2005).

Pregnancy

Acute nephritic syndromes during pregnancy can be difficult to differentiate from severe preeclampsia or eclampsia. One example is systemic lupus erythematosus with a flare during the second half of pregnancy (Bramham, 2012; Zhao, 2013). In some cases, renal biopsy may be necessary to determine etiology as well as to direct management (Lindheimer, 2007a; Ramin, 2006). This is discussed further in Chapter 59 (p. 1170).

Whatever the underlying etiology, acute glomerulonephritis has profound effects on pregnancy outcome. In an older study, Packham and coworkers (1989) described 395 pregnancies in 238 women with *primary* glomerulonephritis diagnosed before pregnancy. The most common lesions on biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Although most of these women had normal renal function, half developed hypertension, a fourth were delivered preterm, and the perinatal mortality rate after 28 weeks' gestation was 80 per 1000. As expected, the worst perinatal outcomes were in women with impaired renal function, early or severe hypertension, and nephrotic-range proteinuria.

Similar outcomes have been reported for pregnancies in women with IgA nephropathy. From their review of more than 300 such pregnancies, Lindheimer and colleagues (2000) concluded that pregnancy outcome was related to the degree of renal insufficiency and hypertension. Ronkainen and associates (2006) followed a cohort of children with IgA nephritis for an

average of 19 years. They described 22 pregnancies of which half were complicated by hypertension and a third were delivered preterm.

Nephrotic Syndromes

Heavy proteinuria is the hallmark of the nephrotic syndromes, which may be caused by several primary and secondary kidney disorders. These can cause immunological- or toxic-mediated injury with glomerular capillary wall breakdown that allows excessive filtration of plasma proteins. In addition to heavy urine protein excretion, the syndrome is characterized by hypoalbuminemia, hypercholesterolemia, and edema. There frequently is hypertension, and along with albumin nephrotoxicity, renal insufficiency eventually develops.

Some of the more common causes of the nephrotic syndrome are shown in Table 53-4. In most cases, renal biopsy will disclose microscopic abnormalities that may help direct treatment, which depends on etiology. Edema is problematic, especially during pregnancy (Jakobi, 1995). Normal amounts of dietary protein of high biological value are encouraged—indeed, high-protein diets increase proteinuria. The incidence of thromboembolism is increased and varies with the severity of hypertension, proteinuria, and renal insufficiency (Stratta, 2006). Although both arterial and venous thromboses may develop, renal vein thrombosis is particularly worrisome. The value, if any, of prophylactic anticoagulation is unclear. Some cases of nephrosis from primary glomerular disease respond to glucocorticosteroids and other immunosuppressants or cytotoxic drug therapy. In most of those cases caused by infection or drugs, proteinuria recedes when the underlying cause is corrected.

Pregnancy

Maternal and perinatal outcomes in women with the nephrotic syndromes depend on its underlying cause and severity. Whenever possible, these should be ascertained, and renal biopsy may be indicated to determine if there is a treatment-responsive

TABLE 53-4. Causes of the Nephrotic Syndrome in Adults and Percentage of Attributable Cases

Minimal change disease (MCD) (10–15%): primary idiopathic (most cases), drug-induced (NSAIDs), allergies, viral infections
Focal segmental glomerulosclerosis (FSGS) (35%): viruses, hypertension, reflux nephropathy, sickle-cell disease
Membranous glomerulonephritis (30%): idiopathic (most cases), malignancy, infection, connective-tissue diseases
Diabetic nephropathy: most common cause of ESRD
Amyloidosis

ESRD = end-stage renal disease; NSAIDs = nonsteroidal antiinflammatory drugs.
Adapted from Lewis, 2012.

etiology. Half of women with nephrotic-range proteinuria will have rise in daily protein excretion as pregnancy progresses (Packham, 1989). In women with nephrosis cared for at Parkland Hospital, we reported that two thirds had protein excretion that exceeded 3 g/day (Stettler, 1992). At the same time, however, if these women had only mild degrees of renal dysfunction, they had normally augmented glomerular filtration across pregnancy (Cunningham, 1990).

Management of edema during pregnancy can be particularly challenging as it is intensified by normally increasing hydrostatic pressure in the lower extremities. In some women, massive vulvar edema may develop as described by Jakobi and coworkers (1995) in diabetic women. Massive vulvar edema associated with the nephrotic syndrome caused by secondary syphilis is shown in Figure 53-4. Another major problem is that up to half of these women have chronic hypertension that may require treatment (Chap. 50, p. 1005). In these, as well as in previously normotensive women, preeclampsia is common and often develops early in pregnancy.

Most women with nephrotic syndromes who do not have severe hypertension or renal insufficiency will have successful pregnancy outcomes. Conversely, if there is renal insufficiency, moderate to severe hypertension, or both, the prognosis is much worse. Our experiences from women with 65 pregnancies cared

for at Parkland Hospital noted that there are frequent complications (Stettler, 1992). Protein excretion during pregnancy averaged 4 g daily, and a third of the women had classic nephrotic syndrome. There was some degree of renal insufficiency in 75 percent, chronic hypertension in 40 percent, and persistent anemia in 25 percent. Importantly, preeclampsia developed in 60 percent, and 45 percent had preterm deliveries. Even so, after excluding abortions, 53 of 57 infants were born alive. Stratta and associates (2006) reported fetal-growth restriction in a third of these women.

Long-Term Outcomes

Women identified to have nephrotic syndromes either before or during pregnancy are at risk for serious long-term adverse outcomes. In women cared for at Parkland Hospital cited in the report above, all 21 women who subsequently underwent renal biopsy had abnormal histological findings (Stettler, 1992). At least 20 percent of women followed for 10 years progressed to end-stage renal failure. Similarly, Chen and colleagues (2001) reported short-term outcomes in 15 women with nephrotic syndromes in whom they had performed renal biopsy during pregnancy. By 2 years, three of these women had died, three had developed chronic renal failure, and two had progressed to end-stage renal disease. In the report by Imbasciati and coworkers (2007), women whose serum creatinine level was > 1.4 mg/dL and whose 24-hour protein excretion exceeded 1 g/day had the shortest renal survival times following pregnancy.

CHRONIC RENAL DISEASE

This describes a pathophysiological process that can progress to end-stage renal disease. The National Kidney Foundation describes six stages of chronic kidney disease defined by decreasing glomerular filtration rate (GFR). It progresses from stage 0—GFR > 90 mL/min/1.73 m² to stage 5—GFR < 15 mL/min/1.73 m². There are a number of diseases that result in progressively declining renal function, and many result from one of the glomerular diseases that were discussed earlier. Those that most commonly lead to end-stage disease requiring dialysis and kidney transplantation and their approximate percentages include: diabetes, 33 percent; hypertension, 25 percent; glomerulonephritis, 20 percent; and polycystic kidney disease, 15 percent (Abboud, 2010; Bargman, 2012).

FIGURE 53-4 Massive vulvar edema in a pregnant woman with the nephrotic syndrome due to secondary syphilis. (Photograph contributed by Dr. George Wendel, Jr.)

Most reproductive-aged women with these diseases have varying degrees of renal insufficiency, proteinuria, or both. To counsel regarding fertility and pregnancy outcome, the degree of renal functional impairment and of associated hypertension are assessed. Successful pregnancy outcome in general may be more related to these two factors than to the specific underlying renal disorder. A general prognosis can be estimated by considering women with chronic renal disease in arbitrary categories of renal function (Davison, 2011). These include normal or *mild impairment*—defined as a serum creatinine < 1.5 mg/dL; *moderate impairment*—defined as a serum creatinine 1.5 to 3.0 mg/dL; and *severe renal insufficiency*—defined as a serum creatinine > 3.0 mg/dL. Although some have suggested adopting the classification of the National Kidney Foundation, others recommend using the older categories (Davison, 2011; Piccoli, 2010a, 2011). Thus, the obstetrician must be familiar with both.

Pregnancy and Chronic Renal Disease

Most women have relatively mild renal insufficiency, and its severity along with any underlying hypertension is prognostic of pregnancy outcome. Renal disease with comorbidities secondary to a systemic disorder—for example, diabetes or systemic lupus erythematosus—portends a worse prognosis (Davison, 2011; Fischer, 2004). For all women with chronic renal disease, the incidences of hypertension and preeclampsia, preterm and growth-restricted infants, and other problems are high. Despite these, the National High Blood Pressure Education Program Working Group (2000) has concluded that the prognosis has substantively improved since the 1980s. This has subsequently been verified by several reviews (Davison, 2011; Nevis, 2011; Ramin, 2006).

Loss of renal tissue is associated with compensatory intrarenal vasodilation and hypertrophy of the surviving nephrons. The resultant hyperperfusion and hyperfiltration eventually damage surviving nephrons to cause *nephrosclerosis* and worsening renal function. With mild renal insufficiency, pregnancy causes greater augmentation of renal plasma flow and glomerular filtration (Baylis, 2003; Helal, 2012). With progressively declining renal function, there is little, if any, augmented renal plasma flow. In one study, only half of women with moderate renal insufficiency demonstrated pregnancy-augmented glomerular filtration, and women with severe disease had no increase (Cunningham, 1990).

Importantly, chronic renal insufficiency also curtails normal pregnancy-induced hypervolemia. Blood volume expansion during pregnancy is related to disease severity and correlates inversely with serum creatinine concentration. As shown in [Figure 53-5](#), women with mild to moderate renal dysfunction have normal blood volume expansion that averages 55 percent. With severe renal insufficiency, however, volume expansion averages only 25 percent, which is similar to that seen with hemoconcentration from eclampsia. In addition, these women have variable degrees of chronic anemia due to intrinsic renal disease.

Renal Disease with Preserved Function

In some women, although glomerular disease has not yet caused renal dysfunction, there is still an increased incidence

FIGURE 53-5 Blood volume expansion in 44 normally pregnant women at term compared with 29 who had eclampsia; 10 with moderate chronic renal insufficiency (CRI)—serum creatinine 1.5 to 2.9 mg/dL; and four with severe CRI—serum creatinine ≥ 3.0 mg/dL. (Data from Zeeman, 2009; Cunningham, 1990.)

of pregnancy complications. As shown in [Table 53-5](#), these complications are less frequent than in cohorts of women with moderate and severe renal insufficiency. Two studies illustrate this. In one, Surian and colleagues (1984) described outcomes in 123 pregnancies in women with biopsy-proven glomerular disease. Although only a few of these women had renal dysfunction, 40 percent developed obstetrical or renal complications. In another study, Packham and coworkers (1989) described outcomes in 395 pregnancies in women with preexisting

TABLE 53-5. Complications (%) Associated with Chronic Renal Disease During Pregnancy

Complication	Preserved Function	Renal Insufficiency	
		Moderate and Severe	Severe
Chronic hypertension	25	30–70	50
Gestational hypertension	20–50	30–50	75
Worsening renal function	8–15	20–43	35
Permanent dysfunction	4–5	10–20	35
Preterm delivery	7	30–60	73
Fetal-growth restriction	8–14	30–38	57
Perinatal mortality	5–14	4–7	0

Data from Alsuwaida, 2011; Cunningham, 1990; Farwell, 2013; Imbasciati, 2007; Maruotti, 2012; Nevis, 2011; Packham, 1989; Piccoli, 2010a, 2011; Stettler, 1992; Surian, 1984; Trevisan, 2004.

glomerulonephritis and minimal renal insufficiency. Impaired renal function developed in 15 percent of these women during pregnancy, and 60 percent had worsening proteinuria. Only 12 percent had antecedent chronic hypertension, however, more than half of the 395 pregnancies were complicated by hypertension. The perinatal mortality rate was 140 per 1000, but even without early-onset or severe hypertension or nephrotic-range proteinuria, the rate was 50 per 1000. Importantly, in 5 percent, worsening renal function was permanent.

Chronic Renal Insufficiency

As indicated, pregnancy complication rates are greater in women with chronic kidney disease who also have renal insufficiency compared with women with preserved renal function. Furthermore, adverse outcomes are generally directly related to the degree of renal impairment. Of the more recent reports shown in Table 53-5, outcomes of women with moderate versus severe renal insufficiency are usually not separated. That said, Piccoli and associates (2010a) described 91 pregnancies complicated by stage 1 chronic kidney disease. Primarily because of hypertension, 33 percent were delivered preterm, and 13 percent had fetal-growth restriction. Alsuwaida and colleagues (2011) reported similar observations.

Other investigators have described pregnancies complicated by moderate or severe renal insufficiency (Cunningham, 1990; Imbasciati, 2007; Jones, 1996). Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally acceptable. As shown in Figure 53-6, fetal growth is frequently impaired and related to renal dysfunction severity.

Management

There are several important aspects of prenatal care for women with chronic renal disease. Frequent monitoring of blood pressure is paramount, and serum creatinine levels and 24-hour protein excretion are quantified as indicated. Bacteriuria is treated to decrease the risk of pyelonephritis and further nephron loss.

FIGURE 53-6 Birthweight percentiles of infants born to 29 women at Parkland Hospital with mild to moderate renal insufficiency—serum creatinine 1.4–2.4 mg/dL (*black points*) and severe renal insufficiency—serum creatinine ≥ 2.5 mg/dL (*red points*). (Data from Cunningham, 1990; Stettler, 1992. Growth curves are those reported by Alexander, 1996.)

Protein-restricted diets are not recommended (Lindheimer, 2000; Ruggenenti, 2001). In some women with anemia from chronic renal insufficiency, a response is seen with recombinant erythropoietin. However, hypertension is a common side effect. Serial sonography is performed to follow fetal growth (Chap. 44, p. 880). The differentiation between worsening hypertension and superimposed preeclampsia is problematic. Preliminary data indicate that the angiogenic biomarkers placental growth factor (PlGF) and its soluble receptor (sFlt-1) may be useful to separate chronic from gestational hypertension. This is described in Chapter 40 (p. 747).

Long-Term Effects

In some women, pregnancy may accelerate chronic renal disease progression by increasing hyperfiltration and glomerular pressure to worsen nephrosclerosis (Baylis, 2003; Helal, 2012). Women with more severe renal insufficiency have increased susceptibility. For example, Jungers and associates (1995) reported few long-term pregnancy-related adverse effects in 360 women with chronic glomerulonephritis and antecedent normal renal function. In women with severe chronic renal insufficiency, however, renal insufficiency may become worse during pregnancy (Abe, 1991; Jones, 1996). In the study by Imbasciati and coworkers (2007), worsening renal function was more likely in women who had a serum creatinine ≥ 1.4 mg/dL and > 1 g/day protein excretion.

As noted, progression is common for many women with chronic renal disorders. At 1 year after pregnancy, Jones and Hayslett (1996) reported that 10 percent of the women had developed end-stage renal failure—stage 5 chronic kidney disease. In a study from Parkland Hospital, we found that 20 percent of pregnant women with moderate to severe insufficiency had developed end-stage renal failure by a mean of 4 years (Cunningham, 1990). Similar findings in women with a median follow-up of 3 years were described by Imbasciati and colleagues (2007). By this time, end-stage disease was apparent in 30 percent of women whose serum creatinine was ≥ 1.4 mg/dL and who had proteinuria > 1 g/day. Chronic proteinuria is also a marker for subsequent development of renal failure. In another report from Parkland Hospital, we found that 20 percent of women with chronic proteinuria discovered during pregnancy progressed to end-stage renal failure within several years (Stettler, 1992).

Dialysis During Pregnancy

Significantly impaired renal function is accompanied by subfertility that may be corrected with chronic renal replacement therapy—either hemodialysis or peritoneal dialysis (Hladunewich, 2011; Shahir, 2013). Not unexpectedly, these pregnancies can be complicated. Chou and associates (2008) reviewed 131 cases reported since 1990. They found that mean fetal birthweight was higher in women who conceived while undergoing dialysis—1530 g versus 1245 g in women who conceived before starting dialysis. This was also true for 77 pregnancies reported to the Australian and New Zealand Dialysis and Transplantation Registry (Jesudason, 2014). Similar outcomes from several reports since 1999 are shown in Table 53-6.

TABLE 53-6. Pregnancy Outcomes in 156 Women Undergoing Dialysis During Pregnancy

Study (Year)	Pregnancies			Pregnancy Outcomes (%)			
	N	Delivery (wk)	Birthweight (g)	Hypertension	Hydramnios	Perinatal Mortality	Surviving Infants
Toma (1999)	54	31.9	1545	35	44	33	67
Chao (2002)	13	32	1540	72	46	31	69
Tan (2006)	11	31	1390	36	18	18	82
Chou (2008)	13	30.8	1510	57	71	50	50
Luders (2010)	52	32.7	1555	67	40	13	87
Shahir (2013)	13	NS	2130	19 ^a	14	22	78
Jesudason (2014)	77	33.8	1750	NS	NS	20	80
Approximate averages	233	~32	~1600	~45–5	~44	~20–5	~80

^aPreeclampsia only.

NS = not stated.

These reports described similar outcomes with either hemodialysis or peritoneal dialysis. Thus, for the woman already undergoing either method, it seems reasonable to continue that method with consideration for its increasing frequency. In the woman who has never been dialyzed, the threshold for initiation during pregnancy is unclear. Lindheimer and colleagues (2007a) recommend initiation when serum creatinine levels are between 5 and 7 mg/dL. Because it is imperative to avoid abrupt volume changes that cause hypotension, dialysis frequency may be extended to five to six times weekly (Reddy, 2007).

Hladunewich and coworkers (2011) recommend attention to certain protocols that include replacement of substances lost through dialysis. Multivitamin doses are doubled, and calcium and iron salts are provided along with sufficient dietary protein and calories. Chronic anemia is treated with erythropoietin. To meet pregnancy changes, extra calcium is added to the dialysate along with less bicarbonate.

Maternal complications are common and include severe hypertension, placental abruption, heart failure, and sepsis. Piccoli and associates (2010b) reviewed reported outcomes in 90 pregnancies in 78 women. They found that these studies were heterogeneous for definitions; types of dialysis, frequency, and prescription; and perinatal outcomes. Although they were encouraged by their findings, they described high incidences of maternal hypertension and anemia, preterm and growth-restricted infants, stillbirths, and hydramnios.

ACUTE KIDNEY INJURY

Previously termed *acute renal failure*, acute kidney injury is now used to describe sudden impairment of kidney function with retention of nitrogenous and other waste products normally excreted by the kidneys (American Society of Nephrology, 2005; Waikar, 2012). Acute kidney injury has become less common today. For example, in a 6-year period the overall incidence at the Mayo Clinic was 0.4 percent (Gurrieri, 2012). Although the incidence of acute kidney injury in pregnancy has decreased substantially, it still occasionally causes significant obstetrical morbidity, and women who require acute dialysis

have increased mortality rates (Kuklina, 2009; Singri, 2003). Outcomes are available from four older studies comprising a total of 266 women with renal failure (Drakeley, 2002; Nzerue, 1998; Sibai, 1990; Turney, 1989). Approximately 70 percent had preeclampsia, 50 percent had obstetrical hemorrhage, and 30 percent had a placental abruption. Almost 20 percent required dialysis, and the maternal mortality rate in these was approximately 15 percent.

Obstetrical cases of acute kidney injury that require dialysis have become less common today. That said, acute renal ischemia is still commonly associated with severe preeclampsia and hemorrhage (Gurrieri, 2012). Particularly contributory are HELLP syndrome and placental abruption (Audibert, 1996; Drakeley, 2002). Septicemia is another common comorbidity, especially in resource-poor countries (Acharya, 2013; Srinil, 2011; Zeeman, 2003). Acute kidney injury is also common in women with acute fatty liver of pregnancy (Sibai, 2007). Nelson and colleagues (2013) reported some degree of renal insufficiency in virtually all of 52 such women cared for at Parkland Hospital (Chap. 55, p. 1087). Another woman from Parkland Hospital developed acute kidney injury from dehydration caused by severe hyperemesis gravidarum at 15 weeks (Hill, 2002). Her serum creatinine level peaked at 10.7 mg/dL, and she required hemodialysis for 5 days. Other causes that are discussed further in Chapter 56 (p. 1116) include thrombotic microcoagulopathies (Ganesan, 2011).

Diagnosis and Management

In most women, renal failure develops postpartum, thus management is usually not complicated by fetal considerations. An acute increase in serum creatinine is most often due to renal ischemia (Abuelo, 2007). Oliguria is an important sign of acutely impaired renal function. In obstetrical cases, both prerenal and intrarenal factors are commonly operative. For example, with total placental abruption, severe hypovolemia is common from massive hemorrhage, and frequently associated preeclampsia causes preexistent renal ischemia.

When azotemia is evident and severe oliguria persists, some form of renal replacement treatment is indicated, and

hemofiltration or dialysis is initiated before marked deterioration occurs. Hemodynamic measurements are normalized. Medication dose adjustments are imperative, and magnesium sulfate is a prominent example (Singri, 2003; Waikar, 2012). Early dialysis appears to reduce the mortality rate appreciably and may enhance the extent of renal function recovery. With time, renal function usually returns to normal or near normal.

Prevention

Acute kidney injury in obstetrics is most often due to acute blood loss, especially that associated with preeclampsia. Thus, it may often be prevented by the following means:

1. Prompt and vigorous volume replacement with crystalloid solutions and blood in instances of massive hemorrhage, such as in placental abruption, placenta previa, uterine rupture, and postpartum uterine atony (Chap. 41, p. 814).
2. Delivery or termination of pregnancies complicated by severe preeclampsia or eclampsia, and careful blood transfusion if loss is more than average (Chap. 40, p. 766).
3. Close observation for early signs of sepsis syndrome and shock in women with pyelonephritis, septic abortion, chorioamnionitis, or sepsis from other pelvic infections (Chap. 47, p. 946).
4. Avoidance of loop diuretics to treat oliguria before ensuring that blood volume and cardiac output are adequate for renal perfusion.
5. Judicious use of vasoconstrictor drugs to treat hypotension, and only after it has been determined that pathological vasodilatation is the cause.

Irreversible ischemic renal failure caused by *acute cortical necrosis* has become exceedingly uncommon in obstetrics. Before widespread availability of dialysis, it complicated a fourth of obstetrical renal failure cases (Grünfeld, 1987; Turney, 1989). Most cases followed placental abruption, preeclampsia-eclampsia, and endotoxin-induced shock. Once common with septic abortion, this is a rare cause in this country today (Lim, 2011; Srinil, 2011). Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of acute renal failure, and its differentiation from acute tubular necrosis is not possible during the early phase. The prognosis depends on the extent of the necrosis. Recovery of function is variable, and stable renal insufficiency may result (Lindheimer, 2007a).

Obstructive Renal Failure

Rarely, bilateral ureteral compression by a very large pregnant uterus is greatly exaggerated. Resultant ureteral obstruction in turn, may cause severe oliguria and azotemia. An extreme example is shown in [Figure 53-7](#). Brandes and Fritsche (1991) reviewed 13 cases that were the consequence of a markedly overdistended uterus. They described a woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks' gestation. After amniotomy, urine flow resumed at 500 mL/hr and was followed by a rapid decline in serum creatinine levels to normal range. Eckford and Gingell (1991)

FIGURE 53-7 **A.** Magnetic resonance image in a coronal plane of a pregnant woman with unilateral hydronephrosis caused by ureteral obstruction. The serum creatinine was 8 mg/dL and decreased to 0.8 mg/dL after a percutaneous nephrostomy tube was placed. **B.** Left kidney (arrow) and associated hydronephrosis (asterisk) are again noted in this axial plane image.

described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum. Sadan and coworkers (1994) reported a similar experience in eight such women who underwent stent placement at a mean of 29 weeks for moderate to severe hydronephrosis. The stents remained in situ for a mean of 9 weeks, during which time renal function remained normal.

We have observed this phenomenon on several occasions (Satin, 1993). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In one woman with massive hydramnios (9.4 L) and an anencephalic fetus, amniocentesis and removal of some of the amniotic fluid was followed promptly by diuresis, a decline in the plasma creatinine concentration, and improvement of hypertension. In our experience, women with previous urinary tract surgery for reflux are more likely to have such obstructions.

LOWER GENITAL TRACT LESIONS

Urethral Diverticulum

Infrequently complicating pregnancy, this type of diverticulum is thought to originate from an enlarging paraurethral gland abscess that ruptures into the urethral lumen. As infection clears, the remaining dilated diverticular sac and its ostium into the urethra persist. Urine collecting within and dribbling from the sac, pain, palpable mass, and recurrent urinary infections may be associated findings. In general, a diverticulum is managed expectantly during pregnancy. Rarely, drainage may be necessary, or surgery required (Iyer, 2013). If additional antepartum evaluation is needed, MR imaging is preferred for its superior soft tissue resolution and ability to define complex diverticula (Dwarkasing, 2011; Pathi, 2013).

Genital Tract Fistulas

Fistulas found during pregnancy likely existed previously, but in rare cases, they form during pregnancy. In developed countries, *vesicovaginal fistula* following a McDonald cerclage has been reported (Massengill, 2012). These fistulas may also form with prolonged obstructed labor that is more commonly seen in resource-poor countries. In these cases, the genital tract is compressed between the fetal head and bony pelvis. Brief pressure is not significant, but prolonged pressure leads to tissue necrosis with subsequent fistula formation (Wall, 2012). *Vesicouterine fistulas* that developed after prior cesarean delivery have been described (DiMarco, 2012; Manjunatha, 2012). Rarely, *vesicocervical fistula* may follow cesarean delivery or may form if the anterior cervical lip is compressed against the symphysis pubis (Dudderidge, 2005).

CHAPTER 54

Gastrointestinal Disorders

DIAGNOSTIC TECHNIQUES	1069
LAPAROTOMY AND LAPAROSCOPY	1070
NUTRITIONAL SUPPORT	1070
UPPER GASTROINTESTINAL TRACT DISORDERS	1070
HYPEREMESIS GRAVIDARUM	1070
UPPER GASTROINTESTINAL BLEEDING	1074
DISORDERS OF THE SMALL BOWEL AND COLON	1074
ACUTE DIARRHEA	1074
INFLAMMATORY BOWEL DISEASE	1075
INTESTINAL OBSTRUCTION	1078
APPENDICITIS	1078

During normal pregnancy, the gastrointestinal tract and its appendages undergo remarkable anatomical, physiological, and functional changes. These changes, which are discussed in detail in Chapter 4 (p. 66), can appreciably alter clinical findings normally relied on for diagnosis and treatment of gastrointestinal disorders. Moreover, as pregnancy progresses, gastrointestinal symptoms become more difficult to assess. Physical findings are often obscured by a large uterus that displaces abdominal organs and can alter the location and intensity of pain and tenderness.

GENERAL CONSIDERATIONS

Diagnostic Techniques

Endoscopy

Various methods can evaluate the gastrointestinal tract during pregnancy without reliance on x-ray techniques. Fiberoptic

endoscopic instruments have revolutionized diagnosis and management of most gastrointestinal conditions, and these are particularly well suited for pregnancy. With endoscopy, the esophagus, stomach, duodenum, and colon can be inspected (Cappell, 2006, 2011). The proximal jejunum can also be studied, and the ampulla of Vater cannulated to perform *endoscopic retrograde cholangiopancreatography—ERCP* (Fogel, 2014; Kamani, 2012; Tang, 2009). Experience in pregnancy with *videocapsule endoscopy* for small-bowel evaluation is limited (Storch, 2006).

Upper gastrointestinal endoscopy is used for management as well as diagnosis of several problems. Common bile duct exploration and drainage are used for choledocholithiasis as described in Chapter 55 (p. 1096). It is also used for sclerotherapy as well as placement of *percutaneous endoscopic gastrostomy (PEG)* tubes. A number of concise reviews have been provided (Cappell, 2011; Fogel, 2014; Gilinsky, 2006).

Flexible sigmoidoscopy can be used safely in pregnant women (Siddiqui, 2006). In nonpregnant patients, *colonoscopy* is indispensable for viewing the entire colon and distal ileum for diagnosis and management of inflammatory bowel disease. Except for the midtrimester, reports of colonoscopy during pregnancy are limited, but preliminary results indicate that it should be performed if indicated (Cappell, 2010, 2011). Bowel preparation is completed using polyethylene glycol electrolyte or sodium phosphate solutions. With these, serious maternal dehydration that may cause diminished uteroplacental perfusion should be avoided.

Noninvasive Imaging Techniques

The obvious ideal technique for gastrointestinal evaluation during pregnancy is abdominal sonography. Because computed tomography (CT) use is limited in pregnancy due to radiation exposure, magnetic resonance (MR) imaging is now commonly used to evaluate the abdomen and retroperitoneal space (Khandelwal, 2013). One example is magnetic-resonance cholangiopancreatography—MRCP (Oto, 2009). These and other imaging modalities, and

their safe use in pregnancy, are considered in more detail in Chapter 46 (p. 933).

Laparotomy and Laparoscopy

Surgery is lifesaving for certain gastrointestinal conditions—perforative appendicitis being the most common example. From the Swedish Registry database through 1981, abdominal exploration by laparotomy or laparoscopy was performed in 1331 of 720,000 pregnancies—approximately 1 in every 500 (Mazze, 1989). A similar incidence of 1 in 635 in nearly 50,000 pregnancies was described by Kort (1993). In both studies, the most common indications for surgery were appendicitis, an adnexal mass, and cholecystitis.

Laparoscopic procedures have replaced traditional surgical techniques for many abdominal disorders during pregnancy (Carter, 2004). In an updated report from the Swedish Registry database, there were 2181 pregnant women who underwent laparoscopy and 1522 who had laparotomy for nonobstetrical indications (Reedy, 1997). Use of these procedures was similar to their first study—approximately 1 in every 800 pregnancies. Both approaches were used usually before 20 weeks, and they were found to be safe. Long-term surveillance studies also suggest no deleterious effects for mother or fetus (Rizzo, 2003).

The most common nongynecological laparoscopic procedures performed during pregnancy are cholecystectomy and appendectomy (Fatum, 2001; Rollins, 2004). For more details and for descriptions of surgical technique, see Chapter 46 (p. 928) as well as *Operative Obstetrics*, 2nd edition (Gilstrap, 2002). Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy have been provided by the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2011).

Nutritional Support

Specialized nutritional support can be delivered *enterally*, usually via nasogastric tube feedings, or *parenterally* with nutrition given by venous catheter access, either peripherally or centrally.

When possible, enteral alimentation is preferable because it has fewer serious complications (Bistran, 2012; Hamaoui, 2003). In obstetrical patients, very few conditions prohibit enteral nutrition as a first effort to prevent catabolism. Even in extreme cases, such as recalcitrant hyperemesis gravidarum, percutaneous endoscopic gastrostomy with a jejunal port—PEG (J) tube—has been described (Saha, 2009).

The purpose of *parenteral feeding*, or *hyperalimentation*, is to provide nutrition when the intestinal tract must be kept quiescent. Central venous access is necessary for total parenteral nutrition because its hyperosmolality requires rapid dilution in a high-flow vascular system. These solutions provide 24 to 40 kcal/kg/day, principally as a hypertonic glucose solution.

There have been a variety of conditions for which total parenteral nutrition has been employed during pregnancy (Table 54-1). Gastrointestinal disorders are the most common indication, and in the many studies cited, feeding duration averaged 33 days. It is imperative to emphasize that complications of parenteral nutrition are frequent, and they may be severe (Guglielmi, 2006). In an early report of 26 pregnancies,

TABLE 54-1. Some Conditions Treated with Enteral or Parenteral Nutrition During Pregnancy^a

Achalasia
Anorexia nervosa
Appendiceal rupture
Bowel obstruction
Burns
Cholecystitis
Crohn disease
Diabetic gastropathy
Esophageal injury
Hyperemesis gravidarum
Jejunioileal bypass
Malignancies
Pancreatitis
Preeclampsia syndrome
Preterm labor/ruptured membranes
Short gut syndrome
Stroke

^aRisks are listed alphabetically.

Russo-Stieglitz, 1999; Saha, 2009; Spiliopoulos, 2013.

a 50-percent rate of complications, which included pneumothorax, hemothorax, and brachial plexus injury, was described (Russo-Stieglitz, 1999).

The most frequent serious complication is catheter sepsis, and Folk (2004) reported a 25-percent incidence in 27 women with hyperemesis gravidarum. Although bacterial sepsis is most common, *Candida* septicemia has been described (Paranyuk, 2006). The Centers for Disease Control and Prevention (2002) has published detailed guidelines to prevent catheter-related sepsis, and these have served to lessen the dangers of serious infections. Perinatal complications are uncommon, however, fetal subdural hematoma caused by maternal vitamin K deficiency has been described (Sakai, 2003).

There is also appreciable morbidity from long-term use of a *peripherally inserted central catheter (PICC)*. Ogura (2003) reported infection with long-term access in 31 of 52 pregnant women. Holmgren (2008) reported complications in 21 of 33 women in whom a PICC line was placed for hyperemesis. Infections were the most common, and half of infected women also had bacteremia. From a review of 48 reports of nonpregnant adults, Turcotte and associates (2006) concluded that there were no advantages to peripherally placed catheters compared with centrally placed ones. Still, it seems reasonable for short-term nutrition—weeks—that PICC placement has a greater benefit-versus-risk ratio (Bistran, 2012).

DISORDERS OF THE UPPER GASTROINTESTINAL TRACT

Hyperemesis Gravidarum

Mild to moderate nausea and vomiting are especially common in pregnant women until approximately 16 weeks (Chap. 9,

p. 187). In a small proportion of these, however, it is severe and unresponsive to simple dietary modification and antiemetics. In an attempt to quantify nausea and vomiting severity, Lacasse and colleagues (2008) have proposed a *pregnancy-unique quantification of emesis and nausea (PUQE) scoring index*. Severe unrelenting nausea and vomiting—hyperemesis gravidarum—is defined variably as being sufficiently severe to produce weight loss, dehydration, ketosis, alkalosis from loss of hydrochloric acid, and hypokalemia. Acidosis develops from partial starvation. In some women, transient hepatic dysfunction develops, and there is accumulation of biliary sludge (Matsubara, 2012). Other causes should be considered because hyperemesis gravidarum is a diagnosis of exclusion (Benson, 2013).

Study criteria have not been homogeneous, thus reports of population incidences vary. There does, however, appear to be an ethnic or familial predilection (Grijbovski, 2008). In population-based studies from California and Nova Scotia, the hospitalization rate for hyperemesis gravidarum was 0.5 to 0.8 percent (Bailit, 2005; Fell, 2006). Up to 20 percent of those hospitalized in a previous pregnancy for hyperemesis will again require hospitalization (Dodds, 2006; Trogstad, 2005). In general, obese women are less likely to be hospitalized for this (Cedergren, 2008).

The etiopathogenesis of hyperemesis gravidarum is likely multifactorial and certainly is enigmatic. It appears to be related to high or rapidly rising serum levels of pregnancy-related hormones. Putative culprits include human chorionic gonadotropin (hCG), estrogens, progesterone, leptin, placental growth hormone, prolactin, thyroxine, and adrenocortical hormones (Verberg, 2005). More recently implicated are other hormones that include ghrelin, leptin, nesfatin-1, and PYY-3 (Albayrak, 2013; Gungor, 2013).

Superimposed on this hormonal cornucopia are an imposing number of biological and environmental factors. Moreover, in some but not all severe cases, interrelated psychological components play a major role (Buckwalter, 2002; Christodoulou-Smith, 2011; McCarthy, 2011). Other factors that increase the risk for admission include hyperthyroidism, previous molar pregnancy, diabetes, gastrointestinal illnesses, some restrictive diets, and asthma and other allergic disorders (Fell, 2006; Mullin, 2012). The vestibular system has been implicated (Goodwin, 2008). An association of *Helicobacter pylori* infection has also been proposed, but evidence is not conclusive (Goldberg, 2007). And for unknown reasons—perhaps estrogen-related—a female fetus increases the risk by 1.5-fold (Schiff, 2004; Tan, 2006; Veenendaal, 2011). Finally, Bolin and coworkers (2013) reported an association between hyperemesis gravidarum and preterm labor, placental abruption, and preeclampsia.

Complications

Vomiting may be prolonged, frequent, and severe, and a list of potentially fatal complications is given in Table 54-2. Various degrees of acute kidney injury from dehydration are encountered (Nwoko, 2012). We have cared for a number of women with markedly impaired renal function. The extreme example was a woman who required 5 days of dialysis when her serum

TABLE 54-2. Some Life-Threatening Complications of Recalcitrant Hyperemesis Gravidarum

Acute kidney injury—may require dialysis
Depression—cause versus effect?
Diaphragmatic rupture
Esophageal rupture—Boerhaave syndrome
Hypoprothrombinemia—vitamin K deficiency
Hyperalimentation complications
Mallory-Weiss tears—bleeding, pneumothorax, pneumomediastinum, pneumopericardium
Wernicke encephalopathy—thiamine deficiency

creatinine level rose to 10.7 mg/dL (Hill, 2002). Complications from continuous retching include a Mallory-Weiss tear, such as that shown in Figure 54-1. Others are pneumothorax, pneumomediastinum, diaphragmatic rupture, and gastroesophageal rupture, which is Boerhaave syndrome (Chen, 2012; Schwartz, 1994; Yamamoto, 2001).

In more severe cases, plasma zinc levels are increased, copper levels decreased, and magnesium levels unchanged (Dokmeci, 2004). At least two serious vitamin deficiencies have been reported with hyperemesis in pregnancy. *Wernicke encephalopathy* from thiamine deficiency has been reported with increasing frequency (Di Gangi, 2012; Palacios-Marqués, 2012). In a review of 49 such cases, Chiossi (2006) reported that only half had the triad of confusion, ocular findings, and ataxia. With this encephalopathy, an abnormal electroencephalogram (EEG) may be seen, and usually there are MR imaging findings (Vaknin, 2006; Zara, 2012). At least three maternal deaths have been described, and long-term sequelae include blindness, convulsions, and coma (Selitsky, 2006). Last, *vitamin K deficiency* has been reported to cause maternal coagulopathy and fetal intracranial hemorrhage (Kawamura, 2008; Robinson, 1998; Sakai, 2003).

Management

One algorithm for management of nausea and vomiting of pregnancy is shown in [Figure 54-2](#). A Cochrane review reported a salutary effect from several antiemetics given orally or by rectal suppository as first-line agents (Jewell, 2000). The Food and Drug Administration (2013) recently approved Diclegis—a combination of doxylamine-pyridoxine—for morning sickness. When simple measures fail, intravenous Ringer lactate or normal saline solutions are given to correct dehydration, ketonemia, electrolyte deficits, and acid-base imbalances. There are no benefits to using 5-percent dextrose along with crystalloids (Tan, 2013). Thiamine, 100 mg, is given to prevent Wernicke encephalopathy (Niebyl, 2010).

If vomiting persists after rehydration and failed outpatient management, hospitalization is recommended (American College of Obstetricians and Gynecologists, 2013). Antiemetics such as promethazine, prochlorperazine, chlorpromazine, or metoclopramide are given parenterally. There is little evidence that treatment with *glucocorticosteroids* is effective. Two small trials found no benefits of *methylprednisolone* compared with placebo, but the corticosteroid-treated group had significantly fewer readmissions (Duggar, 2001; Safari, 1998). In another study from Parkland Hospital, Yost (2003) compared placebo with intravenous methylprednisolone plus two different tapered

oral steroid regimens. They noted that a third in each group required readmission. In a study reported by Bondok (2006), pulsed hydrocortisone therapy was superior to metoclopramide to reduce vomiting and readmissions. *Serotonin antagonists* are most effective for controlling chemotherapy-induced nausea and vomiting (Hesketh, 2008). But when used for hyperemesis gravidarum, *ondansetron* was not superior to promethazine (Sullivan, 1996). Serotonin antagonist use in pregnancy is limited, but these drugs appear to be safe (Briggs, 2011).

With persistent vomiting after hospitalization, appropriate steps should be taken to exclude possible underlying diseases as a cause of hyperemesis. In one study, endoscopy did not change management in 49 women (Debby, 2008). Other potential causes include gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer, and pyelonephritis. In addition, severe preeclampsia and fatty liver are more likely after midpregnancy. And although clinical thyrotoxicosis has been implicated as a cause of hyperemesis, it is more likely that abnormally elevated serum thyroxine levels are a surrogate for higher-than-average serum hCG levels (Chap. 5, p. 103). This was termed “chemical hyperthyroidism” by Tan (2002). And of interest, Panesar and associates (2006) showed that a cohort of women with hyperemesis had lower serum thyrotropin levels. In our experiences, serum free thyroxine levels normalize quickly with hydration.

With treatment, most women will have a salutary response and may be sent home with antiemetic therapy. Their readmission rate is 25 to 35 percent in most prospective studies. If associated psychiatric and social factors contribute to the illness, the woman usually improves remarkably while hospitalized (Swallow, 2004). That said, symptoms may relapse in these women, and some go on to develop *posttraumatic stress syndrome* (Christodoulou-Smith, 2011; McCarthy, 2011). For some women, hyperemesis can be an indication for elective termination (Poursharif, 2007).

In the small percentage of women who continue to have recalcitrant vomiting, consideration is given for enteral nutrition. Vaisman (2004) described successful use of nasojejunal feeding for up to 21 days in 11 such women. Use of sonography to confirm correct placement of the tube has been described (Swartzlander, 2013). Percutaneous endoscopic gastrostomy with a jejunal port has also been reported (Saha, 2009; Schrag, 2007).

In our experiences, only a very few women will require parenteral nutrition (Yost, 2003). In a study of 166 women, Folk (2004) reported that 16 percent had central venous access established for nutrition. The litany of complications included line sepsis in 25 percent and thrombosis and infective endocarditis in one woman each.

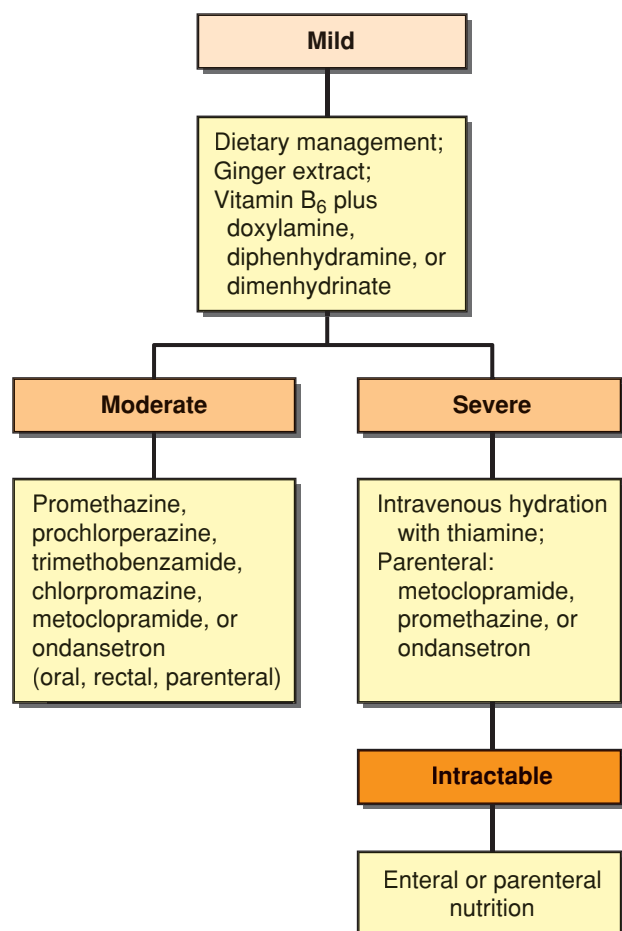

FIGURE 54-2 Algorithm for outpatient and inpatient management of hyperemesis gravidarum.

Gastroesophageal Reflux Disease (GERD)

Reflux disease is seen in up to 15 percent of nonpregnant individuals (Kahrilas, 2012). Heartburn, or *pyrosis*, is especially common in late pregnancy, and it appears at some point in 50 to 80 percent of pregnancies (Mehta, 2010). The retrosternal burning sensation is caused by esophagitis from gastroesophageal reflux related to relaxation of the lower esophageal sphincter (Hyttén, 1991). According to Costigan

and colleagues (2006), common folklore is confirmed in that women with excessive heartburn do give birth to infants with more hair! Long-term complications are chronic esophagitis and adenocarcinoma.

Reflux symptoms usually respond to tobacco and alcohol abstinence, small meals, head of the bed elevation, and avoidance of postprandial recumbency and “trigger” foods. Oral antacids are first-line therapy. If severe symptoms persist, sucralfate is given with an H₂-receptor antagonist such as *cimetidine* or *ranitidine*. If these are not successful, commonly used proton-pump inhibitors such as *omeprazole* or *pantoprazole* are also safe for use in pregnancy (Briggs, 2011; Mahadevan, 2006b). If there is still no relief, then endoscopy should be considered. *Misoprostol* is contraindicated because it stimulates labor (Chap. 26, p. 529).

For medical treatment failures in nonpregnant patients, surgical fundoplication is performed (Kahrilas, 2012). Although the procedure was not done during pregnancy, Biertho (2006) described 25 women who had undergone laparoscopic Nissen fundoplication before pregnancy. Only 20 percent had reflux symptoms during pregnancy.

■ Hiatal Hernia

The older literature is informative regarding hiatal hernias in pregnancy. Upper gastrointestinal radiographs performed in 195 women in late pregnancy showed that 20 percent of 116 multiparas and 5 percent of 79 nulliparas had a hiatal hernia (Rigler, 1935). Of 10 women studied postpartum, hernia persisted in three at 1 to 18 months.

The relationship of hiatal hernia with reflux esophagitis, and thus symptoms, is not clear. One study demonstrated no relationship between reflux and hernia and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically (Cohen, 1971). Nevertheless, during pregnancy, these hiatal hernias may cause vomiting, epigastric pain, and bleeding from ulceration. Schwentner (2011) reported severe herniation requiring surgical repair in a woman with a 12-week gestation. Curran (1999) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia.

■ Diaphragmatic Hernia

These are caused by herniations of abdominal contents through either the foramen of Bochdalek or that of Morgagni. Fortunately, they rarely complicate pregnancy. Kurzel and associates (1988) reviewed the outcomes of 18 pregnant women with such a hernia and who developed acute obstruction. Because the maternal mortality rate was 45 percent, they recommend repair during pregnancy even if a woman is asymptomatic. Herniation has been reported in one pregnant woman from a previous traumatic diaphragmatic defect and in another who had antireflux surgery in early pregnancy (Brygger, 2013; Flick, 1999). Several case reports also describe spontaneous diaphragmatic rupture from increased intraabdominal pressure during delivery (Chen, 2012; Ortega-Carnicer, 1998; Sharifah, 2003).

■ Achalasia

A rare disorder, achalasia is a motility disorder in which the lower esophageal sphincter does not relax properly with swallowing. There is also nonperistaltic contraction activity of the esophageal muscularis to cause symptoms (Kahrilas, 2012; Khudyak, 2006). The defect is caused by inflammatory destruction of the myenteric (Auerbach) plexus within smooth muscle of the lower esophagus and its sphincter. Postganglionic cholinergic neurons are unaffected, thus, there is unopposed sphincter stimulation. Symptoms are dysphagia, chest pain, and regurgitation. Barium swallow radiography demonstrates *bird beak* or *ace of spades* narrowing at the distal esophagus. Endoscopy is performed to exclude gastric carcinoma, and manometry is confirmatory. If dilatation of the esophagus and medical therapy does not provide relief, myotomy is considered (Torquati, 2006).

During pregnancy, normal relaxation of the lower esophageal sphincter in those with achalasia theoretically should not occur. Even so, in most women, pregnancy does not seem to worsen achalasia. One report of 20 affected pregnant women found no excessive reflux esophagitis (Mayberry, 1987). Khudyak and coworkers (2006) reviewed 35 cases and described most women as symptom free, although esophageal dilatation was needed in a few. A maternal death at 24 weeks associated with perforation of a 14-cm diameter megaesophagus has been reported (Fassina, 1995).

Management of achalasia includes soft diet and anticholinergic drugs. With persistent symptoms, other options include nitrates, calcium-channel antagonists, and botulinum toxin A injected locally (Khudyak, 2006; Wataganara, 2009). Balloon dilatation of the sphincter may be necessary, and 85 percent of nonpregnant patients respond to this. Satin (1992) and Fiest (1993) and their associates reported successful use of pneumatic dilatation in pregnancy. *One caveat is that esophageal perforation is a serious complication of dilatation.* Spiliopoulos and colleagues (2013) described a 29-week pregnant woman with achalasia treated for 10 weeks with parenteral nutrition with surgical correction done postpartum.

■ Peptic Ulcer

Erosive ulcer disease more often involves the duodenum rather than the stomach in young women. Gastroduodenal ulcers in nonpregnant women may be caused by chronic gastritis from *H pylori*, or they develop from use of aspirin or other nonsteroidal antiinflammatory drugs. Neither is common in pregnancy (McKenna, 2003; Weyermann, 2003). Acid secretion is also important, and thus underlies the efficacy of antisecretory agents (Suerbaum, 2002). Gastroprotection during pregnancy is probably due to reduced gastric acid secretion, decreased motility, and considerably increased mucus secretion (Hytten, 1991). Despite this, ulcer disease may be underdiagnosed because of frequent treatment for reflux esophagitis (Cappell, 1998; Mehta, 2010). In the past 45 years at Parkland Hospital, during which time we have cared for more than 500,000 pregnant women, we have encountered very few who had symptomatic ulcer disease. Before appropriate therapy was commonplace, Clark (1953) studied 313 pregnancies in 118 women with

proven ulcer disease. They noted a clear remission during pregnancy in almost 90 percent. However, benefits were short lived. Symptoms recurred in more than half by 3 months postpartum and in almost all by 2 years.

Antacids are first-line therapy, and H₂-receptor blockers or proton-pump inhibitors are safely prescribed for those who do not respond (Briggs, 2011; Diav-Citrin, 2005; Mahadevan, 2006b). *Sucralfate* is the aluminum salt of sulfated sucrose that inhibits pepsin. It provides a protective coating at the ulcer base. Approximately 10 percent of the aluminum salt is absorbed, and it is considered safe for pregnant women (Briggs, 2011).

With active ulcers, a search for *H pylori* is undertaken. Diagnostic aids include the urea breath test, serological testing, or endoscopic biopsy. If any of these are positive, antimicrobial therapy is indicated. There are several effective oral treatment regimens that do not include tetracycline and that can be used during pregnancy. These 14-day regimens include amoxicillin, 1000 mg twice daily along with clarithromycin, 500 mg twice daily; or metronidazole, 500 mg twice daily (Dzieniszewski, 2006; Mehta, 2010).

Upper Gastrointestinal Bleeding

In some women, persistent vomiting is accompanied by worrisome upper gastrointestinal bleeding. Occasionally, there is a bleeding peptic ulceration, however, most of these women have small linear mucosal tears near the gastroesophageal junction—*Mallory-Weiss tears*, as shown in Figure 54-1. Bleeding usually responds promptly to conservative measures, including iced saline irrigations, topical antacids, and intravenously administered H₂-blockers or proton-pump inhibitors. Transfusions may be needed, and if there is persistent bleeding, then endoscopy may be indicated (O'Mahony, 2007). With persistent retching, the less common, but more serious, esophageal rupture—*Boerhaave syndrome*—may develop from greatly increased esophageal pressure.

DISORDERS OF THE SMALL BOWEL AND COLON

The small bowel has diminished motility during pregnancy. Using a nonabsorbable carbohydrate, Lawson (1985) showed that small bowel mean transit times were 99, 125, and 137 minutes in each

trimester, compared with 75 minutes when nonpregnant. In a study cited by Everson (1992), mean transit time for a mercury-filled balloon from the stomach to the cecum was 58 hours in term pregnant women compared with 52 hours in nonpregnant women.

Muscular relaxation of the colon is accompanied by increased absorption of water and sodium that predisposes to constipation. This complaint is reported by almost 40 percent of women at some time during pregnancy (Everson, 1992). Such symptoms are usually only mildly bothersome, and preventive measures include a high-fiber diet and bulk-forming laxatives. Wald (2003) has reviewed treatment options. We have encountered several pregnant women who developed megacolon from impacted stool. These women almost invariably had chronically abused stimulatory laxatives.

Acute Diarrhea

Most cases of acute diarrhea are caused by infectious agents. The large variety of viruses, bacteria, helminths, and protozoa that cause diarrhea in adults inevitably also afflict pregnant women. Some of these are discussed in Chapter 64. Evaluation of acute diarrhea depends on its severity and duration. According to Camilleri and Murray (2012), some indications for evaluation include profuse diarrhea with dehydration, grossly bloody stools, fever $\geq 38.5^{\circ}\text{C}$, duration of > 48 hours without improvement, recent antimicrobial use, immunocompromise, and new community outbreaks. Cases of moderately severe diarrhea with fecal leukocytes or gross blood may best be treated with empirical antibiotics rather than evaluation. Some features of the more common acute diarrheal syndromes are shown in Table 54-3.

The mainstay of treatment is intravenous hydration using normal saline or Ringer lactate with potassium supplementation in amounts to restore maternal blood volume and to ensure uteroplacental perfusion. Vital signs and urine output are monitored for signs of sepsis syndrome. For moderately severe nonfebrile illness without bloody diarrhea, antimotility agents such as loperamide may be useful. Bismuth subsalicylate may also alleviate symptoms.

Judicious use of antimicrobial agents is warranted. For moderate to severely ill women, some recommend empirical treatment with ciprofloxacin, 500 mg twice daily for 3 to 5 days.

TABLE 54-3. Causative Agents and Clinical Features of Common Acute, Infectious Diarrheal Syndromes

Agents	Incubation	Emesis	Pain	Fever	Diarrhea
Toxin-producers (<i>Staphylococcus</i> , <i>Clostridium perfringens</i> , enterotoxigenic <i>E coli</i>)	1-72 hr	3-4+	1-2+	0-1+	3-4+, watery
Enteroadherent (<i>E coli</i> , <i>Giardia</i> , helminths)	1-8 day	0-1+	1-3+	0-2+	1-2+, watery, mushy
Cytotoxin producers (<i>C difficile</i> , hemorrhagic <i>E coli</i>)	1-3 day	0-1+	3-4+	1-2+	1-3+, watery, then bloody
Inflammatory					
Minimal (rotavirus, norovirus)	1-3 day	1-3+	2-3+	3-4+	1-3+, watery
Variable (<i>Salmonella</i> , <i>Campylobacter</i> , <i>Vibrio</i> , <i>Yersinia</i>)	1-11 day	0-3+	2-4+	3-4+	1-4+, watery or bloody
Severe (<i>Shigella</i> , <i>E coli</i> , <i>Entamoeba histolytica</i>)	1-8 day	0-1+	3-4+	3-4+	1-2+, bloody

C difficile = *Clostridium difficile*; *E coli* = *Escherichia coli*.

TABLE 54-4. Some Shared and Differentiating Characteristics of Inflammatory Bowel Disease

	Ulcerative Colitis	Crohn Disease
Shared Characteristics		
Hereditary	More than 100 disease-associated genetic loci—a third shared; Jewish predominance; familial in 5–10% of cases; Turner syndrome; immune dysregulation	
Other	Chronic and intermittent with exacerbations and remissions; arthritis, erythema nodosum; uveitis	
Differentiating Characteristics		
Major symptoms	Diarrhea, tenesmus, rectal bleeding, cramping pain; chronic, intermittent	<u>Fibrostenotic</u> —recurrent RLQ colicky pain; fever
Bowel involvement	Mucosa and submucosa of large bowel; usually begins at rectum (40% proctitis only)	<u>Fistulizing</u> —cutaneous, bladder, interenteric Deep layers small and large bowel; commonly transmural; discontinuous involvement; strictures and fistulas
Endoscopy	Granular and friable erythematous mucosa; rectal involvement	Patchy; rectum spared; perianal involvement
Serum antibodies	Antineutrophil cytoplasmic (pANCA) ~ 70%	Anti- <i>S cerevisiae</i> ~ 50%
Complications	Toxic megacolon; strictures; arthritis; cancer (3–5%)	Fistulas; arthritis; toxic megacolon
Management	Medical; proctocolectomy curative	Medical; segmental and fistula resection

RLQ = right lower quadrant.

From Friedman, 2012; Lichtenstein, 2009; Podolsky, 2002.

Specific pathogens are treated as needed when identified. Syndromes for which treatment is usually unnecessary include those caused by *Escherichia coli*, staphylococcus, *Bacillus cereus*, and Norwalk-like virus. Severe illness caused by *Salmonella* is treated with trimethoprim-sulfamethoxazole or azithromycin; *Campylobacter* with azithromycin; *Clostridium difficile* with oral metronidazole or vancomycin; and *Giardia* and *Entamoeba histolytica* with metronidazole (Mehta, 2010).

Inflammatory Bowel Disease

The two presumably noninfectious forms of intestinal inflammation are ulcerative colitis and Crohn disease. Differentiation between the two is important because treatment differs. That said, they both share common factors, and sometimes are indistinguishable if Crohn disease involves the colon. The salient clinical and laboratory features shown in Table 54-4 permit a reasonably confident diagnostic differentiation in most cases.

The etiopathogenesis of both disorders is enigmatic, but there is genetic predisposition toward either. Inflammation is thought to result from dysregulated mucosal immune function in response to normal bacterial flora, with or without an autoimmune component (Friedman, 2012).

Ulcerative Colitis

This is a mucosal disorder with inflammation confined to the superficial luminal layers of the colon. It typically begins at the rectum and extends proximally for a variable distance. In approximately 40 percent, disease is confined to the rectum and rectosigmoid, and 20 percent have pancolitis. Endoscopic findings include mucosal granularity and friability that is interspersed with mucosal ulcerations and a mucopurulent exudate (Fig. 54-3).

Major symptoms of ulcerative colitis include diarrhea, rectal bleeding, tenesmus, and abdominal cramps. The disease can be acute or intermittent and is characterized by exacerbations and remissions. For unknown reasons, prior appendectomy protects

FIGURE 54-3 Causes of colitis. **A.** Chronic ulcerative colitis with diffuse ulcerations and exudates. **B.** Crohn colitis with deep ulcers. **C.** Pseudomembranous colitis with yellow pseudomembranes. (From Song, 2012, with permission.)

against development of ulcerative colitis (Friedman, 2012; Selby, 2002). *Toxic megacolon* and catastrophic hemorrhage are particularly dangerous complications that may necessitate colectomy. *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. Another serious problem is that the risk of colon cancer approaches 1 percent per year. With either ulcerative colitis or Crohn disease, there is also concern for possible increased risks for thromboembolism (Kappelman, 2011; Novacek, 2010).

Crohn Disease

Also known as regional enteritis, Crohn ileitis, and granulomatous colitis, Crohn disease has more protean manifestations than ulcerative colitis. It involves not only the bowel mucosa but also the deeper layers, and sometimes there is transmural involvement. Lesions can be seen throughout the entire gastrointestinal tract, from the mouth to the anus (Friedman, 2012). It is typically segmental. Approximately 30 percent of patients have small-bowel involvement, 25 percent have isolated colonic involvement, and 40 percent have both, usually with the terminal ileum and colon involved. Perirectal fistulas and abscesses develop in a third of those with colonic involvement.

Symptoms depend on which bowel segment(s) is involved. Thus, complaints may include right-sided lower cramping abdominal pain, diarrhea, weight loss, low-grade fever, and obstructive symptoms. The disease is chronic with exacerbations and remissions, and importantly, it cannot be cured medically or surgically (Lichtenstein, 2009). Approximately a third of patients require surgery within the first year after diagnosis, and thereafter, 5 percent per year. Reactive arthritis is common, and the gastrointestinal cancer risk, although not as great as with ulcerative colitis, is increased substantially.

Inflammatory Bowel Disease and Fertility

Subfertility is commonly linked to chronic medical disease. That said, Mahadevan (2006a) cited a normal fertility rate for inflammatory bowel disease unless severe disease warranted surgery. Alstead (2003) reported that decreased female fertility from active Crohn disease returned to normal with remission. For women requiring surgical resection, laparoscopic anastomosis has a higher subsequent fertility rate (Beyer-Berjot, 2013). Even though fertility is improved after colectomy, up to half of women will still be infertile (Bartels, 2012; Waljee, 2006). Subfertility may also be partially due to sulfasalazine, which causes reversible sperm abnormalities (Feagins, 2009).

Inflammatory Bowel Disease and Pregnancy

Because ulcerative colitis and Crohn disease are relatively common in young women, they are encountered with some frequency in pregnancy. In this regard, a few generalizations can be made. The consensus is that pregnancy does not increase the likelihood of an inflammatory bowel disease flare. To the contrary, in a 10-year surveillance of women in the European Collaborative on Inflammatory Bowel Disease, the likelihood of a flare during pregnancy was decreased compared with the preconceptional rate (Riis, 2006). This diminished rate

persisted for years after pregnancy and was attributed to close attention and monitoring of enrolled women.

Although most of those with quiescent disease in early pregnancy uncommonly have relapses, when a flare develops, it may be severe. Conversely, active disease in early pregnancy increases the likelihood of poor pregnancy outcome. In general, most usual treatment regimens may be continued during pregnancy. If needed to direct management, diagnostic evaluations should be undertaken, and if indicated, surgery should be performed. For women who successfully complete pregnancy, half experience improvement in their health-related quality of life (Ananthakrishnan, 2012).

At first glance, it appears that adverse pregnancy outcomes are increased with inflammatory bowel disease (Bush, 2004; Cornish, 2012; Elbaz, 2005; Mahadevan, 2005). Initially, this was attributed to the fact that most studies included women with either form of disease. Specifically, Crohn disease was noted to be linked to excessive morbidity (Dominitz, 2002; Stephansson, 2010). But, according to Reddy (2008) as well as others, these adverse outcomes were in women with severe disease and multiple recurrences. Indeed, in the prospective *European case-control ECCO-EpiCom study* of 332 pregnant women with inflammatory disease, Bortoli and coworkers (2011) found similar outcomes in women with ulcerative colitis or Crohn disease compared with normally pregnant women. Importantly, even reports of adverse outcomes found that perinatal mortality rates are not appreciably increased.

Ulcerative Colitis and Pregnancy. Pregnancy has no significant effects on ulcerative colitis. In a metaanalysis of 755 pregnancies, Fonager (1998) reported that ulcerative colitis quiescent at conception worsened in approximately a third of pregnancies. In women with active disease at the time of conception, approximately 45 percent worsened, 25 percent remained unchanged, and only 25 percent improved. These observations are similar to those previously described in an extensive review by Miller (1986) and a report from Oron and colleagues (2012).

Calcium supplementation is provided for osteoporosis. Folic acid is given in high doses to counteract the antifolate actions of sulfasalazine. Flares may be caused by psychogenic stress, and reassurance is important. Management for colitis for the most part is the same as for nonpregnancy. Treatment of active colitis, as well as maintenance therapy, is with drugs that deliver 5-aminosalicylic acid (5-ASA) or mesalamine. *Sulfasalazine* is the prototype, and its 5-ASA moiety inhibits prostaglandin synthase in colonic mucosa. Others include olsalazine (Dipentum) and coated 5-ASA derivatives (Asacol, Pentasa, Lialda). Glucocorticoids are given orally, parenterally, or by enema for more severe disease that does not respond to 5-ASA. Recalcitrant disease is managed with immunomodulating drugs, including *azathioprine*, *6-mercaptopurine*, or *cyclosporine*, which appear relatively safe in pregnancy (Briggs, 2011; Moskovitz, 2004). Importantly, *methotrexate* is contraindicated in pregnancy. High-dose intravenous cyclosporine may be beneficial for severely ill patients and used in lieu of colectomy. Parenteral nutrition is occasionally necessary for women with prolonged exacerbations.

Colorectal endoscopy is performed as indicated (Katz, 2002). During pregnancy, colectomy and ostomy creation for fulminant colitis may be needed as a lifesaving measure, and it has been described during each trimester. Dozois (2006) reviewed 42 such cases and found that, in general, outcomes have been good in recent reports. Most women underwent partial or complete colectomy, but Ooi and colleagues (2003) described decompression colostomy with ileostomy in a 10- and a 16-week pregnancy.

More commonly for nonpregnant women undergoing proctocolectomy for ulcerative colitis, an ileal pouch is constructed and an anal anastomosis completed. For women with this procedure performed before pregnancy, sexual function and fertility are improved (Cornish, 2007). Disadvantages include frequent bowel movements, fecal incontinence that includes nocturnal soilage in almost half of patients, and pouchitis. *Pouchitis* is an inflammatory condition of the ileoanal pouch, probably due to bacterial proliferation, stasis, and endotoxin release. It usually responds to cephalosporins or metronidazole. Although these disadvantages temporarily worsen during pregnancy, they typically abate postpartum. In one rare case, adhesions to the growing uterus led to ileal pouch perforation (Aouthmany, 2004).

Women who have had a prior proctocolectomy and ileal pouch–anal anastomosis can safely deliver vaginally (Ravid, 2002). Hahnloser (2004) reviewed routes of delivery in women with 235 pregnancies before and 232 pregnancies after ileoanal pouch surgery. Functional outcomes were similar, and it was concluded that cesarean delivery should be reserved for obstetrical indications. Postcesarean delivery ileoanal pouch obstruction has been described (Malecki, 2010).

As previously discussed, ulcerative colitis likely has minimal adverse effects on pregnancy outcome. Modigliani (2000) reviewed perinatal outcomes in 2398 pregnancies and reported them to be not substantively different from those in the general obstetrical population. Specifically, the incidences of spontaneous abortion, preterm delivery, and stillbirth were remarkably low. In a population-based cohort study of 107 women from Washington state, perinatal outcomes, with two exceptions, were similar to those of 1308 normal pregnancies (Dominitz, 2002). One exception was an inexplicably increased incidence of congenital malformations, and the other was a cesarean delivery rate that was increased from 20 to 29 percent compared with normal controls. The previously described ECCO-EpiCom study reported similar outcomes in 187 women with ulcerative colitis compared with their normal controls (Bortoli, 2011). There are smaller studies in which the risks for preterm birth and low birthweight are increased (Emerson, 2013).

Crohn Disease and Pregnancy. In general, Crohn disease activity during pregnancy is related to its status around the time of conception. In a cohort study of 279 pregnancies, for 186 women whose disease was inactive at conception, a fourth relapsed during pregnancy (Fonager, 1998). In 93 with active disease at conception, however, two thirds either remained active or worsened. Miller (1986) had described similar findings from his earlier review as did Oron and associates (2012).

Calcium and folic acid supplementation are given as for ulcerative colitis. There is no regimen that is universally effective for maintenance during asymptomatic periods. *Sulfasalazine* is effective for some, but the newer 5-ASA formulations are better tolerated. As a class, they appear to be safe in pregnancy (Briggs, 2011; Rahimi, 2008). *Prednisone* therapy may control moderate to severe flares but is less effective for small-bowel involvement. Immunomodulators such as *azathioprine*, *6-mercaptopurine*, and *cyclosporine* are used for active disease and for maintenance and appear relatively safe during pregnancy (Briggs, 2011; Moskovitz, 2004; Prefontaine, 2009). As discussed in Chapter 12 (p. 248), methotrexate, mycophenolate mofetil, and mycophenolic acid are contraindicated in pregnancy (Briggs, 2011; Food and Drug Administration, 2008). Anti-tumor necrosis factor (TNF)- α antibodies, which include *infliximab*, *adalimumab*, and *certolizumab*, are also effective for active Crohn disease and maintenance (Casanova, 2013; Colombel, 2010; Cominelli, 2013; Friedman, 2012; Sandborn, 2007; Schreiber, 2007). This class of immunomodulators is considered safe in pregnancy, but data are limited (Katz, 2004; Roux, 2007; Schnitzler, 2011). Parenteral hyperalimentation has been used successfully during severe recurrences (Russo-Stieglitz, 1999).

Endoscopy or conservative surgery is indicated for complications. Patients with small-bowel involvement more likely will require surgery for complications that include fistulas, strictures, abscesses, and intractable disease. An abdominal surgical procedure was required during 5 percent of pregnancies described by Woolfson (1990). Those with an ileal loop colostomy may have significant problems as discussed below. Women with a perianal fistula—unless these are rectovaginal—usually can undergo vaginal delivery without complications (Forsnes, 1999; Takahashi, 2007).

As discussed, there seems to be a greater likelihood that Crohn disease may be associated with adverse pregnancy outcomes compared with ulcerative colitis (Stephansson, 2010). Outcomes are probably related to disease activities. For example, based on a 20-year review, Korelitz (1998) concluded that perinatal outcomes were generally good with quiescent disease. That said, in a case-control Danish study, Norgård (2007) reported a twofold risk of preterm births. Dominitz (2002) reported a two- to threefold increase in preterm delivery, low birthweight, fetal-growth restriction, and cesarean delivery in 149 women with Crohn disease. Recall, however, that the prospective ECCO-EpiCom study found outcomes to be similar to those for normal pregnancies.

Ostomy and Pregnancy

A colostomy or an ileostomy can be problematic during pregnancy because of its location (Hux, 2010). In a report of 82 pregnancies in 66 women with an ostomy, *stomal dysfunction* was common, but it responded to conservative management in all cases (Gopal, 1985). Surgical intervention was necessary, however, in three of six women who developed *bowel obstruction* and in another four with *ileostomy prolapse*—almost 10 percent overall. In this older study, only a third of 82 women underwent cesarean delivery, but Takahashi (2007) described six of

seven cesarean deliveries in women with Crohn disease and a stoma. Fortunately, Farouk and coworkers (2000) reported that pregnancy did not worsen long-term ostomy function.

Intestinal Obstruction

The incidence of bowel obstruction is not increased during pregnancy, although it generally is more difficult to diagnose. Meyerson (1995) reported a 20-year incidence of 1 in 17,000 deliveries at two Detroit hospitals. In one study, adhesive disease leading to small bowel obstruction was the second most common cause of an acute abdomen in pregnancy following appendicitis—15 versus 30 percent, respectively (Unal, 2011). As shown in Table 54-5, approximately half of cases are due to adhesions from previous pelvic surgery that includes cesarean delivery (Al-Sunaidi, 2006; Andolf, 2010; Lyell, 2011). Another 25 percent of bowel obstruction is caused by volvulus—sigmoid, cecal, or small bowel. These have been reported in late pregnancy or early puerperium (Alshawi, 2005; Biswas, 2006; Lal, 2006). Wax and colleagues (2013) described small bowel obstruction in pregnancy following the currently popular Roux-en-Y gastric bypass. Intussusception is occasionally encountered (Gould, 2008; Harma, 2011). Bowel obstruction subsequent to colorectal surgery for cancer was increased threefold in women who had open versus laparoscopic surgery (Haggar, 2013).

Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. According to Davis and Bohon (1983), this more likely occurs: (1) around midpregnancy, when the uterus becomes an abdominal organ; (2) in the third trimester, when the fetal head descends; or (3) immediately postpartum, when there is an acute change in uterine size. Perdue (1992) reported that 98 percent of pregnant women had either continuous or colicky abdominal pain, and 80 percent had nausea and vomiting. Abdominal tenderness was found in 70 percent, and abnormal bowel sounds noted in only 55 percent. Plain abdominal radiographs following soluble contrast showed evidence of obstruction in 90 percent of women. Plain radiographs, however, are less accurate for diagnosing small-bowel obstruction,

FIGURE 54-4 Massively dilated colon in a pregnant woman with colonic volvulus. (Courtesy of Dr. Lowell Davis.)

and we and others have found that CT and MR imaging can be diagnostic (Biswas, 2006; Essilfie, 2007; McKenna, 2007). Colonoscopy can be both diagnostic and therapeutic for colonic volvulus (Dray, 2012; Khan, 2012).

During pregnancy, mortality rates with obstruction can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery (Firstenberg, 1998; Shui, 2011). In an older report of 66 pregnancies, Perdue and associates (1992) described a 6-percent maternal mortality rate and 26-percent fetal mortality rate. Two of the four women who died were in late pregnancy, and they had sigmoid or cecal volvulus caused by adhesions. Perforation from massive bowel dilation such as that shown in Figure 54-4 causes severe sepsis syndrome.

Colonic Pseudo-obstruction

Also known as *Ogilvie syndrome*, pseudo-obstruction is caused by adynamic colonic ileus. It is characterized by massive abdominal distention with cecal and right-hemicolon dilatation. Approximately 10 percent of all cases are associated with pregnancy. The syndrome usually develops postpartum—most commonly after cesarean delivery—but it has been reported antepartum (Tung, 2008). Although this is unusual, the large bowel may rupture (Singh, 2005). Treatment with an intravenous infusion of neostigmine, 2 mg, usually results in prompt decompression (Ponec, 1999). In some cases, colonoscopic decompression is performed, but laparotomy is done for perforation (De Giorgio, 2009; Rawlings, 2010).

Appendicitis

Suspected appendicitis is one of the most common indications for abdominal exploration during pregnancy. The frequency for suspected appendicitis approximated 1 in 1000 women in the Swedish registry of 720,000 pregnancies (Mazze, 1991). Disease was confirmed in 65 percent for an incidence of approximately 1 in 1500 births. Inexplicably, the incidence was much lower

TABLE 54-5. Causes of Intestinal Obstruction During Pregnancy and the Puerperium	
Cause of Obstruction	Percent
Adhesions:	~ 60
1st and 2nd trimester ~ 30%	
3rd trimester ~ 5%	
Postpartum ~ 25%	
Volvulus:	~ 25
Midgut ~ 2%	
Cecal ~ 5%	
Sigmoid ~ 10%	
Intussusception	~ 5
Hernia, carcinoma, other	~ 5
Data from Connolly, 1995; Khan, 2012; Redlich, 2007.	

in the Danish registry of more than 320,000 pregnancies—the confirmed appendicitis rate was only 1 per 5500 pregnancies (Hée, 1999).

It is repeatedly—and appropriately—emphasized that pregnancy makes the diagnosis of appendicitis more difficult. Nausea and vomiting accompany normal pregnancy, but also, as the uterus enlarges, the appendix commonly moves upward and outward from the right-lower quadrant (Baer, 1932; Pates, 2009). Another often-stated reason for late diagnosis is that some degree of leukocytosis accompanies normal pregnancy. For these and other reasons, pregnant women—especially those late in gestation—frequently do not have clinical findings “typical” for appendicitis. Thus, it commonly is confused with cholecystitis, preterm labor, pyelonephritis, renal colic, placental abruption, or uterine leiomyoma degeneration.

Most reports indicate increasing morbidity and mortality rates with increasing gestational age. And as the appendix is progressively deflected upward by the growing uterus, omental containment of infection becomes increasingly unlikely. It is indisputable that appendiceal perforation is more common during later pregnancy. In the studies by Andersson (2001) and Ueberrueck (2004), the incidence of perforation was approximately 8, 12, and 20 percent in successive trimesters.

Diagnosis

Persistent abdominal pain and tenderness are the most reproducible findings. Right-lower quadrant pain is the most frequent, although pain migrates upward with appendiceal displacement (Mourad, 2000). For evaluation, sonographic abdominal imaging is reasonable in suspected appendicitis, even if to exclude an obstetrical cause of right-lower quadrant pain (Butala, 2010). That said, *graded compression sonography* is difficult because of cecal displacement and uterine imposition (Pedrosa, 2009). *Appendiceal computed tomography* is more sensitive and accurate than sonography to confirm suspected appendicitis (Gearhart, 2008; Katz, 2012; Raman, 2008). Specific views can be designed to decrease fetal radiation exposure (Chap. 46, p. 933). In one study, the negative appendectomy rate was 54 percent with clinical diagnosis alone, but only 8 percent if sonography and CT scanning were used (Wallace, 2008). *MR imaging* may be preferable, and as shown in [Figure 54-5](#), we and others have had good results with its use (Dewhurst, 2013; Israel, 2008). One metaanalysis cited positive- and negative-predictive values of 90 and 99.5 percent, respectively (Blumenfeld, 2011). Using a decision-analysis model, CT and MR imaging were found to be cost effective (Kastenberg, 2013).

Management

When appendicitis is suspected, treatment is prompt surgical exploration. Although diagnostic errors may lead to removal of a normal appendix, surgical evaluation is preferable to postponed intervention and generalized peritonitis. In earlier reports, the diagnosis was verified in only 60 to 70 percent of pregnant women. However, as indicated above, with CT and MR imaging, these figures have improved (Blumenfeld, 2011; Wallace, 2008). Importantly, the accuracy of diagnosis is inversely proportional to gestational age (Mazze, 1991).

FIGURE 54-5 Anterior-posterior magnetic resonance image of a periappendiceal abscess in a midtrimester pregnancy. The abscess is approximately 5 × 6 cm, and the appendiceal lumen (*arrow*) is visible within the right-lower quadrant mass.

Laparoscopy is almost always used to treat suspected appendicitis during the first two trimesters. There were similar perinatal outcomes reported from the Swedish database of nearly 2000 laparoscopic appendectomies compared with those of more than 1500 open laparotomies done before 20 weeks (Reedy, 1997). Conversely, from their review, Wilasrusmee and coworkers (2012) reported a higher fetal loss with laparoscopy. It has evolved that in many centers, laparoscopic appendectomy is performed in most cases during the third trimester (Barnes, 2004; Donkervoort, 2011). This is sanctioned and encouraged by the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2011; Soper, 2011). Some are of the opinion that laparoscopic surgery in pregnancy after 26 to 28 weeks should be performed only by the most experienced endoscopic surgeons (Parangi, 2007).

Before exploration, intravenous antimicrobial therapy is begun, usually with a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Without generalized peritonitis, the prognosis is excellent. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common, and although some clinicians recommend tocolytic agents, we do not. De Veciana (1994) reported that tocolytic use substantially increased the risk for pulmonary-permeability edema caused by sepsis syndrome (Chap. 47, p. 947).

Pregnancy Outcomes

Appendicitis increases the likelihood of abortion or preterm labor, especially if there is peritonitis. In two studies, spontaneous labor after 23 weeks ensued with greater frequency following surgery for appendicitis compared with surgery for other indications (Cohen-Kerem, 2005; Mazze, 1991). In one study, the fetal loss rate was 22 percent if surgery was performed after 23 weeks. There are at least two large population-based studies that attest to the adverse outcomes from appendicitis in pregnancy. From the California Inpatient File of 3133 pregnant

women undergoing surgery for suspected appendicitis, the fetal loss rate was 23 percent, and it was doubled—6 versus 11 percent—with simple versus complicated disease (McGory, 2007). A nationwide study from Taiwan found that there were 1.5- to twofold increased risks for low birthweight and preterm delivery when outcomes in 908 women with acute appendicitis were compared with those of controls (Wei, 2012).

Long-term complications are not common. The possible link between sepsis and neonatal neurological injury has not been verified (Mays, 1995). Finally, appendicitis during pregnancy does not appear to be associated with subsequent infertility (Viktrup, 1998).

Postpartum Acute Appendicitis

Although new-onset appendicitis during the immediate puerperium is uncommon, in some women it is undiagnosed before delivery. Appendicitis in these women often stimulated labor and when the large uterus rapidly empties, walled-off infection may be disrupted to result in an acute surgical abdomen. In some cases, acute appendicitis or a periappendiceal abscess or phlegmon may be found at the time of cesarean delivery or puerperal tubal ligation (see Fig. 54-5). It is important to remember that puerperal pelvic infections typically do not cause peritonitis.

ACUTE ACETAMINOPHEN OVERDOSE 1094

HEPATIC ADENOMA 1094

GALLBLADDER DISORDERS 1095

PANCREATIC DISORDERS 1096

Disorders of the liver, gallbladder, and pancreas together comprise a formidable list of complications that may arise in pregnancy from preexisting conditions or from some that are unique to pregnancy. The relationships of several of these with pregnancy can be fascinating, intriguing, and challenging.

HEPATIC DISORDERS

It is customary to divide liver diseases complicating pregnancy into three general categories. The first includes those specifically related to pregnancy that resolve either spontaneously or following delivery. Examples are hepatic dysfunction from hyperemesis gravidarum, intrahepatic cholestasis, acute fatty liver, and hepatocellular damage with preeclampsia—the *HELLP syndrome*—hemolysis, elevated serum liver aminotransferase levels, and low platelet counts (Mufti, 2012; Reau, 2014). The

second category includes acute hepatic disorders that are coincidental to pregnancy, such as acute viral hepatitis. The third category includes chronic liver diseases that predate pregnancy, such as chronic hepatitis, cirrhosis, or esophageal varices.

There are several pregnancy-induced physiological changes that induce appreciable liver-related clinical and laboratory manifestations (Chap. 4, p. 67, and Appendix, p. 1289). Findings such as elevated serum alkaline phosphatase levels, palmar erythema, and spider angiomas, which might suggest liver disease, are commonly found during normal pregnancy. Metabolism is also affected, due to altered expression of the cytochrome P450 system that is mediated by higher levels of estrogen, progesterone, and other hormones. For example, in pregnancy, hepatic CYP1A2 expression is decreased, whereas that of CYP2D6 and CYP3A4 is increased. Importantly, cytochrome enzymes are expressed in many organs besides the liver, most notably the placenta. The net effect is complex and likely influenced by gestational age and organ of expression (Isoherranen, 2013). Despite all of these functional changes, no major hepatic histological changes are induced by normal pregnancy.

Hyperemesis Gravidarum

Pernicious nausea and vomiting of pregnancy may involve the liver. There may be mild hyperbilirubinemia with serum aminotransferase levels elevated in up to half of women hospitalized. However, these levels seldom exceed 200 U/L (Table 55-1). Liver biopsy may show minimal fatty changes. Hyperemesis gravidarum is discussed in detail in Chapter 54 (p. 1070).

Intrahepatic Cholestasis of Pregnancy

This disorder also has been referred to as recurrent jaundice of pregnancy, cholestatic hepatosis, and icterus gravidarum. It is characterized clinically by pruritus, icterus, or both. It may be more common in multifetal pregnancy, and there is a significant

TABLE 55-1. Clinical and Laboratory Findings with Acute Liver Diseases in Pregnancy

Disorder	Onset in Pregnancy	Clinical Findings	Hepatic		Renal	Hematological and Coagulation

genetic influence (Lausman, 2008; Webb, 2014). Because of this, the incidence of the disorder varies by population. For example, cholestasis is uncommon in North America, with an overall incidence of approximately 1 in 500 to 1000 pregnancies, but is as high as 5.6 percent among Latina women in Los Angeles (Lee, 2006). In Israel, the incidence reported by Sheiner and associates (2006) is approximately 1 in 400. In Sweden, it is 1.5 percent, and in Chile, it is 4 percent (Glantz, 2004; Lee, 2006; Reyes, 1997).

Pathogenesis

The cause of obstetrical cholestasis is unknown. Both increases and decreases in sex steroid levels have been implicated, but current research centers on the numerous mutations that have been identified in the many genes that control hepatocellular transport systems. One example involves mutations of the *ABCB4* gene, which encodes multidrug resistance protein 3 (MDR3) associated with *progressive familial intrahepatic cholestasis*, as well as a bile salt export pump encoded by *ABCB11* (Anzivino, 2013; Davit-Spraul, 2010, 2012; Dixon, 2014). Other potential gene products of interest include the Farnesoid X receptor and transporting ATPase encoded by *ATP8B1* (Davit-Spraul, 2012; Müllenbach, 2005). Some drugs that similarly decrease canalicular transport of bile acids aggravate the disorder. For example, we have encountered impressive cholestatic jaundice in pregnant women taking azathioprine following renal transplantation.

Whatever the inciting cause(s), bile acids are cleared incompletely and accumulate in plasma. Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. Alkaline phosphatase is usually elevated even more so than in normal pregnancy. Serum aminotransferase levels are normal to moderately elevated but seldom exceed 250 U/L (see Table 55-1). Liver biopsy shows mild cholestasis with bile plugs in the hepatocytes and canaliculi of the centrilobular regions, but without inflammation or necrosis. These changes disappear after delivery but often recur in subsequent pregnancies or with estrogen-containing contraceptives.

Clinical Presentation

Pruritus develops in late pregnancy, although it occasionally manifests earlier. There are no constitutional symptoms, and generalized pruritus shows predilection for the soles. Skin changes are limited to excoriations from scratching. Biochemical tests may be abnormal at presentation, but pruritus may precede laboratory findings by several weeks. Approximately 10 percent of women have jaundice.

With normal liver enzymes, the differential diagnosis of pruritus includes other skin disorders (Chap. 62, p. 1214). Findings are unlikely to be due to preeclamptic liver disease if there are no blood pressure changes or proteinuria. Sonography may be warranted to exclude cholelithiasis and biliary obstruction. *Acute viral hepatitis* is an unlikely diagnosis because of the usually low serum aminotransferase levels seen with cholestasis. Conversely, *chronic hepatitis C* is associated with a significantly increased risk of cholestasis, which may be as high as 20-fold among women who are hepatitis C RNA positive (Marschall, 2013; Paternoster, 2002).

Management

Pruritus may be troublesome and is thought to result from elevated serum bile salt concentrations. *Antihistamines* and *topical emollients* may provide some relief. Although cholestyramine has been reported to be effective, this compound also causes further decreased absorption of fat-soluble vitamins, which may lead to vitamin K deficiency. Fetal coagulopathy may develop, and there are reports of intracranial hemorrhage and stillbirth (Matos, 1997; Sadler, 1995).

A recent metaanalysis suggests that *ursodeoxycholic acid* relieves pruritus, lowers bile acid and serum enzyme levels, and may reduce certain neonatal complications such as preterm birth, fetal distress, respiratory distress syndrome, and neonatal intensive care unit (NICU) admission (Bacq, 2012). Lucangioli and colleagues (2009) documented an especially profound decrease in serum lithocholic acid levels. Kondrackiene and associates (2005) randomly assigned 84 symptomatic women to receive either ursodeoxycholic acid (8 to 10 mg/kg/d) or

cholestyramine (8 g/d). They reported superior relief with ursodeoxycholic acid—67 versus 19 percent, respectively. Similarly, Glantz and coworkers (2005) found superior benefits to women randomly assigned to ursodeoxycholic acid versus dexamethasone. The American College of Obstetricians and Gynecologists (2012a) has concluded that ursodeoxycholic acid both relieves pruritus and improves fetal outcomes, although evidence for the latter is not compelling.

Cholestasis and Pregnancy Outcomes

Earlier reports described excessive adverse pregnancy outcomes in women with cholestatic jaundice. Data accrued during the past two decades are ambiguous concerning increased perinatal mortality rates and whether close fetal surveillance is preventative. A review of a few studies illustrates this. Glantz and colleagues (2004) described outcomes in 693 Swedish women. Perinatal mortality rates were slightly increased, but death was limited to infants of mothers with severe disease characterized by total bile acid levels $\geq 40 \mu\text{mol/L}$. Sheiner and coworkers (2006) described no differences in perinatal outcomes in 376 affected pregnancies compared with their overall obstetrical population. There was, however, a significant increase in labor inductions and cesarean deliveries in affected women. Lee and associates (2009) described two cases of sudden fetal death not predicted by nonstress testing. Rook and colleagues (2012) reported outcomes of 101 affected women in Northern California. Although there were no term fetal demises, 87 percent of women underwent labor induction, ostensibly to avoid adverse outcomes. Nonetheless, neonatal complications occurred in a third of the pregnancies, particularly respiratory distress, fetal distress, and meconium-stained amniotic fluid, all of which were reported more frequently with higher total bile acid levels. Finally, Wikström Shemer and coworkers (2013) reported outcomes for a population-based Swedish study of 5477 pregnancies complicated by intrahepatic cholestasis of pregnancy among 1,213,668 singleton deliveries. The authors reported novel associations of cholestasis with preeclampsia and gestational diabetes. Although neonates were more likely to have a low 5-minute Apgar score and to be large for gestational age, there was no increased risk of stillbirth. Importantly, the pregnancies were actively managed to avoid stillbirths, and this was reflected in the higher induction and preterm birth rates. Many recommend early delivery by labor induction to avoid stillbirth.

An intriguing finding indicates that bile acids may cause fetal death. Strehlow and associates (2010) reported that the PR interval on fetal echocardiography was significantly prolonged in women with intrahepatic cholestasis. Gorelik and colleagues (2006) suggest that bile acids may cause fetal cardiac arrest after entering cardiomyocytes in abnormal amounts. Using fetal myocyte cultures, they showed expression of several genes that may play a role in bile transport.

■ Acute Fatty Liver of Pregnancy

The most common cause of acute liver failure during pregnancy is acute fatty liver—also called *acute fatty metamorphosis* or *acute yellow atrophy*. In its worst form, the incidence probably

FIGURE 55-1 Acute fatty liver of pregnancy. Cross section of the liver from a woman who died as the result of pulmonary aspiration and respiratory failure. The liver has a greasy yellow appearance, which was present throughout the entire specimen. Inset: Electron photomicrograph of two swollen hepatocytes containing numerous microvesicular fat droplets (*). The nuclei (N) remain centered within the cells, in contrast to the case with macrovesicular fat deposition. (Photograph contributed by Dr. Don Wheeler.)

approximates 1 in 10,000 pregnancies (Nelson, 2013). Fatty liver recurring in subsequent pregnancy is uncommon, but a few cases have been described (Usta, 1994).

Fatty liver is characterized by accumulation of microvesicular fat that literally “crowds out” normal hepatocytic function (Fig. 55-1). Grossly, the liver is small, soft, yellow, and greasy.

Etiopathogenesis

Although much has been learned about this disorder, interpretation of conflicting data has led to incomplete but intriguing observations. For example, some if not most cases of maternal fatty liver are associated with recessively inherited mitochondrial abnormalities of fatty acid oxidation. These are similar to those in children with Reye-like syndromes. Several mutations have been described for the mitochondrial trifunctional protein enzyme complex that catalyzes the last oxidative steps in the pathway. The most common are the G1528C and E474Q mutations of the gene on chromosome 2 that code for long-chain-3-hydroxyacyl-CoA-dehydrogenase—known as LCHAD. There are other mutations for medium-dehydrogenase—MCHAD, as well as carnitine palmitoyltransferase 1 (CPT1) deficiency (Santos, 2007; Ylitalo, 2005).

Sims and coworkers (1995) observed that some *homozygous* LCHAD-deficient children with Reye-like syndromes had *heterozygous* mothers with fatty liver. This was also seen in

women with a compound heterozygous fetus. Although some conclude that *only* heterozygous LCHAD-deficient mothers are at risk when their fetus is homozygous, this is not always true (Baskin, 2010).

There is a controversial association between fatty acid β -oxidation enzyme defects and severe preeclampsia—especially in women with HELLP syndrome (Chap. 40, p. 742). Most of these observations have been arrived at by retrospectively studying mothers delivered of a child who later developed Reye-like syndrome. For example, Browning and coworkers (2006) performed a case-control study of 50 mothers of children with a fatty-acid oxidation defect and 1250 mothers of matched control infants. During their pregnancy, 16 percent of mothers with an affected child developed liver problems compared with only 0.9 percent of control women. Problems included HELLP syndrome in 12 percent and fatty liver in 4 percent. Despite these findings, the clinical, biochemical, and histopathological findings are sufficiently disparate to suggest that severe preeclampsia, with or without HELLP syndrome, and fatty liver are distinct syndromes (American College of Obstetricians and Gynecologists, 2012a; Sibai, 2007).

Clinical and Laboratory Findings

Acute fatty liver almost always manifests late in pregnancy. Nelson and colleagues (2013) described 51 such women at Parkland Hospital with a mean gestational age of 37 weeks—range 31.7 to 40.9. Almost 20 percent were delivered at 34 weeks' gestation or earlier. Of these 51 women, 41 percent were nulliparous, and two thirds carried a male fetus. Ten to 20 percent of cases are in women with a multifetal gestation (Fesenmeier, 2005; Vigil-De Gracia, 2011).

Fatty liver has a clinical spectrum of severity. In the worst cases, symptoms usually develop over several days. Persistent nausea and vomiting are major complaints, and there are varying degrees of malaise, anorexia, epigastric pain, and progressive jaundice. Perhaps half of affected women have hypertension, proteinuria, and edema, alone or in combination—signs suggestive of preeclampsia. As shown in [Tables 55-1 and 55-2](#), there are variable degrees of moderate to severe liver dysfunction manifest by hypofibrinogenemia, hypoalbuminemia, hypocholesterolemia, and prolonged clotting times. Serum

bilirubin levels usually are < 10 mg/dL, and serum aminotransferase levels are modestly elevated and usually < 1000 U/L.

In almost all severe cases, there is profound endothelial cell activation with capillary leakage causing hemoconcentration, acute kidney injury, ascites, and sometimes pulmonary permeability edema (Bernal, 2013). With severe hemoconcentration, uteroplacental perfusion is reduced and this, along with maternal acidosis, can cause fetal death even before presentation for care. Maternal and fetal acidemia is also related to a high incidence of fetal jeopardy with a concordantly high cesarean delivery rate.

Hemolysis can be severe and evidenced by leukocytosis, nucleated red cells, mild to moderate thrombocytopenia, and elevated serum levels of lactic acid dehydrogenase (LDH). Because of hemoconcentration, however, the hematocrit is often within the normal range. The peripheral blood smear demonstrates echinocytosis, and it has been suggested that hemolysis is caused by the effects of hypocholesterolemia on erythrocyte membranes (Cunningham, 1985).

Various liver imaging techniques have been used to confirm the diagnosis, however, none are particularly reliable. Specifically, Castro and associates (1996) reported poor sensitivity for confirmation by sonography—three of 11 patients, computed tomography (CT)—five of 10, and magnetic resonance (MR) imaging—none of five. Similarly, in a prospective evaluation of the Swansea criteria proposed by Ch'ng and coworkers (2002), only a quarter of women had classic sonographic findings such as maternal ascites or an echogenic hepatic appearance (Knight, 2008). Our experiences are similar (Nelson, 2013).

The syndrome typically continues to worsen after diagnosis. Hypoglycemia is common, and obvious hepatic encephalopathy, severe coagulopathy, and some degree of renal failure each develop in approximately half of women. Fortunately, delivery arrests liver function deterioration.

We have encountered several women with a *forme fruste* of this disorder. Clinical involvement is relatively minor and laboratory aberrations—usually only hemolysis and decreased plasma fibrinogen—herald the syndrome. Thus, the spectrum of liver involvement varies from milder cases that go unnoticed or are attributed to preeclampsia, to overt hepatic failure with encephalopathy.

TABLE 55-2. Laboratory Findings in 137 Women with Acute Fatty Liver of Pregnancy

Series	No.	Most Abnormal Laboratory Values Mean \pm 1 SD (range) ^a			
		Fibrinogen (mg/dL)	Platelets ($10^3/\mu$ L)	Creatinine (mg/dL)	AST (U/L)
Castro (1996)	28	125 (32–446)	113 (11–186)	2.5 (1.1–5.2)	210 (45–1200)
Pereira (1997)	32	ND	123 (26–262)	2.7 (1.1–8.4)	99 (25–911)

Fesenmeier (2005)	16	ND	88 (22–226)	3.3 (0.5–8.6)	692 (122–3195)
Nelson (2013) ^b	51	147 \pm 96 (27–400)	99 \pm 68 (9–385)	2.0 \pm 0.8 (0.7–5.0)	449 \pm 375 (53–2245)
Estimated average		140	105	2.5	330

^aFibrinogen and platelet values listed reflect the nadir for each patient, whereas creatinine and AST values reflect peak values for each patient.

^bExtended data courtesy of Dr. David Nelson.

AST = aspartate aminotransferase; ND = not done.

Coagulopathy. The degree of clotting dysfunction is also variable and can be serious and life threatening, especially if operative delivery is undertaken. Coagulopathy is caused by diminished hepatic procoagulant synthesis, although there is also some evidence for increased consumption with disseminated intravascular coagulation. As shown in Table 55-2, hypofibrinogenemia sometimes is profound. Of 51 women with fatty liver cared for at Parkland Hospital, almost a third had a plasma fibrinogen nadir < 100 mg/dL (Nelson, 2013). Modest elevations of serum D-dimers or fibrin split product levels indicate an element of consumptive coagulopathy. Although usually modest, occasionally there is profound thrombocytopenia (Table 55-2). Among the 51 women from Parkland Hospital, 20 percent had platelet counts < 100,000/ μ L and 10 percent had platelet counts < 50,000/ μ L (Nelson, 2013).

Management

Intensive supportive care and good obstetrical management are essential. In some cases, the fetus may be already dead when the diagnosis is made, and the route of delivery is less problematic. Often, viable fetuses tolerate labor poorly. Because significant procrastination in effecting delivery may increase maternal and fetal risks, we prefer a trial of labor induction with close fetal surveillance. Although some recommend cesarean delivery to hasten hepatic healing, this increases maternal risk when there is severe coagulopathy. Nonetheless, cesarean delivery is common, and rates approach 90 percent. Transfusions with whole blood or packed red cells, along with fresh-frozen plasma, cryoprecipitate, and platelets, are usually necessary if surgery is performed or if obstetrical lacerations complicate vaginal delivery (Chap. 41, p. 815).

Hepatic dysfunction resolves postpartum. It usually normalizes within a week, and in the interim, intensive medical support may be required. There are two associated conditions that may develop around this time. Perhaps a fourth of women have evidence for *transient diabetes insipidus*. This presumably is due to elevated vasopressinase concentrations caused by diminished hepatic production of its inactivating enzyme. Finally, *acute pancreatitis* develops in approximately 20 percent.

With supportive care, recovery usually is complete. Maternal deaths are caused by sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. There were two maternal deaths in the series of 51 women at Parkland Hospital. One was an encephalopathic woman who aspirated before intubation during transfer to Parkland Hospital. The other was in a woman with massive liver failure and nonresponsive hypotension (Nelson, 2013). In some centers, other measures have included plasma exchange and even liver transplantation (Fesenmeier, 2005; Franco, 2000; Martin, 2008).

Maternal and Perinatal Outcomes

Although maternal mortality rates with acute fatty liver of pregnancy have approached 75 percent in the past, the contemporaneous outlook is much better. From his review, Sibai (2007) cites an average mortality rate of 7 percent. He also cited a 70-percent preterm delivery rate and a perinatal mortality rate

of approximately 15 percent, which in the past was nearly 90 percent. At Parkland Hospital, the maternal and perinatal mortality rates during the past four decades have been 4 percent and 12 percent, respectively (Nelson, 2013).

Preeclampsia Syndrome

Hepatic involvement is relatively common in women with severe preeclampsia and eclampsia (see Table 55-1). These changes are discussed in detail in Chapter 40 (p. 741).

Viral Hepatitis

Although most viral hepatitis syndromes are asymptomatic, during the past 25 years, acute symptomatic infections have become even less common in the United States (Centers for Disease Control and Prevention, 2008). There are at least five distinct types of viral hepatitis: A (HAV), B (HBV), D (HDV) caused by the hepatitis B-associated delta agent, C (HCV), and E (HEV). The clinical presentation is similar in all, and although the viruses themselves probably are not hepatotoxic, the immunological response to them causes hepatocellular necrosis (Dienstag, 2012a,b). Asymptomatic chronic viral hepatitis remains the leading cause of liver cancer and the most frequent reason for liver transplantation.

Acute Hepatitis

As discussed above, acute infections are most often subclinical and *anicteric*. When they are clinically apparent, nausea and vomiting, headache, and malaise may precede jaundice by 1 to 2 weeks. Low-grade fever is more common with hepatitis A. By the time jaundice develops, symptoms are usually improving. Serum aminotransferase levels vary, and their peaks do not correspond with disease severity (see Table 55-1). Peak levels that range from 400 to 4000 U/L are usually reached by the time jaundice develops. Serum bilirubin typically continues to rise, despite falling aminotransferase levels, and peaks at 5 to 20 mg/dL.

Any evidence for severe disease should prompt hospitalization. These include incessant nausea and vomiting, prolonged prothrombin time, low serum albumin level, hypoglycemia, high serum bilirubin level, or central nervous system symptoms. In most cases, however, there is complete clinical and biochemical recovery within 1 to 2 months in all cases of hepatitis A, in most cases of hepatitis B, but in only a small proportion of cases of hepatitis C.

When patients are hospitalized, their feces, secretions, bedpans, and other articles in contact with the intestinal tract should be handled with glove-protected hands. Extra precautions, such as double gloving during delivery and surgical procedures, are recommended. Due to significant exposure of health-care personnel to hepatitis B, the Centers for Disease Control and Prevention (CDC) recommend active and passive vaccination. There is no vaccine for hepatitis C, so recommendations are for postexposure serosurveillance only.

Acute hepatitis has a case-fatality rate of 0.1 percent. For patients ill enough to be hospitalized, it is as high as 1 percent. Most fatalities are due to *fulminant hepatic necrosis*, which in

later pregnancy may resemble acute fatty liver. In these cases, hepatic encephalopathy is the usual presentation, and the mortality rate is 80 percent. Approximately half of patients with fulminant disease have hepatitis B infection, and co-infection with the delta agent is common.

Chronic Hepatitis

The Centers for Disease Control and Prevention (2012) estimates that 4.4 million Americans are living with chronic viral hepatitis. By far, the most frequent complication of hepatitis B and C is subsequent development of chronic hepatitis, which is usually diagnosed serologically (Table 55-3). Chronic infection follows acute hepatitis B in approximately 5 to 10 percent of cases in adults. Most become asymptomatic carriers, but a small percentage have low-grade chronic persistent hepatitis or chronic active hepatitis with or without cirrhosis. With acute hepatitis C, however, chronic hepatitis develops in most patients. With persistently abnormal biochemical tests, liver biopsy usually discloses active inflammation, continuing necrosis, and fibrosis that may lead to cirrhosis. Chronic hepatitis is classified by cause; grade, defined by histological activity; and stage, which is the degree of progression (Dienstag, 2012b). In these cases, there is evidence that a cellular immune reaction is interactive with a genetic predisposition.

Although most chronically infected persons are asymptomatic, approximately 20 percent develop cirrhosis within 10 to 20 years (Dienstag, 2012b). When present, symptoms are nonspecific and usually include fatigue. Diagnosis can be confirmed by liver biopsy, however, treatment is usually given to patients after serological or virological diagnosis. In some patients, cirrhosis with liver failure or bleeding varices may be the presenting findings. The management of chronic hepatitis B and hepatitis C is discussed in their respective sections.

Chronic Hepatitis and Pregnancy. Most young women with chronic hepatitis either are asymptomatic or have only mild liver disease. For seropositive asymptomatic women, there usually are no problems with pregnancy. With *symptomatic* chronic active hepatitis, pregnancy outcome depends primarily on disease and fibrosis intensity, and especially on the presence of portal hypertension. The few women whom we

have managed have done well, but their long-term prognosis is poor. Accordingly, they should be counseled regarding possible liver transplantation as well as abortion and sterilization options.

Hepatitis A

Because of vaccination programs, the incidence of hepatitis A has decreased 95 percent since 1995. In 2010, the rate was 0.6 per 100,000 individuals—the lowest rate ever reported in the United States (Centers for Disease Control and Prevention, 2012). This 27-nm RNA picornavirus is transmitted by the fecal–oral route, usually by ingestion of contaminated food or water. The incubation period is approximately 4 weeks. Individuals shed virus in their feces, and during the relatively brief period of viremia, their blood is also infectious. Signs and symptoms are often nonspecific and usually mild, although jaundice develops in most patients. Symptoms usually last less than 2 months, although 10 to 15 percent of patients may remain symptomatic or relapse for up to 6 months (Dienstag, 2012a). Early serological detection is by identification of IgM anti-HAV antibody that may persist for several months. During convalescence, IgG antibody predominates, and it persists and provides subsequent immunity. There is no chronic stage of hepatitis A.

Management of hepatitis A in pregnant women consists of a balanced diet and diminished physical activity. Women with less severe illness may be managed as outpatients. In developed countries, the effects of hepatitis A on pregnancy outcomes are not dramatic (American College of Obstetricians and Gynecologists, 2012a,b). Both perinatal and maternal mortality rates, however, are substantively increased in resource-poor countries. There is no evidence that hepatitis A virus is teratogenic, and transmission to the fetus is negligible. Preterm birth may be increased, and neonatal cholestasis has been reported (Urganci, 2003). Although hepatitis A RNA has been isolated in breast milk, no cases of neonatal hepatitis A have been reported secondary to breast feeding (Daudi, 2012).

Preventatively, vaccination during childhood with formalin-inactivated hepatitis viral vaccine is more than 90-percent effective. HAV vaccination is recommended by the American College

From the Centers for Disease Control and Prevention, 2010; Dienstag, 2012a.

of Obstetricians and Gynecologists (2012b) and the Centers for Disease Control and Prevention (2010) for high-risk adults, a category that includes behavioral and occupational populations and travelers to high-risk countries. These countries are listed by the Centers for Disease Control and Prevention in the 2014 CDC Health Information for International Travel “yellow book,” which is available at: <http://wwwnc.cdc.gov/travel/yellowbook/2014/table-of-contents>.

Passive immunization for the pregnant woman recently exposed by close personal or sexual contact with a person with hepatitis A is provided by a 0.02 mL/kg dose of immune globulin (Centers for Disease Control and Prevention, 2010). Victor and colleagues (2007) reported that a single dose of HAV vaccine given in the usual dosage within 2 weeks of exposure to exposed persons was as effective as immune serum globulin to prevent hepatitis A. In both groups, HAV developed in 3 to 4 percent.

Hepatitis B

This is a double-stranded DNA virus of the Hepadnaviridae family. It is found worldwide and is endemic in Africa, Central and Southeast Asia, China, Eastern Europe, the Middle East, and certain areas of South America, with prevalence rates as high as 5 to 20 percent. The World Health Organization (2009) estimates that more than two billion people worldwide are infected with HBV, and of these, 370 million have chronic infection. The Centers for Disease Control and Prevention (2012) estimated that there were 43,000 acute hepatitis B cases in the United States in 2010—a decline of more than 80 percent since vaccination was introduced in the 1980s. The World Health Organization considers hepatitis B to be second only to tobacco among human carcinogens.

The hepatitis B virus is transmitted by exposure to blood or body fluids from infected individuals. In endemic countries, vertical transmission, that is, from mother to fetus or newborn, accounts for at least 35 to 50 percent of chronic HBV infections. In low-prevalence countries such as the United States, which has a prevalence < 2 percent, the more frequent mode of HBV transmission is via sexual transmission or sharing of contaminated needles. HBV can be transmitted by any body fluid, but exposure to virus-laden serum is the most efficient.

Acute hepatitis B develops after an incubation period of 30 to 180 days with a mean of 8 to 12 weeks. At least half of acute infections are asymptomatic. If symptoms are present, they are usually mild and include anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. Acute HBV accounts for half of cases of fulminant hepatitis. Complete resolution of symptoms occurs within 3 to 4 months in more than 90 percent of patients. Figure 55-2 details the sequence of the various HBV antigens and antibodies in acute infection. The first serological marker to be detected is the hepatitis B surface antigen (HBsAg), often preceding the increase in aminotransferase levels. As HBsAg disappears, antibodies to the surface antigen develop (anti-HBs), marking complete resolution of disease. Hepatitis B core antigen is an intracellular antigen and not detectable in serum. However, anti-HBc is detectable within

FIGURE 55-2 Sequence of various antigens and antibodies in acute hepatitis B. ALT = alanine aminotransferase; anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to hepatitis B e antigen; anti-HBs = antibody to hepatitis B surface antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen. (Redrawn from Dienstag, 2012a.)

weeks of HBsAg appearance. The hepatitis Be antigen (HBeAg) is present during times of high viral replication and often correlates with detectable HBV DNA. After acute hepatitis, approximately 90 percent of adult persons recover completely. The 10 percent who remain chronically infected are considered to have chronic hepatitis B.

Chronic HBV infection is often asymptomatic but may be clinically suggested by persistent anorexia, weight loss, fatigue, and hepatosplenomegaly. Extrahepatic manifestations may include arthritis, generalized vasculitis, glomerulonephritis, pericarditis, myocarditis, transverse myelitis, and peripheral neuropathy. One risk factor for chronic disease is age at acquisition—more than 90 percent in newborns, 50 percent in young children, and less than 10 percent in immunocompetent adults. Another risk is an immunocompromised state such as those with human immunodeficiency virus (HIV) infection, transplant recipients, or persons receiving chemotherapy. Chronically infected persons may be asymptomatic carriers or have chronic disease with or without cirrhosis. Patients with chronic disease have persistent HBsAg serum positivity. The patients with evidence of high viral replication—HBV DNA with or without HBeAg, have the highest likelihood of developing cirrhosis and hepatocellular carcinoma. HBV DNA has been found to be the best correlate of liver injury and disease progression risk.

Pregnancy

Hepatitis B infection is not a cause of excessive maternal morbidity and mortality. It is often asymptomatic and found only on routine prenatal screening (Connell, 2011; Stewart, 2013). A review of the National Inpatient Sample (NIS) Agency for Healthcare Research and Quality reported a modest increase in preterm birth rates in HBV-positive mothers but no effect on fetal-growth restriction or preeclampsia rates (Reddick, 2011). Others have shown similar results (Connell, 2011; Safir, 2010). Transplacental viral infection is uncommon, and Towers and

associates (2001) reported that viral DNA is rarely found in amniotic fluid or cord blood. Interestingly, HBV DNA has been found in the ovaries of HBV-positive pregnant women, and the highest levels were found in women who transmitted HBV to their fetuses (Hu, 2012; Lou, 2010; Yu, 2012).

In the absence of HBV immunoprophylaxis, 10 to 20 percent of women positive for HBsAg transmit viral infection to their infant. This rate increases to almost 90 percent if the mother is HBsAg and HBeAg positive. Immunoprophylaxis and hepatitis B vaccine given to infants born to HBV-infected mothers has decreased transmission dramatically and prevented approximately 90 percent of infections (Smith, 2012). But, women with high HBV viral loads—106 to 108 copies/mL, or those who are HBeAg positive, still have a least a 10-percent vertical transmission rate, regardless of immunoprophylaxis.

To decrease vertical transmission in women at highest risk because of high HBV DNA levels, some have recommended antiviral therapy. Lamivudine, a cytidine nucleoside analogue, has been found to significantly decrease the risk of fetal HBV infection in women with high HBV viral loads (Dusheiko, 2012; Giles, 2011; Han, 2011; Shi, 2010; Xu, 2009). Safety data in early pregnancy, although limited, are promising (Yi, 2012; Yu, 2012). Early reports of two other antiviral medications, telbivudine and tenofovir, for use in pregnancy also show promise (Deng, 2012; Han, 2011; Liu, 2013; Pan, 2012a,b). Hepatitis B immunoglobulin (HBIG) given antepartum to women at highest risk of transmission has also been shown to be effective in decreasing transmission rates (Shi, 2010). Antiviral therapy or HBIG has been shown to be cost-effective in recent analyses (Nayeri, 2012).

Infants born to seropositive mothers are given HBIG very soon after birth. This is accompanied by the first of a three-dose hepatitis B recombinant vaccine. Hill and colleagues (2002) applied this strategy in 369 infants and reported that the 2.4-percent transmission rate was not increased with breast feeding if vaccination was completed. Although virus is present in breast milk, the incidence of transmission is not lowered by formula feeding (Shi, 2011). The American Academy of Pediatrics does not consider maternal HBV infection a contraindication to breast feeding.

For high-risk mothers who are seronegative, hepatitis B vaccine can be given during pregnancy. The efficacy has been shown to be similar to that for nonpregnant adults, with overall seroconversion rates approaching 95 percent after three doses (Stewart, 2013). The traditional vaccination schedule of 0, 1, and 6 months may be difficult to complete during a pregnancy, and compliance rates decline after delivery. Sheffield and coworkers (2006) reported that the three-dose regimen given prenatally—initially and at 1 and 4 months—resulted in seroconversion rates of 56, 77, and 90 percent, respectively. This regimen was noted to be easily completed during routine prenatal care.

■ Hepatitis D

Also called *delta hepatitis*, this is a defective RNA virus that is a hybrid particle with an HBsAg coat and a delta core. The virus must co-infect with hepatitis B either simultaneously or secondarily. It cannot persist in serum longer than hepatitis B virus.

Transmission is similar to hepatitis B. Chronic co-infection with B and D hepatitis is more severe and accelerated than with HBV alone, and up to 75 percent of affected patients develop cirrhosis. HDV infection is detected by the presence of anti-HDV and HDV DNA. Neonatal transmission is unusual as neonatal HBV vaccination usually prevents delta hepatitis.

■ Hepatitis C

This is a single-stranded RNA virus of the family Flaviviridae. There are at least six major genotypes—type 1 accounts for 70 percent of HCV infections in the United States. Transmission occurs via blood and body fluids, although sexual transmission is inefficient. Up to a third of anti-HCV positive persons have no identifiable risk factors (Dienstag, 2012b). Screening for HCV is recommended for HIV-infected individuals, persons with injection drug use, hemodialysis patients, children born to mothers with HCV, persons exposed to HCV-positive blood or body fluids, persons with unexplained elevations in aminotransferase values, and recipients of blood or transplants before July 1992. Prenatal screening has been recommended in high-risk women, and in the United States, seroprevalence rates as high as 1 to 2.4 percent have been reported (American College of Obstetricians and Gynecologists, 2012b; Arshad, 2011; Connell, 2011). It is higher in women who are HIV positive, and Santiago-Munoz and associates (2005) found that 6.3 percent of HIV-infected pregnant women at Parkland Hospital were co-infected with hepatitis B or C.

Acute HCV infection is usually asymptomatic or with mild symptoms. Only 10 to 15 percent develop jaundice. The incubation period ranges from 15 to 160 days with a mean of 7 weeks. Aminotransferase levels are elevated episodically during the acute infection. Hepatitis C RNA testing is now considered the “gold standard” for the diagnosis of HCV—levels may be detected even before aminotransferase elevations and the development of anti-HCV. Anti-HCV antibody is not detected for an average of 15 weeks and in some cases as long as a year (Dienstag, 2012a).

As many as 80 to 90 percent of patients with acute HCV will be chronically infected. Although most remain asymptomatic, approximately 20 to 30 percent progress to cirrhosis within 20 to 30 years. Aminotransferase values fluctuate, and HCV RNA levels vary over time. Liver biopsy reveals chronic disease and fibrosis in up to 50 percent, however, these findings are often mild. Overall, the long-term prognosis for most patients is excellent.

As expected, most pregnant women diagnosed with HCV have chronic disease. HCV infection was initially thought to have limited pregnancy effects. However, more recent reports have chronicled modestly increased fetal risks for low birthweight, NICU admission, preterm delivery, and mechanical ventilation (Berkley, 2008; Pergam, 2008; Reddick, 2011). In some women, these adverse outcomes may have been influenced by concurrent high-risk behaviors associated with HCV infection.

The primary adverse perinatal outcome is vertical transmission of HCV infection to the fetus-infant. This is higher in mothers with viremia (Indolfi, 2014; Joshi, 2010). From their review, Airolidi and Berghella (2006) cited a rate of 1 to

3 percent in HCV-positive, RNA-negative women compared with 4 to 6 percent in those who were RNA-positive. In a report from Dublin, McMenamin and colleagues (2008) described transmission rates in 545 HCV-positive women. They found a 7.1-percent vertical transmission rate in RNA-positive women compared with none in those who were RNA-negative. Some have found an even greater risk when the mother is co-infected with HIV (Ferrero, 2003). Approximately two thirds of prenatal transmission occurs peripartum. HCV genotype, invasive prenatal procedures, breast feeding, and delivery mode are not associated with mother-to-child transmission (Babik, 2011; Cottrell, 2013; Ghamar Chehreh, 2011; López, 2010). That said, invasive procedures such as internal electronic fetal heart rate monitoring should be avoided. HCV infection is not a contraindication to breast feeding.

There is currently no licensed vaccine for HCV prevention. The chronic HCV infection treatment has traditionally included alpha interferon (standard and pegylated), alone or in combination with ribavirin. This regimen is contraindicated in pregnancy because of the teratogenic potential of ribavirin in animals (Joshi, 2010). The initial 5-year review of the Ribavirin Pregnancy Registry found no evidence for human teratogenicity. However, the registry has enrolled fewer than half of the necessary numbers to allow a conclusive statement to be made (Roberts, 2010). The development and study of direct acting and host-targeted antiviral drugs in the past decade has shown great promise for the management of chronic hepatitis C (Liang, 2013; Lok, 2012; Poordad, 2013). Current interferon-free, ribavirin-free regimens are being evaluated, although no data are available for pregnant women.

■ Hepatitis E

This water-borne RNA virus usually is enterically transmitted by contaminated water supplies. Hepatitis E is probably the most common cause of acute hepatitis (Hoofnagle, 2012). It causes epidemic outbreaks in third-world countries with substantial morbidity and mortality rates. Pregnant women have a higher case-fatality rate than nonpregnant individuals. Rein and coworkers (2012) suggested a 20-percent mortality rate using modeling estimates from the developing world. Fulminant hepatitis, although rare overall, is more common in pregnant women and contributes to the increased mortality rates (Labrique, 2012; Mehta, 2012).

Higher hepatitis E viral loads and increased cytokine secretion in pregnant compared with nonpregnant women may be factors in the development of fulminant hepatitis (Borkakoti, 2013; Salam, 2013). Recombinant HEV vaccine efficacy is reported to be > 90 percent, and preliminary data from inadvertently vaccinated pregnant women have shown no adverse maternal or fetal events. Even so, there is no currently available Food and Drug Administration (FDA)-approved vaccine (Labrique, 2012; Wedemeyer, 2012; Wu, 2012).

■ Hepatitis G

This blood-borne infection with a flavivirus-like RNA virus does not actually cause hepatitis (Dienstag, 2012a). Its

seroprevalence ranges from 0.08 to 5 percent, and there is currently no recommended treatment aside from basic blood and body fluid precautions. Infant transmission has been described (Feucht, 1996; Inaba, 1997).

■ Autoimmune Hepatitis

This is a generally progressive chronic hepatitis that is important to distinguish from chronic viral hepatitis because treatments are markedly different. According to Krawitt (2006), an environmental agent—a virus or drug—triggers events that mediate T cells to destroy liver antigens in genetically susceptible patients. Type 1 hepatitis is more common and is characterized by multiple autoimmune antibodies such as antinuclear antibodies (ANA) as well as certain human leukocyte genes. Treatment employs corticosteroids, alone or combined with azathioprine (Gossard, 2012). In some patients, cirrhosis or hepatocellular carcinoma develops.

As with other autoimmune disorders, chronic autoimmune hepatitis is more common in women and frequently coexists with thyroiditis, ulcerative colitis, type 1 diabetes, and rheumatoid arthritis. Hepatitis is usually subclinical, but exacerbations can cause fatigue and malaise that can be debilitating.

In general, pregnancy outcomes of women with autoimmune hepatitis are poor, but the prognosis is good with well-controlled disease (Uribe, 2006). In one study, Schramm and colleagues (2006) described 42 pregnancies in 22 German women with autoimmune hepatitis. A fifth had a flare antepartum, and half had a flare postpartum. One woman underwent liver transplantation at 18 weeks' gestation, and another died of sepsis at 19 weeks. In their 38-year review, Candia and associates (2005) found 101 pregnancies in 58 women. They reported that preeclampsia developed in approximately a fourth, and there were two maternal deaths. Westbrook and coworkers (2012) reported the outcomes of 81 pregnancies in 53 women. Flares occurred in a third of the women. There were more common in those not taking medication and those with active disease in the year before conception. Only a minority—20 of 81—were not taking medications. Maternal and fetal complications were higher among women with cirrhosis, particularly with respect to the risks of death or need for liver transplantation during the pregnancy or within 12 months postpartum.

■ Nonalcoholic Fatty Liver Disease

Steatohepatitis is an increasingly recognized condition that may occasionally progress to hepatic cirrhosis. As a macrovesicular fatty liver condition, it resembles alcohol-induced liver injury but is seen without alcohol abuse. Obesity, type 2 diabetes, and hyperlipidemia—*syndrome X*—frequently coexist and likely are etiological agents or “triggers” (McCullough, 2006). Nonalcoholic fatty liver disease (NAFLD) is common in obese persons, and as many as 50 percent of the morbidly obese are affected (Chap. 48, p. 963). Moreover, half of persons with type 2 diabetes have NAFLD. Browning and associates (2004) used magnetic resonance spectroscopy to determine the prevalence of NAFLD in Dallas County and found that approximately a third of adults were affected. This

varied by ethnicity, with 45 percent of Hispanics, 33 percent of whites, and 24 percent of blacks being affected. Most people—80 percent—found to have steatosis had normal liver enzymes. Welsh and colleagues (2013) showed that non-alcoholic fatty liver disease among adolescents increased from 3.9 to 10.7 percent between 1988 to 1994 and 2007 to 2010. The risk increased with age, body mass index, male gender, and Mexican American race. And half of obese male adolescents are affected.

There is a continuum or spectrum of liver damage in which fatty liver progresses to *nonalcoholic steatohepatitis*—*NASH*, and then *hepatic fibrosis* develops that may progress to cirrhosis (Levene, 2012). Still, in most persons, the disease is usually asymptomatic, and it is a frequent explanation for elevated aminotransferase levels found in blood donors and other routine screening testing. Indeed, it is the cause of elevated asymptomatic aminotransferase levels in up to 90 percent of cases in which other liver disease is excluded. It also is the most common cause of abnormal liver tests among adults in this country. Currently, weight loss along with diabetes and dyslipidemia control is the only recommended treatment.

Pregnancy

Fatty liver infiltration is probably much more common than realized in obese and diabetic pregnant women. During the past decade, we encountered an increasing number of pregnant women with these disorders. Once severe liver injury, that is, acute fatty liver of pregnancy, was excluded, gravidas with fatty liver infiltration had no adverse outcomes relative to liver involvement. Page and Girling (2011) reported five women who had mild liver enzyme abnormalities after exclusion of other obstetrical and nonobstetrical etiologies. Four women had steatosis diagnosed by sonography, and a fifth woman without sonographic abnormalities had biopsy-confirmed steatosis postpartum. Forbes and colleagues (2011) studied women with and without a history of gestational diabetes who had nondiabetic glucose tolerance testing postpartum. Although body mass index did not differ significantly, women with a history of gestational diabetes were more than twice as likely to have NAFLD diagnosed sonographically, and this correlated with increased dyslipidemia and measures of insulin resistance. As the obesity epidemic worsens, any adverse effects of this liver disorder on pregnancy outcome should become apparent.

Cirrhosis

Irreversible chronic liver injury with extensive fibrosis and regenerative nodules is the final common pathway for several disorders. *Laënnec cirrhosis* from chronic alcohol exposure is the most frequent cause in the general population. But in young women—including pregnant women—most cases are caused by *postnecrotic cirrhosis* from chronic hepatitis B and C. Many cases of *cryptogenic cirrhosis* are now known to be caused by nonalcoholic fatty liver disease (Dienstag, 2012b). Clinical manifestations of cirrhosis include jaundice, edema, coagulopathy, metabolic abnormalities, and portal hypertension with gastroesophageal varices and splenomegaly. The incidence of deep-vein thromboembolism is increased (Søgaard, 2009). The

prognosis is poor, and 75 percent have progressive disease that leads to death in 1 to 5 years.

Cirrhosis and Pregnancy

Women with symptomatic cirrhosis frequently are infertile. Those who become pregnant generally have poor outcomes. Common complications include transient hepatic failure, variceal hemorrhage, preterm delivery, fetal-growth restriction, and maternal death (Tan, 2008). Outcomes are generally worse if there are coexisting esophageal varices.

Another potentially fatal complication of cirrhosis arises from associated splenic artery aneurysms. Up to 20 percent of ruptures occur during pregnancy, and 70 percent of these rupture in the third trimester (Tan, 2008). In a review of 32 cases of these aneurysms, Ha and coworkers (2009) found that the mean diameter was 2.25 cm, and in half of cases, the diameter was < 2 cm. The maternal mortality rate of 22 percent was likely related to the emergent diagnosis of these cases, as almost all were diagnosed at the time of rupture.

Portal Hypertension and Esophageal Varices

Approximately half of esophageal varices cases in pregnant women are caused by either cirrhosis or extrahepatic portal vein obstruction, which leads to portal system hypertension. Some cases of extrahepatic hypertension develop following portal vein thrombosis associated with one of the *thrombophilia syndromes* (Chap. 52, p. 1029). Others follow thrombosis from umbilical vein catheterization when the woman was a neonate, especially if she was born preterm.

With either intrahepatic or extrahepatic resistance to flow, portal vein pressure rises from its normal range of 5 to 10 mm Hg, and values may exceed 30 mm Hg. Collateral circulation develops that carries portal blood to the systemic circulation. Drainage is via the gastric, intercostal, and other veins to the esophageal system, where varices develop. Bleeding is usually from varices near the gastroesophageal junction, and hemorrhage can be torrential. Bleeding during pregnancy from varices occurs in a third to half of affected women and is the major cause of maternal mortality (Tan, 2008).

Maternal prognosis is largely dependent on whether there is variceal hemorrhage. Mortality rates are higher if varices are associated with cirrhosis compared with rates for varices without cirrhosis—18 versus 2 percent, respectively. Perinatal mortality rates are high in women with varices and are worse if cirrhosis caused the varices.

Management

Treatment is the same as for nonpregnant patients. Preventatively, all patients with cirrhosis, including pregnant women, should undergo screening endoscopy for identification of variceal dilatation (Tan, 2008). Beta-blocking drugs such as propranolol are given to reduce portal pressure and hence the bleeding risk (Groszmann, 2005).

For acute bleeding, endoscopic band ligation is preferred to sclerotherapy, as it avoids any potential risks of injecting sclerotherapeutic chemicals (Tan, 2008). Zeeman and Moise (1999) described a pregnant woman who underwent *prophylactic* banding at 15, 26, and 31 weeks' gestation to prevent

bleeding. Acute medical management for bleeding varices verified by endoscopy includes intravenous vasopressin or octreotide and somatostatin (Chung, 2005). *Balloon tamponade* using a triple-lumen tube placed into the esophagus and stomach to compress bleeding varices can be lifesaving if endoscopy is not available. The interventional radiology procedure—*transjugular intrahepatic portosystemic stent shunting (TIPSS)*—can also control bleeding from gastric varices that is unresponsive to other measures (Khan, 2006; Tan, 2008). TIPSS can be done electively in patients with previous variceal hemorrhage.

■ Acute Acetaminophen Overdose

Nonsteroidal antiinflammatory drugs (NSAIDs) are often used in suicide attempts. In a study from Denmark, Flint and associates (2002) reported that more than half of such attempts by 122 pregnant women were with either acetaminophen or aspirin. In the United States, acetaminophen is much more commonly used during pregnancy, and overdose may lead to hepatocellular necrosis and acute liver failure (Lee, 2008). Massive necrosis causes a *cytokine storm* and multiorgan dysfunction. Early symptoms of overdose are nausea, vomiting, diaphoresis, malaise, and pallor. After a latent period of 24 to 48 hours, liver failure ensues and usually begins to resolve in 5 days. In a prospective Danish study, only 35 percent of patients who were treated for fulminant hepatic failure spontaneously recovered before being listed for liver transplantation (Schmidt, 2007).

The antidote is *N-acetylcysteine*, which must be given promptly. The drug is thought to act by increasing glutathione levels, which aid metabolism of the toxic metabolite, *N-acetyl-para-benzoquinoneimine*. The need for treatment is based on projections of possible plasma hepatotoxic levels as a function of the time from acute ingestion. Many poison control centers use the nomogram established by Rumack and Matthew (1975). A plasma level is measured 4 hours after ingestion, and if the level is $> 120 \mu\text{g/mL}$, treatment is given. If plasma determinations are not available, empirical treatment is given if the ingested amount exceeded 7.5 g. An oral loading dose of 140 mg/kg of *N-acetylcysteine* is followed by 17 maintenance doses of 70 mg/kg every 4 hours for 72 hours of total treatment time. Both the oral and an equally efficacious intravenous dosing regimen have been recently reviewed by Hodgman and Garrard (2012). Although the drug reaches therapeutic concentrations in the fetus, any protective effects are unknown (Heard, 2008).

After 14 weeks, the fetus has some cytochrome P450 activity necessary for metabolism of acetaminophen to the toxic metabolite. Riggs and colleagues (1989) reported follow-up data from the Rocky Mountain Poison and Drug Center in 60 such women. The likelihood of maternal and fetal survival was better if the antidote was given soon after overdose. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after maternal ingestion. In another case, Wang and associates (1997) confirmed acetaminophen placental transfer with maternal and cord blood levels that measured $41 \mu\text{g/mL}$. Both mother and infant died from hepatorenal failure.

■ Focal Nodular Hyperplasia

This is considered a benign lesion of the liver, characterized in most cases by a well-delineated accumulation of normal but disordered hepatocytes that surround a central stellate scar. These usually can be differentiated from hepatic adenomas by MR and CT imaging. Except in the rare situation of unremitting pain, surgery is rarely indicated, and most women remain asymptomatic during pregnancy. Rifai and coworkers (2013) reviewed 20 cases at a single center in Germany. None of the women had complications during pregnancy, and tumor size did not vary significantly before, during, or after pregnancy. Three women had 20-percent tumor growth; in 10 patients, the tumor decreased in size; and the remaining seven were unchanged across pregnancy. Ramirez-Fuentes and associates (2013) studied 44 lesions in 30 women, who each had a minimum of two MR imaging studies 12 months apart. They reported that 80 percent of the lesions were unchanged in size, and most of the remainder decreased in size. They concluded that changes in size were unrelated to pregnancy, oral contraceptive use, or menopause. As noted in Chapter 38 (p. 709), this lesion is not a contraindication to estrogen-containing contraceptives.

■ Hepatic Adenoma

This benign neoplasm has a significant risk of rupture-associated hemorrhage, particularly in pregnancy. As discussed above, adenomas can usually be differentiated from focal nodular hyperplasia by MR or CT imaging. Adenomas have a 9:1 predominance among women and are strongly linked with combination oral contraceptive use. The risk of rupture increases with lesion size, and surgery is generally recommended for tumors measuring $> 5 \text{ cm}$. From their review, Cobey and Salem (2004) found 27 cases in pregnancy, 23 of which became apparent in the third trimester and puerperium. They found no cases of hemorrhage when the tumor size was $< 6.5 \text{ cm}$. In their review, 16 of 27 (60 percent) women with an adenoma presented with tumor rupture that resulted in seven maternal deaths and six fetal deaths. Of note, 13 of 27 women presented within 2 months postpartum, and in half, hemorrhage heralded rupture. Santambrogio and coworkers (2009) provided a case report of a woman with a 12-cm adenoma that ruptured shortly after emergent cesarean for placental abruption and that ultimately prompted liver transplantation.

■ Liver Transplantation

According to the Organ Procurement and Transplantation Network (2012), liver transplant patients comprise nearly 18 percent of all proposed waiting organ recipients. Approximately a fourth of these are women of childbearing age. The first human liver transplant was performed 50 years ago, and a recent literature review cited 450 pregnancies in 306 women who had undergone transplantation (Deshpande, 2012). Although their livebirth rate of 80 percent and miscarriage rates compared favorably with those of the general population, there were significantly increased risks of preeclampsia, cesarean delivery, and preterm birth. A fourth of pregnancies were complicated by

TABLE 55-4. Pregnancy Complications (%) in 558 Pregnancies after Liver Transplantation

Series	No.	Preeclampsia/ Hypertension	Cesarean Delivery	Rejection	Live Birth
Jain (2003)	49	2–8	45	24	100
Nagy (2003)	38	21	46	17	63

NA = not available.

hypertension, approximately a third resulted in preterm birth, and in 10 percent, there was one or more rejection episodes (Table 55-4). Importantly, 4 percent of mothers had died within a year after delivery, but this rate is comparable with nonpregnant liver transplantation patients.

In pregnant women who have undergone transplantation, close surveillance is mandatory to detect hypertension, renal dysfunction, preeclampsia, and graft rejection. Management considerations, including immunosuppressive therapy, were reviewed by Mastrobattista and Gomez-Lobo (2008) and by McKay and Josephson (2006). Because of increased metabolic clearance, serum levels of some antirejection drugs should be determined. Ethical considerations of pregnancy in transplant recipients were reviewed earlier by Ross (2006).

GALLBLADDER DISORDERS

Cholelithiasis and Cholecystitis

In the United States, 20 percent of women older than 40 years have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in stone formation. Biliary sludge, which may increase during pregnancy, is an important precursor to gallstone formation. The incidence of sonographically identified asymptomatic gallstones in more than 1500 pregnant or postpartum women was 2.5 to 10 percent (Maringhini, 1993; Valdivieso, 1993). Moreover, the cumulative risk of all patients with silent gallstones to require surgery for symptoms or complications is 10 percent at 5 years, 15 percent at 10 years, and 18 percent at 15 years (Greenberger, 2008). For these reasons, prophylactic cholecystectomy is not warranted for *asymptomatic* stones. For *symptomatic* gallstone disease, nonsurgical approaches have been used and include oral bile acid therapy with ursodeoxycholic acid and extracorporeal shock wave lithotripsy. There is no experience with these during pregnancy.

Acute cholecystitis usually develops when there is obstruction of the cystic duct. Bacterial infection plays a role in 50 to 85 percent of cases. In more than half of patients with acute cholecystitis, a history of previous right upper quadrant pain from cholelithiasis is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and

mild leukocytosis. As shown in Figure 55-3, sonography can be used to see stones as small as 2 mm, and false-positive and false-negative rates are 2 to 4 percent (Greenberger, 2008).

Symptomatic gallbladder disorders in young women include acute cholecystitis, biliary colic, and acute pancreatitis. Rarely, a gallbladder undergoes torsion or a neoplasm is found (Kleiss, 2003; Wiseman, 2008). In most symptomatic patients, cholecystectomy is warranted. Although acute cholecystitis responds to medical therapy, contemporary consensus is that early cholecystectomy is indicated (Greenberger, 2008). In acute cases, medical therapy consists of intravenous fluids, antimicrobials, analgesics, and in some instances, nasogastric suction, before surgical therapy. Laparoscopic cholecystectomy has become the preferred treatment for most patients.

Gallbladder Disease During Pregnancy

The incidence of cholecystitis during pregnancy is reported to be approximately 1 in 1000. There is no doubt that pregnancy is “lithogenic.” After the first trimester, the gallbladder fasting volume as well as the residual volume after postprandial emptying are doubled. Incomplete emptying may result in retention

FIGURE 55-3 This sonogram shows multiple hyperechoic gallstones filling an anechoic gallbladder.

of cholesterol crystals, a prerequisite for cholesterol gallstones. Maringhini and colleagues (1993) showed that the incidence of biliary sludge—which can be a forerunner to gallstones—and gallstones in pregnancy are 31 and 2 percent, respectively. Ko and colleagues (2014), however, cited a combined incidence to be lower at about 5 percent. Postpartum, there is frequently regression of sludge, and occasionally gallstones will resorb. Still, after delivery, hospitalization for gallbladder disease within a year remains relatively common. Ko (2006) studied Washington state discharge databases and documented that 0.5 percent of postpartum women were hospitalized within a year for various conditions. Of these 6211 women, 76 had uncomplicated cholecystitis, and 55 underwent cholecystectomy.

Medical versus Surgical Management

Acute cholecystitis during pregnancy or the puerperium is usually associated with gallstones or biliary sludge. Symptomatic cholecystitis is initially managed in a manner similar to that for nonpregnant women. In the past, most favored medical therapy. However, the recurrence rate during the same pregnancy is high, and 25 to 50 percent of women ultimately required cholecystectomy for persistent symptoms. Moreover, if cholecystitis recurs later in gestation, preterm labor is more likely and cholecystectomy technically more difficult.

For these reasons, operative and endoscopic interventions are increasingly favored over conservative measures. Othman and coworkers (2012) showed that women managed conservatively had more pain, more recurrent visits to the emergency department, more hospitalizations, and a higher rate of cesarean delivery. Dhupar and associates (2010) reported more complications with conservative management of gallbladder disease compared with laparoscopic cholecystectomy in pregnancy. These included multiple admissions, prolonged total parenteral nutrition, and unplanned labor induction for worsening gallbladder symptoms.

Cholecystectomy was performed safely in all trimesters. Only one of 19 patients who underwent laparoscopic cholecystectomy had a complication, which did not require further surgery. Date and coworkers (2008) reviewed the literature and found no increased risk of preterm birth or fetal demise for operative compared with conservative management. There was, however, a significantly higher rate of fetal death from gallstone pancreatitis when women were managed conservatively compared with surgical management. There were no perinatal deaths in 20 women undergoing cholecystectomy and in nine undergoing endoscopic retrograde cholangiopancreatography. Management at Parkland Hospital has evolved to a more aggressive surgical approach, especially if there is concomitant biliary pancreatitis as subsequently discussed. During the past two decades, laparoscopic cholecystectomy has evolved as the favored surgical approach and is discussed in Chapter 46 (p. 928).

Endoscopic Retrograde Cholangiopancreatography

Relief from symptomatic biliary duct gallstones during pregnancy has been greatly aided by use of endoscopic retrograde cholangiopancreatography—ERCP (Fogel, 2014; Menees, 2006). The procedure is performed if there is suspected or proven common duct obstruction, usually from stones.

Approximately 10 percent of patients with symptomatic stone disease have common duct stones (Greenberger, 2008). ERCP can be modified in many cases so that radiation exposure from fluoroscopy is avoided (Shelton, 2008; Simmons, 2004).

Tang and associates (2009) reported results from 68 ERCP procedures performed in 65 pregnant women at Parkland Hospital. All but two women had gallstones, and sphincterotomy was performed in all but one woman. Common duct stones were identified in half of these 65 women, and in all but one, the stones were successfully removed. A biliary stent was placed in 22 percent and removed after delivery. Complications were minimal, and post-ERCP pancreatitis developed in 16 percent. Pregnancy outcomes were not different than for the general obstetrical population. As a less invasive approach, magnetic resonance cholangiopancreatography (MRCP) has been reported to have utility in pregnancy, particularly with otherwise unexplained biliary duct dilatation identified sonographically (Oto, 2009). Use of MRCP in this situation identified the cause of the biliary ductal dilatation in four cases and excluded obstructive pathology in the remaining four cases.

PANCREATIC DISORDERS

Pancreatitis

Acute pancreatic inflammation is triggered by activation of pancreatic trypsinogen followed by autodigestion. It is characterized by cellular membrane disruption and proteolysis, edema, hemorrhage, and necrosis (Fogel, 2014; Whitcomb, 2006). Approximately 20 percent have severe pancreatitis, and mortality rates in these patients reach up to 25 percent (Swaroop, 2004).

In nonpregnant patients, acute pancreatitis is almost equally associated with gallstones and alcohol abuse. During pregnancy, however, cholelithiasis is almost always the predisposing condition. Other causes are hyperlipidemias, usually hypertriglyceridemia; hyperparathyroidism; congenital ductal anomalies; and rarely autoimmune pancreatitis (Crisan, 2008; Finkelberg, 2006). Nonbiliary pancreatitis occasionally develops postoperatively, or it is associated with trauma, drugs, or some viral infections. Certain metabolic conditions, including acute fatty liver of pregnancy and familial hypertriglyceridemia, also predispose to pancreatitis (Nelson, 2013). Acute and chronic pancreatitis have been linked to the more than 1000 mutations of the cystic fibrosis transmembrane conductance regulator gene (Rowntree, 2003).

At Parkland Hospital, with a large Mexican American population, acute pancreatitis complicated approximately 1 in 3300 pregnancies (Ramin, 1995). At Brigham and Women's Hospital, with a more diversely ethnic population, Hernandez and colleagues (2007) reported an incidence of 1 in 4450. In a multiple-institution Midwestern three-state review of more than 305,000 pregnancies, Eddy and associates (2008) found the incidence of acute pancreatitis to be 1 in 3450.

Diagnosis

Acute pancreatitis is characterized by mild to incapacitating epigastric pain, nausea and vomiting, and abdominal distention.

TABLE 55-5. Laboratory Values in 173 Pregnant Women with Acute Pancreatitis

Test	Mean	Range	Normal
Serum amylase (IU/L)	1980	111–8917	28–100
Serum lipase (IU/L)	3076	36–41,824	7–59
Total bilirubin (mg/dL)	1.7	0.1–8.71	0.2–1.3
Aspartate transferase (U/L)	115	11–1113	10–35
Leukocytes (per μ L)	10,700	1000–27,200	3900–10,700

From Ramin, 1995; Tang, 2010; Turhan, 2010.

Patients are usually in distress and have low-grade fever, tachycardia, hypotension, and abdominal tenderness. As many as 10 percent have systemic inflammatory response syndrome, which causes endothelial activation and can lead to *acute respiratory distress syndrome* (Chap. 47, p. 943).

Laboratory confirmation is from serum amylase levels three times upper normal values. As shown in Table 55-5, the mean amylase value was approximately 2000 IU/L in 173 pregnant women with pancreatitis, and the mean lipase value approximated 3000 IU/L. *Importantly, there is no correlation between the degree of enzyme elevation and disease severity.* Indeed, by 48 to 72 hours, amylase levels may return to normal despite other evidence for continuing pancreatitis. Serum lipase activity is also increased and usually remains elevated with continued inflammation. There is usually leukocytosis, and 25 percent of patients have hypocalcemia. Elevated serum bilirubin and aspartate aminotransferase levels may signify gallstone disease.

Several prognostic factors may be used to predict disease severity (Whitcomb, 2006). Some of these are respiratory failure, shock, need for massive colloid replacement, hypocalcemia < 8 mg/dL, and dark hemorrhagic fluid removed with paracentesis. If three of the first four features are documented, survival is only 30 percent.

Management

Medical treatment is the same as that for nonpregnant patients and includes analgesics, intravenous hydration, and measures to decrease pancreatic secretion by interdiction of oral intake. Other than supportive therapy, no particular treatment schemes have improved outcomes (Whitcomb, 2006). In the series by Ramin and colleagues (1995), all 43 affected pregnant women responded to conservative treatment and were hospitalized for a mean of 8.5 days. Nasogastric suction does not improve outcomes of mild to moderate disease, but enteral feeding may be helpful once pain improves and associated ileus resolves. Although we try to avoid parenteral nutrition, in 65 women with acute pancreatitis described by Eddy and coworkers (2008), a fourth had total parenteral nutrition. If there is bacterial superinfection of necrotizing pancreatitis, then antimicrobials are indicated. If common duct stones are

found, then ERCP is indicated (Fogel, 2014). For pregnant patients with gallstone pancreatitis, ERCP for removal of common duct stones and papillotomy has been used successfully (Simmons, 2004; Tang, 2009). Cholecystectomy should be considered after inflammation subsides if there is gallbladder disease. Hernandez and associates (2007) reported that half of such women who did not undergo cholecystectomy had recurrent pancreatitis during the same pregnancy. Severe necrotizing pancreatitis can be life threatening, and laparotomy for debridement and drainage may be required (Gosnell, 2001; Robertson, 2006).

Pregnancy outcomes appear to be related to acute pancreatitis severity. Eddy and associates (2008) reported a 30-percent preterm delivery rate, and 11 percent were delivered before 35 weeks' gestation. There were two pancreatitis-related deaths. Importantly, almost a third of 73 women had recurrent pancreatitis during pregnancy.

Pancreatic Transplantation

According to the United Network for Organ Sharing, the 5-year graft survival for pancreatic transplantation is 80 percent. Because there is improved survival when a combined pancreas and kidney are grafted for those with type 1 diabetes and renal failure, most transplants include both organs.

Mastrobattista and Gomez-Lobo (2008) reported results from the National Transplantation Pregnancy Registry. Of 44 pregnancies in 73 women following pancreas-kidney transplantation, outcomes have been encouraging, and vaginal delivery has been described. Although the incidence of hypertension, preeclampsia, preterm delivery, and fetal-growth restriction was high, there was only one perinatal death. There were four rejection episodes during pregnancy, which were treated successfully.

Pancreatic islet autotransplantation may be performed to prevent diabetes following pancreatectomy, and at least three successful pregnancies have been described (Jung, 2007).

THALASSEMIA SYNDROMES	1112
PLATELET DISORDERS	1114
INHERITED COAGULATION DEFECTS	1117
VON WILLEBRAND DISEASE	1118

Pregnant women are susceptible to hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias, immunological thrombocytopenia, and malignancies such as leukemias and lymphomas. Other disorders arise during pregnancy because of pregnancy-induced demands. Two examples are iron deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological disorders such as compensated hemolytic anemias caused by hemoglobinopathies or red cell membrane defects. Finally, any hematological disease may first arise during pregnancy. Importantly, pregnancy induces physiological changes that often confuse the diagnosis of these hematological disorders and assessment of their treatment. Several pregnancy-induced hematological changes are discussed in detail in Chapter 4 (p. 55).

ANEMIAS

Extensive hematological measurements have been made in healthy nonpregnant women. Concentrations of many cellular elements that are normal during pregnancy are listed in the Appendix (p. 1287). The Centers for Disease Control and Prevention (CDC) (1998) defined anemia in iron-supplemented pregnant women using a cutoff of the 5th percentile—11 g/dL in the first and third trimesters, and 10.5 g/dL in the second trimester (**Fig. 56-1**). An ongoing study of 278 women is currently evaluating the accuracy of an erythrogram and serum ferritin levels for anemia diagnosis and prediction of responsiveness to oral iron (Bresani, 2013).

The modest fall in hemoglobin levels during pregnancy is caused by a relatively greater expansion of plasma volume compared with the increase in red cell volume (Chap. 4, p. 55). The disproportion between the rates at which plasma and erythrocytes are added to the maternal circulation is greatest during the second trimester. Late in pregnancy, plasma expansion essentially ceases, while hemoglobin mass continues to increase.

General Considerations

The causes of anemia in pregnancy and their frequency are dependent on multiple factors such as geography, ethnicity, nutritional status, preexisting iron status, and prenatal iron supplementation. Other factors are socioeconomic, and anemia is more prevalent among indigent women (American College of Obstetricians and Gynecologists, 2013a). Approximately 25 percent of almost 48,000 Israeli pregnant women had a hemoglobin level < 10 g/dL (Kessous, 2013). Ren and colleagues (2007) found that 22 percent of 88,149 Chinese women were anemic in the first trimester. Of 1000 Indian women, half were anemic at some point, and 40 percent were throughout pregnancy (Kumar, 2013). The importance of

FIGURE 56-1 Mean hemoglobin concentrations (black line) and 5th and 95th percentiles (blue lines) for healthy pregnant women taking iron supplements. (Data from the Centers for Disease Control and Prevention, 1989.)

prenatal iron therapy is illustrated by the study of Taylor and associates (1982), who reported that hemoglobin levels at term averaged 12.7 g/dL among women who took supplemental iron compared with 11.2 g/dL for those who did not. Bodnar and coworkers (2001) studied a cohort of 59,248 pregnancies and found a postpartum anemia prevalence of 27 percent that correlated both with prenatal anemia and hemorrhage at delivery.

The etiologies of the more common anemias encountered in pregnancy are listed in Table 56-1. The specific cause of anemia is important when evaluating effects on pregnancy outcome. For example, maternal and perinatal outcomes are seldom affected by moderate iron deficiency anemia, yet they are altered markedly in women with sickle-cell anemia.

Effects on Pregnancy Outcomes

Most studies of anemia during pregnancy describe large populations. As indicated, these likely deal with nutritional anemias, specifically those due to iron deficiency. Klebanoff and associates (1991) studied nearly 27,000 women and found a slightly increased risk of preterm birth with midtrimester anemia. Ren and colleagues (2007) found that a low first-trimester hemoglobin concentration increased the risk

of low birthweight, preterm birth, and small-for-gestational age infants. In a study from Tanzania, Kidanto and coworkers (2009) reported that the incidence of preterm delivery and low birthweight was increased as the severity of anemia increased. They did not, however, take into account the cause(s) of anemia, which was diagnosed in almost 80 percent of their obstetrical population. Kumar and colleagues (2013) studied 1000 Indian women and also found that second- and third-trimester anemia was associated with preterm birth and low birthweight. Chang and associates (2013) followed 850 children born to women classified as iron deficient in the third trimester. Children without iron supplementation had lower mental development at 12, 18, and 24 months of age, suggesting that prenatal iron deficiency is associated with mental development. Tran and associates (2014) reported similar findings from a Vietnamese study.

A seemingly paradoxical finding is that healthy pregnant women with a higher hemoglobin concentration are also at increased risk for adverse perinatal outcomes (von Tempelhoff, 2008). This may result from lower than average plasma volume expansion of pregnancy concurrent with normal red cell mass increase. Murphy and coworkers (1986) described more than 54,000 singleton pregnancies in the Cardiff Birth Survey and reported excessive perinatal morbidity with high maternal hemoglobin concentrations. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and preterm or growth-restricted infants in 173,031 pregnancies. Women whose hemoglobin concentration was three standard deviations above the mean at 12 or 18 weeks' gestation had 1.3- to 1.8-fold increases in the incidence of fetal-growth restriction. These findings have led some to the illogical conclusion that withholding iron supplementation to cause iron deficiency anemia will improve pregnancy outcomes (Ziaei, 2007).

Iron Deficiency Anemia

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss. The CDC (1989) estimated that as many as 8 million American women of childbearing age were iron deficient. In a study of more than 1300 women, 21 percent had third-trimester anemia with 16 percent due to iron deficiency anemia (Vandevijvere, 2013). In a typical singleton gestation, the maternal need for iron averages close to 1000 mg. Of this, 300 mg is for the fetus and placenta; 500 mg for maternal hemoglobin mass expansion; and 200 mg that is shed normally through the gut, urine, and skin. The total amount of 1000 mg considerably exceeds the iron stores of most women and results in iron deficiency anemia unless iron supplementation is given.

Iron deficiency is often manifested by an appreciable drop in hemoglobin concentration. In the third trimester, additional iron is needed to augment maternal hemoglobin and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn infant of a severely anemic mother does not suffer from iron deficiency anemia. As discussed in Chapter 33 (p. 643), neonatal iron stores are related to maternal iron status and to timing of cord clamping.

TABLE 56-1. Causes of Anemia During Pregnancy

Acquired

- Iron deficiency anemia
- Anemia caused by acute blood loss
- Anemia of inflammation or malignancy
- Megaloblastic anemia
- Acquired hemolytic anemia
- Aplastic or hypoplastic anemia

Hereditary

- Thalassemias
- Sickle-cell hemoglobinopathies
- Other hemoglobinopathies
- Hereditary hemolytic anemias

Diagnosis

Classic morphological evidence of iron deficiency anemia—erythrocyte hypochromia and microcytosis—is less prominent in the pregnant woman compared with that in the nonpregnant woman. Moderate iron deficiency anemia during pregnancy usually is not accompanied by obvious morphological changes in erythrocytes. Serum ferritin levels, however, are lower than normal, and there is no stainable bone marrow iron. Iron deficiency anemia during pregnancy is the consequence primarily of expansion of plasma volume without normal expansion of maternal hemoglobin mass.

The initial evaluation of a pregnant woman with moderate anemia should include measurements of hemoglobin, hematocrit, and red cell indices; careful examination of a peripheral blood smear; a sickle-cell preparation if the woman is of African origin; and measurement of serum iron or ferritin levels, or both. Expected values in pregnancy are found in the Appendix (p. 1287). Serum ferritin levels normally decline during pregnancy (Goldenberg, 1996). Levels less than 10 to 15 mg/L confirm iron deficiency anemia (American College of Obstetricians and Gynecologists, 2013a). Pragmatically, the diagnosis of iron deficiency in moderately anemic pregnant women usually is presumptive and based largely on exclusion.

When pregnant women with moderate iron deficiency anemia are given adequate iron therapy, a hematological response is detected by an elevated reticulocyte count. The rate of increase of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the increasing and larger blood volumes during pregnancy.

Treatment

Regardless of anemia status, daily oral supplementation with 30 to 60 mg of elemental iron and 400 µg of folic acid is recommended in pregnancy (Peña-Rosas, 2012; World Health Organization, 2012). Anemia resolution and restitution of iron stores can be accomplished with simple iron compounds—ferrous sulfate, fumarate, or gluconate—that provide about 200 mg daily of *elemental iron*. If a woman cannot or will not take oral iron preparations, then parenteral therapy is given. Although both are administered intravenously, ferrous sucrose has been shown to be safer than iron-dextran (American College of Obstetricians and Gynecologists, 2013a). There are equivalent increases in hemoglobin levels in women treated with either oral or parenteral iron therapy (Bayouneu, 2002; Sharma, 2004).

Anemia from Acute Blood Loss

In early pregnancy, anemia caused by acute blood loss is common with abortion, ectopic pregnancy, and hydatidiform mole. Anemia is much more common postpartum from obstetrical hemorrhage. Massive hemorrhage demands immediate treatment as described in Chapter 41 (p. 814). If a moderately anemic woman—defined by a hemoglobin value of approximately 7 g/dL—is hemodynamically stable, is able to ambulate without adverse symptoms, and is not septic, then blood transfusions are not indicated. Instead, iron therapy is given for at least 3 months (Krafft, 2005). In a randomized trial, Van Wyck and colleagues

(2007) reported that intravenous ferric carboxymaltose given weekly was as effective as thrice-daily oral ferrous sulfate tablets for hemoglobin regeneration for postpartum anemia.

Anemia Associated with Chronic Disease

Weakness, weight loss, and pallor have been recognized since antiquity as characteristics of chronic disease. Various disorders, such as chronic renal failure, cancer and chemotherapy, human immunodeficiency virus (HIV) infection, and chronic inflammation, result in moderate and sometimes severe anemia, usually with slightly hypochromic and microcytic erythrocytes. It is the second most common form of anemia worldwide (Weiss, 2005).

In nonpregnant patients with chronic inflammatory diseases, the hemoglobin concentration is rarely < 7 g/dL; bone marrow cellular morphology is not altered; and serum iron concentrations are decreased. However, ferritin levels usually are elevated. The low levels of iron are mediated by *hepcidin*, a polypeptide produced in the liver that participates in iron balance and transport (Weiss, 2005). These anemias share similar features that include alterations in reticuloendothelial function, iron metabolism, and decreased erythropoiesis (Cullis, 2013).

Pregnancy

Women with chronic disorders may develop anemia for the first time during pregnancy. In those with preexisting anemia, it may be intensified as plasma volume expands disproportionately to red cell mass expansion. Causes include chronic renal insufficiency, inflammatory bowel disease, and connective-tissue disorders. Others are granulomatous infections, malignant neoplasms, rheumatoid arthritis, and chronic suppurative conditions.

Of these, chronic renal insufficiency is the most common disorder that we have encountered as a cause of anemia during pregnancy. Some cases are accompanied by erythropoietin deficiency. As discussed in Chapter 53 (p. 1060), during pregnancy in women with mild chronic renal insufficiency, the degree of red cell mass expansion is inversely related to renal impairment. At the same time, plasma volume expansion usually is normal, and thus anemia is intensified (Cunningham, 1990). Anemia often accompanies acute pyelonephritis but is due to acute endotoxin-mediated erythrocyte destruction. With normal erythropoietin production, red cell mass is restored as pregnancy progresses (Cavenee, 1994; Dotters-Katz, 2013).

Treatment

Adequate iron stores must be ensured. *Recombinant erythropoietin* has been used successfully to treat chronic anemia (Weiss, 2005). In pregnancies complicated by chronic renal insufficiency, recombinant erythropoietin is usually considered when the hematocrit approximates 20 percent (Ramin, 2006). Cyganek and coworkers (2011) described good results in five pregnant renal transplant recipients treated with human recombinant erythropoietin. One worrisome side effect is hypertension, which is already prevalent in women with renal disease. In addition, Casadevall and colleagues (2002) reported pure red cell aplasia and antierythropoietin antibodies in 13 nonpregnant patients given recombinant human erythropoietin. Numerous additional cases have been reported. However,

because of changes in manufacturing and new regulations, it is an infrequent toxicity today (McKoy, 2008).

■ Megaloblastic Anemia

These anemias are characterized by blood and bone-marrow abnormalities from impaired DNA synthesis. Worldwide, the prevalence of megaloblastic anemia during pregnancy varies considerably. In the United States, it is rare.

Folic Acid Deficiency

In the United States, megaloblastic anemia beginning during pregnancy almost always results from folic acid deficiency. In the past, this condition was referred to as *pernicious anemia of pregnancy*. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often becomes intense and further aggravates the dietary deficiency. In some instances, excessive ethanol ingestion either causes or contributes to folate deficiency.

In nonpregnant women, the folic acid requirement is 50 to 100 µg/day. During pregnancy, requirements are increased, and 400 µg/day is recommended (Chap. 9, p. 181). The earliest biochemical evidence is low plasma folic acid concentrations (Appendix, p. 1287). Early morphological changes usually include neutrophils that are hypersegmented and newly formed erythrocytes that are macrocytic. With preexisting iron deficiency, macrocytic erythrocytes cannot be detected by measurement of the mean corpuscular volume. Careful examination of a peripheral blood smear, however, usually demonstrates some macrocytes. As the anemia becomes more intense, peripheral nucleated erythrocytes appear, and bone marrow examination discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta extract folate from maternal circulation so effectively that the fetus is not anemic despite severe maternal anemia. There have been instances in which newborn hemoglobin levels were 18 g/dL or more, whereas maternal values were as low as 3.6 g/dL (Pritchard, 1970). A Cochrane review by Lassi and associates (2013) evaluated the effectiveness of oral prenatal folic acid supplementation alone or with other micronutrients versus no folic acid. There was no conclusive evidence of supplement benefit for pregnancy outcomes that included preterm birth and perinatal mortality. There was, however, increased mean birthweight and a significant reduction in the incidence of megaloblastic anemia.

Treatment. Folic acid is given along with iron, and a nutritious diet is encouraged. As little as 1 mg of folic acid administered orally once daily produces a striking hematological response. By 4 to 7 days after beginning folic acid treatment, the reticulocyte count is increased, and leukopenia and thrombocytopenia are corrected.

Prevention. A diet sufficient in folic acid prevents megaloblastic anemia. The role of folate deficiency in the genesis of neural-tube defects has been well studied (Chap. 14, p. 283). Since the early 1990s, nutritional experts and the American College

of Obstetricians and Gynecologists (2013c) have recommended that all women of childbearing age consume at least 400 µg of folic acid daily. More folic acid is given in circumstances in which requirements are increased. These include multifetal pregnancy, hemolytic anemia, Crohn disease, alcoholism, and inflammatory skin disorders. There is evidence that women who previously have had infants with neural-tube defects have a lower recurrence rate if a daily 4-mg folic acid supplement is given preconceptionally and throughout early pregnancy.

Vitamin B₁₂ Deficiency

During pregnancy, vitamin B₁₂ levels are lower than nonpregnant values because of decreased levels of binding proteins that include haptocorrin—transcobalamins I and III—and transcobalamin II (Morkbak, 2007). During pregnancy, megaloblastic anemia is rare from deficiency of vitamin B₁₂, that is, cyanocobalamin. The typical example is *Addisonian pernicious anemia*, which results from absent intrinsic factor that is requisite for dietary vitamin B₁₂ absorption. This autoimmune disorder usually has its onset after age 40 years (Stabler, 2013).

In our limited experience, vitamin B₁₂ deficiency in pregnancy is more likely encountered following gastric resection. Those who have undergone total gastrectomy require 1000 µg of vitamin B₁₂ given intramuscularly each month. Those with a partial gastrectomy usually do not need supplementation, but adequate serum vitamin B₁₂ levels should be ensured during pregnancy (Appendix, p. 1290). Other causes of megaloblastic anemia from vitamin B₁₂ deficiency include Crohn disease, ileal resection, and bacterial overgrowth in the small bowel (Stabler, 2013).

■ Hemolytic Anemia

There are several conditions in which accelerated erythrocyte destruction is stimulated by a congenital red cell abnormality or by antibodies directed against red cell membrane proteins. The cause may also go unproven. In some cases, hemolysis may be the primary disorder—some examples include sickle-cell disease and hereditary spherocytosis. In other cases, hemolysis develops secondary to an underlying disorder—examples include lupus erythematosus and the preeclampsia syndrome.

Autoimmune Hemolysis

The cause of aberrant antibody production in this uncommon condition is unknown. Typically, both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes also may be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the latter include lymphomas and leukemias, connective-tissue diseases, infections, chronic inflammatory diseases, and drug-induced antibodies (Provan, 2000). *Cold-agglutinin disease* may be induced by infectious etiologies such as *Mycoplasma pneumoniae* or Epstein-Barr viral mononucleosis (Dhingra, 2007). Hemolysis and positive antiglobulin test results may be the consequence of either IgM or IgG antierythrocyte antibodies. Spherocytosis and reticulocytosis are characteristic of the

peripheral blood smear. When there is concomitant thrombocytopenia, it is termed *Evans syndrome* (Wright, 2013).

During pregnancy, there may be marked acceleration of hemolysis. This usually responds to glucocorticoids, and treatment is given with prednisone, 1 mg/kg given orally each day, or its equivalent. Coincidental thrombocytopenia usually is corrected by therapy. Transfusion of red cells is complicated by antierythrocyte antibodies, but warming the donor cells to body temperature may decrease their destruction by cold agglutinins.

Drug-Induced Hemolysis

These hemolytic anemias must be differentiated from other causes of autoimmune hemolysis. In most cases, hemolysis is mild, it resolves with drug withdrawal, and recurrence is prevented by avoidance of the drug. One mechanism is by hemolysis induced through drug-mediated immunological injury to red cells. The drug may act as a high-affinity hapten when bound to a red cell protein to which antidrug antibodies attach—for example, IgM antipenicillin or anticephalosporin antibodies. Some other drugs act as low-affinity haptens and adhere to cell membrane proteins—examples include probenecid, quinidine, rifampin, and thiopental. A more common mechanism for drug-induced hemolysis is related to a congenital erythrocyte enzymatic defect. An example is *glucose-6-phosphate dehydrogenase (G6PD) deficiency*, which is common in African American women (p. 1106).

Drug-induced hemolysis is usually chronic and mild to moderate, but occasionally there is severe acute hemolysis. For example, Garratty and coworkers (1999) described seven women with severe Coombs-positive hemolysis stimulated by cefotetan given as prophylaxis for obstetrical procedures. Alpha-methyldopa can cause similar hemolysis (Grigoriadis, 2013). Moreover, maternal hemolysis has been reported after intravenous immune globulin (IVIG) given for fetal and neonatal alloimmune thrombocytopenia (Rink, 2013). As treatment, response to glucocorticoids may be suboptimal, but withdrawal of the offending drug frequently halts the hemolysis.

Pregnancy-Induced Hemolysis

In some cases, unexplained severe hemolytic anemia develops during early pregnancy and resolves within months postpartum. There is no evidence of an immune mechanism or intraerythrocytic or extraerythrocytic defects (Starksen, 1983). Because the fetus-infant also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment is often—but not always—effective (Kumar, 2001). We have cared for a woman who during each pregnancy developed intense severe hemolysis with anemia that was controlled by prednisone. Her fetuses were not affected, and in all instances, hemolysis abated spontaneously after delivery.

Paroxysmal Nocturnal Hemoglobinuria

Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm (Nguyen, 2006). One mutated X-linked gene responsible for this condition is termed *PIG-A* because it codes for phosphatidylinositol glycan

protein A. Resultant abnormal anchor proteins of the erythrocyte and granulocyte membrane make these cells unusually susceptible to lysis by complement (Provan, 2000). The most serious complication is thrombosis, which is heightened in the hypercoagulable state of pregnancy.

Chronic hemolysis has an insidious onset, and its severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboses and may also experience renal failure, hypertension, and Budd-Chiari syndrome. Because of the thrombotic risk, prophylactic anticoagulation is recommended (Parker, 2005). Median survival after diagnosis is 10 years, and bone marrow transplantation is the definitive treatment. Successful treatment of nonpregnant patients has been reported with eculizumab, an antibody that inhibits complement activation (Hillmen, 2006; Parker, 2009). Kelly and colleagues (2010) described seven pregnant women exposed to eculizumab with successful outcomes.

During pregnancy, paroxysmal nocturnal hemoglobinuria can be serious and unpredictable. Complications have been reported in up to three fourths of affected women, and the maternal mortality rate is 10 to 20 percent (De Gramont, 1987). Complications more often develop postpartum, and half of affected women develop venous thrombosis during the puerperium (Fieni, 2006; Greene, 1983; Ray, 2000). In one report of 27 pregnancies in 22 women, the maternal mortality rate was 8 percent and related to postpartum thrombosis (de Guibert, 2011).

Severe Preeclampsia and Eclampsia

Fragmentation or microangiopathic hemolysis with thrombocytopenia is relatively common with severe preeclampsia and eclampsia (Kenny, 2014; Pritchard, 1976). Mild degrees are likely present in most cases of severe preeclampsia and may be referred to as *HELLP syndrome*—hemolysis, elevated liver enzymes, and low platelet count (Chap. 40, p. 742).

Acute Fatty Liver of Pregnancy

This syndrome is associated with moderate to severe hemolytic anemia (Nelson, 2013). It is discussed further in Chapter 55 (p. 1086).

Bacterial Toxins

The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* or by group A β -hemolytic streptococcus (Chap. 47, p. 949). Endotoxin of gram-negative bacteria, that is, lipopolysaccharide—especially with bacteremia from severe pyelonephritis—may be accompanied by hemolysis and mild to moderate anemia (Cox, 1991).

Inherited Erythrocyte Membrane Defects

The normal erythrocyte is a biconcave disc. Its shape allows numerous cycles of reversible deformations as the erythrocyte withstands arterial shearing forces and negotiates through splenic slits half the width of its cross-sectional diameter. Several genes encode expression of erythrocyte structural membrane proteins or intraerythrocytic enzymes. Various mutations of these genes

may result in inherited membrane defects or enzyme deficiencies that destabilize the lipid bilayer. The loss of lipids from the erythrocyte membrane causes a surface area deficiency and poorly deformable cells that undergo hemolysis. Anemia severity depends on the degree of rigidity or decreased distensibility. Erythrocyte morphology similarly is dependent on these factors, and these disorders are usually named after the most dominant red-cell shape characteristic of the disorder. Three examples are *hereditary spherocytosis*, *pyropoikilocytosis*, and *ovalocytosis*.

Hereditary Spherocytosis. Hemolytic anemias that comprise this group of inherited membrane defects are probably the most common identified in pregnant women. Mutations are usually an autosomally dominant, variably penetrant *spectrin* deficiency. Others are autosomally recessive or de novo gene mutations that result from deficiency of *ankyrin*, *protein 4.2*, *moderate band 3*, or combinations of these (Gallagher, 2010; Yawata, 2000). Clinically, varying degrees of anemia and jaundice result from hemolysis. Diagnosis is confirmed by identification of spherocytes on peripheral smear, reticulocytosis, and increased osmotic fragility (Fig. 56-2).

Spherocytic anemias may be associated with the so-called *crisis* that is characterized by severe anemia from accelerated hemolysis, and it develops in patients with an enlarged spleen. Infection can also accelerate hemolysis or suppress erythropoiesis to worsen anemia. An example of the latter is infection with parvovirus B19 (Chap. 64, p. 1244). In severe cases, splenectomy reduces hemolysis, anemia, and jaundice.

Pregnancy. In general, women with inherited red-cell membrane defects do well during pregnancy. Folic acid supplementation is given to sustain erythropoiesis. Pregnancy outcomes in women with hereditary spherocytosis cared for at Parkland Hospital were reported by Maberry and associates (1992). Twenty-three women with 50 pregnancies were described. In late pregnancy, these women had hematocrits ranging from 23 to 41 volume percent—mean 31. Their reticulocyte count ranged from 1 to 23 percent. Eight women miscarried. Four of 42 infants were born preterm, but none were growth restricted. Infection in four women intensified hemolysis, and three of these required transfusions. Similar results were reported by Pajor and coworkers (1993) in 19 pregnancies in eight women.

FIGURE 56-2 Scanning electron micrograph showing (A) normal-appearing erythrocytes from a heterozygous carrier of recessive spherocytosis, and (B) from her daughter, a homozygote with severe anemia. (From Agre, 1989, with permission.)

Because these disorders are inherited, the newborn may be affected. Celkan and Alhaj (2008) report prenatal diagnosis via cordocentesis at 18 weeks' gestation and testing for osmotic fragility. Those with hereditary spherocytosis may manifest hyperbilirubinemia and anemia shortly after birth.

Erythrocyte Enzyme Deficiencies

An intraerythrocytic deficiency of enzymes that permit anaerobic glucose metabolism may cause *hereditary nonspherocytic anemia*. Most of these mutations are autosomal recessive traits, and *pyruvate kinase deficiency* is probably the most clinically significant. Another is X-linked *glucose-6-phosphate dehydrogenase (G6PD) deficiency* (Puig, 2013). Other rare enzyme abnormalities may cause varying degrees of chronic hemolysis. As discussed on page 1105, most episodes of severe anemia with enzyme deficiencies are induced by drugs or infections. During pregnancy, oxidant drugs are avoided, infections are treated promptly, and iron and folic acid are given.

Pyruvate kinase deficiency is associated with variable anemia and hypertensive complications (Wax, 2007). Due to recurrent transfusions in homozygous carriers, iron overload is frequent, and associated myocardial dysfunction should be monitored (Dolan, 2002). The fetus that is homozygous for this mutation may develop *hydrops fetalis* from anemia and heart failure (Chap. 15, p. 315). Gilsanz and colleagues (1993) used funipuncture to diagnose fetal anemia and pyruvate kinase deficiency.

Glucose-6-phosphate dehydrogenase deficiency is complex because there are more than 400 known enzyme variants. The most common are caused by a base substitution that leads to an amino acid replacement and a broad range of phenotypic severity (Beutler, 1991; Puig, 2013). In the homozygous or A variant, both X chromosomes are affected, and erythrocytes are markedly deficient in G6PD activity. Approximately 2 percent of African American women are affected. The heterozygous variant that is found in 10 to 15 percent of African American women may confer some degree of protection against malaria (Mockenhaupt, 2003). In both instances, random X-chromosome inactivation—*lyonization*—results in a variable deficiency of enzyme activity.

During pregnancy, infections or drugs can induce hemolysis in both heterozygous and homozygous women, and the severity is related to enzyme activity. Anemia is usually episodic, although some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity than older erythrocytes, in the absence of bone marrow depression, anemia ultimately stabilizes and is corrected soon after the inciting cause is eliminated. Newborn screening for G6PD deficiency is not recommended by the American College of Medical Genetics (2013) as discussed in Chapter 32 (Table 32-3, p. 632).

Aplastic and Hypoplastic Anemia

Although rarely encountered during pregnancy, aplastic anemia is a grave complication. It is characterized by pancytopenia and markedly hypocellular bone marrow (Young, 2008). There are multiple etiologies, and at least one is linked to autoimmune diseases (Stalder, 2009). The inciting cause can be identified in

approximately a third of cases. These include drugs and other chemicals, infection, irradiation, leukemia, immunological disorders, and inherited conditions such as *Fanconi anemia* and *Diamond-Blackfan syndrome* (Green, 2009; Lipton, 2009). The functional defect appears to be a marked decrease in committed marrow stem cells.

Hematopoietic stem-cell transplantation is optimal therapy in a young patient (Young, 2008). Immunosuppressive therapy is given. In some nonresponders, *eltrombopag* has been used successfully (Olmes, 2012). Definitive treatment is bone marrow transplantation, and approximately three fourths of patients have a good response with long-term survival when treated with antithymocyte globulin and cyclosporine (Rosenfeld, 2003). There is a potential for transplantation with umbilical cord blood-derived stem cells (Moise, 2005; Pinto, 2008). Previous blood transfusions and even pregnancy enhance the risk of graft rejection, which is the most common serious complication, causing two thirds of deaths within the first 2 years (Socié, 1999).

Pregnancy

Hypoplastic or aplastic anemia complicating pregnancy is rare. In most cases, the diagnosis precedes conception, or the condition develops during pregnancy as a chance occurrence. That said, there are a few well-documented cases of *pregnancy-induced hypoplastic anemia* (Bourantas, 1997; Choudhry, 2002). We have cared for a few such women in whom hypoplastic anemia was first identified during a pregnancy. Anemia and other cytopenias improved or remitted following delivery or pregnancy termination. In some cases, recurrence in a subsequent pregnancy was documented.

Diamond-Blackfan anemia is a rare form of pure red-cell hypoplasia, and approximately 40 percent are familial and have autosomal dominant inheritance (Orfali, 2004). There is usually a good response to glucocorticoid therapy. However, continuous treatment is necessary, and most become at least partially transfusion dependent (Vlachos, 2008). In 64 pregnancies complicated by this syndrome, Faivre and associates (2006) reported that two thirds had complications related to placental vascular etiologies that included miscarriage, preeclampsia, preterm birth, stillbirth, or growth-restricted newborn.

Gaucher disease is an autosomally recessive lysosomal enzyme deficiency characterized by deficient *acid β -glucosidase* activity. It involves multiple systems, including bone marrow. Affected women have anemia and thrombocytopenia that is usually worsened by pregnancy (Granovsky-Grisaru, 1995). Elstein and colleagues (1997) described six pregnant women whose disease improved when they were given *alglucerase* enzyme replacement. Imiglucerase therapy, which is human recombinant enzyme replacement therapy, has been available since 1994. European guidelines recommend treatment in pregnancy, whereas the Food and Drug Administration states it may be given in pregnancy with “clear indications” (Granovsky-Grisaru, 2011).

The major risks to pregnant woman with hypoplastic anemia are hemorrhage and infection. Management depends on gestational age, disease severity, and whether treatment has been given. Supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are

given only during infections. Red cells are transfused to improve symptomatic anemia and routinely to maintain the hematocrit at or above 20 volume percent. Platelet transfusions may be needed to control hemorrhage. Even when thrombocytopenia is intense, the risk of severe hemorrhage can be minimized by vaginal rather than cesarean delivery. Maternal mortality rates reported since 1960 have averaged nearly 50 percent (Choudhry, 2002). Better outcomes are reported with more recent series (Kwon, 2006).

Pregnancy after Bone Marrow Transplantation

There have been several reports of successful pregnancies in women who have undergone bone marrow transplantation (Borgna-Pignatti, 1996; Eliyahu, 1994). In their review, Sanders and coworkers (1996) reported 72 pregnancies in 41 women who had undergone transplantation. In the 52 pregnancies resulting in a liveborn infant, almost half were complicated by preterm delivery or hypertension. Our experiences with a few of these women indicate that they have normal pregnancy-augmented erythropoiesis and total blood volume expansion.

POLYCYTHEMIAS

Secondary Polycythemia

Excessive erythrocytosis during pregnancy is usually related to chronic hypoxia from maternal congenital cardiac disease or a chronic pulmonary disorder. Unusually heavy cigarette smoking can cause polycythemia. We have encountered otherwise healthy pregnant women who were heavy smokers, had chronic bronchitis, and had hematocrits ranging from 55 to 60 volume percent! Brewer and colleagues (1992) described a woman with persistent erythrocytosis associated with a placental site tumor. If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia Vera

This is a primary myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. It is uncommon and likely an acquired genetic disorder of stem cells (Spivak, 2008). Virtually all patients have either a *JAK2V617F* or a *JAK2* exon 12 gene mutation (Harrison, 2009). Serum erythropoietin level measurement is helpful to differentiate polycythemia vera—low values—from secondary erythrocytosis—high values. Symptoms are related to increased blood viscosity, and thrombotic complications are common. Fetal loss has been reported to be high in women with polycythemia vera, and pregnancy outcome may be improved with aspirin therapy (Griesshammer, 2006; Robinson, 2005; Tefferi, 2000).

HEMOGLOBINOPATHIES

Sickle-Cell Hemoglobinopathies

Hemoglobin A is the most common hemoglobin tetramer and consists of two α - and two β -chains. In contrast, sickle hemoglobin (hemoglobin S) originates from a single β -chain

substitution of glutamic acid by valine, which stems from an A-for-T substitution at codon 6 of the β -globin gene. Hemoglobinopathies that can result in clinical features of the *sickle-cell syndrome* include sickle-cell anemia—Hb SS; sickle cell-hemoglobin C disease—Hb SC; sickle cell- β -thalassemia disease—either Hb S/B⁰ or Hb S/B⁺; and sickle-cell E disease—Hb SE (Stuart, 2004). All are also associated with increased maternal and perinatal morbidity and mortality.

Inheritance

Sickle-cell anemia originates from the inheritance of the gene for S hemoglobin from each parent. In the United States, 1 of 12 African Americans has sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African Americans is 1 in 576 ($1/12 \times 1/12 \times 1/4 = 1/576$). But, the disease is less common in adults and therefore during pregnancy because of earlier mortality, especially during early childhood.

Hemoglobin C originates from a single β -chain substitution of glutamic acid by lysine at codon 6 of the β -globin gene. Approximately 1 in 40 African Americans has the gene for hemoglobin C. Thus, the theoretical incidence for coinheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African American child is about 1 in 2000 ($1/12 \times 1/40 \times 1/4$). β -Thalassemia minor is approximately 1 in 40, thus S- β -thalassemia also is found in approximately 1 in 2000 ($1/12 \times 1/40 \times 1/4$).

Pathophysiology

Red cells with hemoglobin S undergo sickling when they are deoxygenated, and the hemoglobin aggregates. Constant sickling and unsickling cause membrane damage, and the cell may become irreversibly sickled. Events that slow erythrocyte transit through the microcirculation contribute to vasoocclusion. These include endothelial cell adhesion, erythrocytic dehydration, and vasomotor dysregulation. Clinically, the hallmarks of sickling episodes are periods during which there is ischemia and infarction in various organs. These produce clinical symptoms, predominately pain, which is often severe—the *sickle-cell crisis*. There may be aplastic, megaloblastic, sequestration, and hemolytic crises.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients and splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, pulmonary hypertension, cerebrovascular accidents, leg ulcers, and a propensity for infection and sepsis (Driscoll, 2003; Gladwin, 2004; Stuart, 2004). Of increasing importance is acquisition of pulmonary hypertension, which can be demonstrated in 20 percent of adults with SS hemoglobin (Gladwin, 2008). Depending on its severity, this complication increases the relative risk for death from four- to 11-fold. Another emerging problem with improved survival is chronic sickle-cell disease nephropathy (Maigne, 2010). The median age at death for women is 48 years. Even so, Serjeant and associates (2009) described a cohort of 102 patients followed since birth in which 40 were still alive at 60 to 87 years!

Treatment

Good supportive care is essential to prevent mortality in patients with sickle-cell syndromes. Specific therapies are evolving, and many are still experimental (Stuart, 2004). One treatment is hemoglobin F induction given for both sickling and thalassemia syndromes. These drugs stimulate gamma-chain synthesis. This increases hemoglobin F (fetal hemoglobin), which inhibits hemoglobin S polymerization. One inducing agent, *hydroxyurea*, when given to patients with moderate to severe disease, increases hemoglobin F production and mitigates erythrocyte membrane damage. This reduces the number of clinical sickling episodes (Platt, 2008). It is not known yet if hydroxyurea increases long-term patient survival (Brawley, 2008). Hydroxyurea is teratogenic in animals, although a preliminary 17-year surveillance of antenatally exposed children was reassuring (Ballas, 2009; Briggs, 2011; Italia, 2010).

Various forms of hemopoietic cell transplantation are emerging as “cures” for sickle-cell syndromes and severe thalassemias (Hsieh, 2009). Oringanje and coworkers (2009) performed a Cochrane Review and found that only observational studies have been reported. *Bone marrow transplantation*, as discussed on page 1107, has 5-year survival rates that exceed 90 percent (Dalle, 2013). *Cord-blood stem-cell transplantation* from related donors has also shown great promise (Shenoy, 2013). One intriguing treatment uses cells taken for prenatal diagnosis from a fetus destined to have sickle-cell anemia. Research suggests these cells can be conditioned to produce hemoglobin A and used for replacement after birth (Ye, 2009).

Pregnancy and Sickle-Cell Syndromes

Pregnancy is a serious burden to women with any of the major sickle hemoglobinopathies, particularly those with hemoglobin SS disease. Two large studies define this relationship. The first, by Villers and colleagues (2008), included 17,952 births delivered of women with sickle-cell syndromes from 2000 through 2003. The second study, by Chakravarty and associates (2008), was from 2002 through 2004 and included 4352 pregnancies. A more recent cohort study of 1526 women was reported by Boulet and coworkers (2013). Common obstetrical and medical complications and their relative risks from these studies are shown in [Table 56-2](#). Added to these are findings of Chakravarty and associates (2008), who reported significantly increased risks for renal failure, gestational hypertension, and fetal-growth restriction.

Maternal morbidity common in pregnancy includes ischemic necrosis of multiple organs, especially bone marrow, that causes episodes of severe pain. Pyelonephritis, pneumonia, and other pulmonary complications are frequent. The *acute chest syndrome* is manifest by the radiological appearance of a new pulmonary infiltrate accompanied by fever and respiratory symptoms. There are four precipitants of this—infection, marrow emboli, thromboembolism, and atelectasis (Medoff, 2005). Of these, infection causes approximately half of cases and results from typical bacteria and viruses. When the chest syndrome develops, the mean duration of hospitalization is 10.5 days. Mechanical ventilation is required in approximately 15 percent, and the mortality rate is about 3 percent (Gladwin, 2008).

TABLE 56-2. Increased Rates for Maternal Complications in Pregnancies Complicated by Sickle-Cell Syndromes

Complications	OR or PR	p value
Preexisting Medical Disorders		
Cardiomyopathy	3.7	< .001
Pulmonary hypertension	6.3	< .001
Renal failure	3.5–6.4	< .05
Pregnancy Complications		
Cerebral vein thrombosis	4.9–7.9	< .05
Pneumonia	9.8–17	< .001
Pyelonephritis	1.3–2.1	< .05
Deep-vein thrombosis	2.5–7.8	< .001
Pulmonary embolism	1.7–10.3	< .05
Sepsis syndrome	5.3–6.8	< .001
Delivery Complications		
Gestational hypertension/ preeclampsia	1.2	.01
Eclampsia	2.3–3.2	< .05
Placental abruption	1.1–1.6	< .05
Preterm delivery	1.4	< .001
Fetal-growth restriction	2.2	< .001

OR = odds ratios; PR = prevalence ratio.

Data from Boulet, 2013; Villers, 2008.

Despite these complications, the maternal mortality rate has decreased. And although improved, perinatal morbidity and mortality rates remain formidable (Yu, 2009). Some perinatal outcomes reported since 2000 are shown in Table 56-3. In addition to increased risks for preterm birth shown in Table 56-2, the frequency of fetal-growth restriction and perinatal mortality are daunting.

Hemoglobin SC

In nonpregnant women, morbidity and mortality rates from SC disease are appreciably lower than those from sickle-cell anemia. Indeed, fewer than half of women with SC disease have symptoms before pregnancy. In our experiences, affected pregnant and puerperal women suffer attacks of severe bone pain and episodes of pulmonary infarction and embolization—acute chest syndrome—more commonly compared with when they are not pregnant (Cunningham, 1983). It is arguable whether SC disease has a maternal mortality rate equivalent to that of hemoglobin SS disease (Pritchard, 1973; Serjeant, 2005). In the reports shown in Table 56-3, the perinatal mortality rate is somewhat greater than that of the general obstetrical population, but nowhere as great as with sickle-cell anemia (Tita, 2007).

Management During Pregnancy

Women with sickle-cell hemoglobinopathies require close prenatal observation. These women maintain hemoglobin mass by intense hemopoiesis to compensate for the markedly shortened erythrocyte life span. Thus, any factor that impairs erythropoiesis or increases red cell destruction or both aggravates the anemia. Prenatal folic acid supplementation with 4 mg daily is

TABLE 56-3. Perinatal Outcomes in Women with Hemoglobin SS and SC Disease

Study	Number ^a	Perinatal Outcomes (%)			
		FGR	SB	ND	PMR
Sun (2001)

needed to support the rapid red blood cell turnover (American College of Obstetricians and Gynecologists, 2013b).

One danger is that a symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. Some examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. Thus, the term “sickle-cell crisis” importantly should be applied only after all other possible causes of pain or fever or worsening anemia have been excluded. Pain with sickle-cell syndromes is caused by intense sequestration of sickled erythrocytes and infarction in various organs. These episodes may develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium. Because bone marrow is frequently involved, intense bone pain is common.

A system for care of these women has been appropriately stressed by Rees and colleagues (2003). Marti-Carvajal and coworkers (2009) performed a Cochrane review and reported that no randomized trials have evaluated treatment during pregnancy. At minimum, intravenous fluids are given and opioids administered promptly for severe pain. Oxygen via nasal cannula may decrease the intensity of sickling at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically improve the intensity of the current pain crisis and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent further vasoocclusive episodes and pain crises. Recent reports suggest benefits from epidural analgesia used for severe sickle-cell crisis in nonlaboring obstetrical patients (Verstraete, 2012; Winder, 2011).

During the past few years, we have encountered several affected women who apparently are habituated to narcotics given chronically to alleviate sickle-cell pain. It is problematic that such women complain of “sickling pain” even when they have effectively undergone exchange transfusion with normal AA-hemoglobin-containing donor red cells.

Rates of covert bacteriuria and acute pyelonephritis are increased substantively, and screening and treatment for bacteriuria are essential. If pyelonephritis develops, sickle cells are extremely susceptible to bacterial endotoxin, which can cause dramatic and rapid red cell destruction while simultaneously suppressing erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae*, is common. The CDC (2013a) recommends the following vaccines for those with sickle-cell disease and all asplenic patients: polyvalent pneumococcal, *Haemophilus influenzae* type B, and meningococcal vaccines.

Pulmonary complications are often encountered. *Acute chest syndrome* is characterized by pleuritic chest pain, fever, cough, lung infiltrates, and hypoxia, and usually also by bone and joint pain (Vichinsky, 2000). The spectrum of its pathology includes infection, infarction, pulmonary sequestration, and fat embolization from bone marrow. At least for nonpregnant adults, some recommend rapid simple or exchange transfusions to remove the “trigger” for acute chest syndromes (Gladwin, 2008). In a cohort study of nonpregnant patients, Turner and colleagues (2009) reported that there were no increased benefits of exchange versus simple transfusions, and the former were associated with fourfold increased blood usage. Recurrent episodes of acute chest syndrome may lead to restrictive chronic lung disease or arteriolar vasculopathy and pulmonary hypertension.

Pregnant women with sickle-cell anemia usually have some degree of *cardiac dysfunction* from ventricular hypertrophy. There is increased preload, decreased afterload, normal ejection fraction, and a high cardiac output. Chronic hypertension worsens this pattern (Gandhi, 2000). During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham, 1986). As discussed in Chapter 49 (p. 986), heart failure caused by pulmonary hypertension must also be considered (Chakravarty, 2008; Stuart, 2004).

In the review of 4352 pregnancies in women with sickle-cell syndromes noted earlier, Chakravarty and associates (2008) reported significantly increased pregnancy complications compared with the total population of 11.2 million women. Compared with controls, women with sickling disorders had a 63-percent rate of nondelivery-related admissions. They had a 1.8-fold increased incidence of hypertensive disorders—19 percent; a 2.9-fold increased rate of fetal-growth restriction—6 percent; and a 1.7-fold increased cesarean delivery rate—45 percent.

Prophylactic Red Cell Transfusions. There are several clinical situations for which prophylactic transfusions have been shown to decrease morbidity from sickle-cell syndromes. For example, chronic transfusion therapy prevents strokes in high-risk children. However, there are no randomized trials of such therapy to prevent pulmonary hypertension and chronic sickle-

cell lung disease (Cho, 2014). Preoperative transfusions improved some postoperative outcomes (Howard, 2013). During pregnancy, the most dramatic impact of prophylactic transfusions has been on maternal morbidity. In an observational 10-year prospective study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Transfusions were given throughout pregnancy to maintain the hematocrit above 25 volume percent and the portion of hemoglobin S below 60 percent (Cunningham, 1979). There was minimal maternal morbidity, and erythropoiesis suppression was not problematic. Their outcomes were compared with historical controls who were not routinely transfused. Morbidity and hospitalizations were significantly reduced in the transfused group (Cunningham, 1983). Others have reported similar data (Grossetti, 2009; Howard, 1995). Still, adverse perinatal outcomes are prevalent (Ngô, 2010).

In a multicenter trial, Koshy and coworkers (1988) randomly assigned 72 pregnant women with sickle-cell syndrome to prophylactic or indicated transfusions. They reported a significant decline in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not necessary.

There is no doubt that morbidity from multiple transfusions is significant. Up to 10 percent of women had a delayed hemolytic transfusion reaction, and infections are major concerns (Garratty, 1997). From our experiences from Parkland Hospital cited above, we found the incidence of red cell alloimmunization to be 3 percent per unit of blood transfused (Cox, 1988). Similarly, in 12 studies reviewed by Garratty (1997), alloimmunization developed in a fourth of women undergoing chronic transfusions. According to Kacker and colleagues (2014), it is not cost effective to extensively match blood donors for these women. Finally, although worrisome, we found no evidence of transfusional iron overload, hemochromatosis, or chronic hepatitis in liver biopsies performed in 40 women transfused during pregnancy (Yeomans, 1990).

Because of what some consider marginal benefits, routine prophylactic transfusions during pregnancy remain controversial (American College of Obstetricians and Gynecologists, 2013b). Similar conclusions were reached after a Cochrane Database analysis (Okusayna, 2013). Current consensus is that their use should be individualized. For example, some clinicians recommend prophylactic transfusions for women with either frequent vasoocclusive episodes or poor obstetrical outcomes (Castro, 2003).

Fetal Assessment. Because of the high incidence of fetal-growth restriction and perinatal mortality, serial fetal assessment is necessary. According to the American College of Obstetricians and Gynecologists (2013b), a plan for serial sonographic examinations and antepartum fetal surveillance is reasonable. Anyaegbunam and colleagues (1991) evaluated fetal well-being during 39 sickling crises in 24 women. Almost 60 percent had nonreactive stress tests, which became reactive with crisis resolution, and all had an increased uterine artery systolic-diastolic (S/D) ratio. At the same time, there were no changes in umbilical artery S/D ratios (Chap. 10, p. 219). These investigators concluded that transient effects of sickle-cell

crisis do not compromise umbilical, and hence fetal, blood flow. At Parkland Hospital, we serially assess these women with sonography for fetal growth and amniotic fluid volume changes. Nonstress or contraction stress tests are not done routinely unless complications such as fetal-growth restriction develop or fetal movement is reported to be diminished.

Labor and Delivery. Management is essentially identical to that for women with cardiac disease (Chap. 49, p. 978). Women should be kept comfortable but not oversedated. Labor epidural analgesia is ideal, and conduction analgesia seems preferable for operative delivery (Camous, 2008). Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated, and the hematocrit is < 20 volume percent, then packed erythrocyte transfusions are administered. There is no categorical contraindication to vaginal delivery, and cesarean delivery is reserved for obstetrical indications (Rogers, 2010). Circulatory overload and pulmonary edema from ventricular failure should be avoided.

Contraception and Sterilization

Because of chronic debility, complications caused by pregnancy, and the predictably shortened life span of women with sickle-cell anemia, contraception and possibly sterilization are important considerations. Many clinicians do not recommend combined hormonal pills because of potential adverse vascular and thrombotic effects. After a systematic review, however, it was concluded that there was no increase in complications with their use in women with sickle-cell syndromes (Haddad, 2012). The CDC (2013b) regards the contraceptive pill, patch, and ring along with the copper intrauterine device (IUD) as having “advantages that generally outweigh theoretical or proven risks.” All progestin-only methods may be used without restrictions. Because progesterone has been long known to prevent painful sickle-cell crises, low-dose oral progestins or progesterone injections or implants seem ideal. In one study, de Abood and associates (1997) reported significantly fewer and less intense pain crises in women given depot medroxyprogesterone intramuscularly.

Sickle-Cell Trait

The heterozygous inheritance of the gene for hemoglobin S results in sickle-cell trait, or AS hemoglobin. Hemoglobin A is most abundant, and the amount of hemoglobin S averages approximately 30 percent in each red cell. The frequency of sickle-cell trait among African Americans averages 8 percent. There is evidence that carriers have occasional hematuria, renal papillary necrosis, and hyposthenuria (Tsaras, 2009). And although controversial, we believe that sickle-cell trait is not associated with increased rates of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard, 1973; Tita, 2007; Tuck, 1983). One unquestioned relationship is the twofold increased incidence of asymptomatic bacteriuria and urinary infection. Sickle-cell trait therefore should not be considered a deterrent to pregnancy on the basis of increased maternal risks.

Preliminary findings from a cohort study by Austin and coworkers (2009) suggested that African American women

with sickle trait may have a higher incidence of venous thromboembolism when using hormonal contraceptives compared with women without the trait. However, more data are needed before these effective contraceptive methods are withheld from trait-positive women.

Inheritance is a concern for the infant of a mother with sickle-cell trait whenever the father carries a gene for abnormal hemoglobins that include S, C, and D or for β -thalassemia trait. Prenatal diagnosis through amniocentesis, chorionic villus sampling (CVS), or preimplantation genetic evaluation is available (Chap. 14, p. 297).

Hemoglobin C and C- β -Thalassemia

Approximately 2 percent of African Americans are heterozygous for hemoglobin C, but even if homozygous, hemoglobin C is innocuous (Nagel, 2003). Neither cause severe anemia or adverse pregnancy outcomes. However, when coinherited with sickle-cell trait, hemoglobin SC is the second most common serious sickle-cell syndrome.

Pregnancy and homozygous hemoglobin CC disease or hemoglobin C- β -thalassemia are relatively benign associations. Maberry and colleagues (1990) reported our experiences from Parkland Hospital as shown in Table 56-4. Other than mild to moderate anemia, pregnancy outcomes were not different compared with those of the general obstetrical population. When severe anemia is identified, iron or folic acid deficiency or some other superimposed cause should be suspected. Supplementation with folic acid and iron is indicated.

Hemoglobin E

Although it is uncommon in the United States, hemoglobin E is the second most frequent hemoglobin variant worldwide. Hemoglobin E results from a single β -chain substitution of lysine for glutamic acid at codon 26. The hemoglobin is particularly susceptible to oxidative stress. The heterozygous E trait is common in Southeast Asia. Hurst and coworkers (1983) identified homozygous hemoglobin E, hemoglobin E plus β -thalassemia, or hemoglobin E trait in 36 percent of Cambodians and 25 percent of Laotians. In addition, α - and β -thalassemia traits were prevalent in all groups.

Homozygous hemoglobin EE is associated with little or no anemia, hypochromia, marked microcytosis, or erythrocyte

targeting. In our limited experience, pregnant women do not appear to be at increased risk. Conversely, doubly heterozygous hemoglobin E- β -thalassemia is a common cause of childhood anemia in Southeast Asia (Fucharoen, 2000). In a cohort study of 54 women with singleton pregnancies, Luewan and associates (2009) reported a threefold increased risk of preterm birth and fetal-growth restriction in affected women. It is unclear if hemoglobin SE disease is as ominous during pregnancy as hemoglobin SC or S- β -thalassemia disease (Ramahi, 1988).

Hemoglobinopathy in the Newborn

Infants with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The United States Preventive Services Task Force recommends that all newborn infants be tested for sickle-cell disease (Lin, 2007). In most states, such screening is mandated by law and performed routinely (Chap. 32, p. 632). Screening for sickle hemoglobinopathies leads to clearly decreased mortality rates in children with sickle-cell disease identified at birth.

Prenatal Diagnosis

There are many tests to detect sickle-cell disease prenatally. Most are DNA based and use CVS samples or amniotic fluid specimens (American College of Obstetricians and Gynecologists, 2013b). Several mutations that encode hemoglobin S and other abnormal hemoglobins can be detected by targeted mutation analysis as well as polymerase chain reaction-based techniques (Chap. 13, p. 277).

THALASSEMIA SYNDROMES

Hundreds of mutations have been described for genes that control production of the normal hemoglobins. Some of these mutations impair synthesis of one or more of the normal globin peptide chains and may result in a clinical syndrome characterized by varying degrees of ineffective erythropoiesis, hemolysis, and anemia. Thalassemias are classified according to the globin chain that is deficient. The two major forms involve impaired production or instability of α -peptide chains—causing α -thalassemia, or of β -chains—causing β -thalassemia. These

may form from point mutations, deletions, or translocations involving the α - or non- α -globin gene. The estimated prevalence for thalassemia trait is 16 percent in Southern European, 10 percent in Thai, and 3 to 8 percent in Indian and Chinese populations (Leung, 2012).

Alpha Thalassemias

Because there are four α -globin genes, the inheritance of α -thalassemia is more complicated than for β -thalassemia (Weatherall, 2010). Possible genotypes and phenotypes arising from these mutations are shown in Table 56-5. For each, a close correlation has been established between clinical severity and the degree of α -globin chains synthesis impairment. In most populations, the α -globin chain “cluster” or gene loci are doubled on chromosome 16. Thus, the normal genotype for diploid cells can be expressed as $\alpha\alpha/\alpha\alpha$. There are two main groups of α -thalassemia determinants: α^0 -thalassemia is characterized by the deletion of both loci from one chromosome ($--/\alpha\alpha$), whereas α^+ -thalassemia is characterized by the loss of a single locus from one allele ($-\alpha/\alpha\alpha$ heterozygote) or a loss from each allele alleles ($-\alpha/-\alpha$ homozygote).

There are two major phenotypes. The deletion of all four α -globin chain genes ($--/--$) characterizes *homozygous* α -thalassemia. Because α -chains are contained in fetal hemoglobin, the fetus is affected. With none of the four genes expressed, there are no α -globin chains, and instead, hemoglobin Bart (γ_4) and hemoglobin H (β_4) are formed as abnormal tetramers (Chap. 7, p. 137).

Frequency

The relative frequency of α -thalassemia minor, hemoglobin H disease, and hemoglobin Bart disease varies remarkably among racial groups. All of these variants are encountered in Asians. In those of African descent, although α -thalassemia minor has a frequency of approximately 2 percent, hemoglobin H disease is rare and hemoglobin Bart disease is unreported. This is because Asians usually have α^0 -thalassemia minor inherited with both gene deletions typically from the same chromosome ($--/\alpha\alpha$), whereas blacks usually have α^+ -thalassemia minor in which one gene is deleted from each chromosome ($-\alpha/-\alpha$). The α -thalassemia syndromes appear sporadically in other

TABLE 56-5. Genotypes and Phenotypes of α -Thalassemia Syndromes

racial and ethnic groups. Diagnosis of β -thalassemia minor and α -thalassemia major in the fetus can be accomplished by DNA analysis using molecular techniques (American College of Obstetricians and Gynecologists, 2013b). Fetal diagnosis of hemoglobin Bart has been described using capillary electrophoresis or high-performance liquid chromatography (HPLC) techniques (Sirichotiyakul, 2009; Srivorakun, 2009). Molecular genetic testing for *HBA1* and *HBA2* identifies 90 percent of deletions and 10 percent of point mutations in affected individuals (Galanello, 2011b).

Pregnancy

Important obstetrical aspects of some α -thalassemia syndromes depend on the number of gene deletions in a given woman. The silent carrier state with one gene deletion is of no consequence. Deletion of two genes resulting in *α -thalassemia minor* is characterized by minimal to moderate hypochromic microcytic anemia. This is due to either the α^0 - or the α^+ -thalassemia trait, and thus genotypes may be $-\alpha/-\alpha$ or $-\alpha/\alpha$. Differentiation is possible only by DNA analysis (Weatherall, 2000a,b). Because there are no other clinical abnormalities with either α -thalassemia minor, it often goes unrecognized and is usually of no maternal consequence. The fetus with these forms of thalassemia minor will have hemoglobin Bart at birth, but as its levels drop, it is not replaced by hemoglobin H. Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed.

Hemoglobin H disease (β_4) results from the compound heterozygous state for α^0 - plus α^+ -thalassemia with deletion of three of four alpha genes ($---/-\alpha$). With only one functional α -globin gene per diploid genome, the newborn will have abnormal red cells containing a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. The neonate appears normal but soon develops hemolytic anemia as most of the hemoglobin Bart is replaced by hemoglobin H. Anemia is moderate to severe, and it usually worsens during pregnancy.

Inheritance of all four abnormal alpha genes causes homozygous α -thalassemia with predominant production of hemoglobin Bart, which has an appreciably increased affinity for oxygen. This is incompatible with extended survival, and stillbirths caused by the homozygous condition are especially common in Southeast Asia. Hsieh and colleagues (1989) reported that blood obtained by funipuncture from 20 hydropic fetuses contained 65 to 98 percent Bart hemoglobin. Either these fetuses are stillborn, or they die very soon after birth and have the typical features of nonimmune hydrops fetalis shown in Figure 16-4 (p. 330).

Lam and associates (1999) reported that sonographic measurement of the fetal cardiothoracic ratio at 12 to 13 weeks' gestation was 100-percent sensitive and specific for identifying affected fetuses. Sonographic evaluation of the myocardial performance index—the *Tei index*—in the first half of pregnancy has been evaluated. Changes predating hydrops are seen in affected fetuses (Luewan, 2013). Severe anemia can be detected using Doppler velocimetry of the middle cerebral artery (Chap. 10, p. 221). Although a successful case of hemopoietic cell transplantation with a fetal “cure” has been described, this remains experimental (Galanello, 2011a; Yi, 2009).

Beta Thalassemias

The β -thalassemias are the consequences of impaired β -globin chain production or α -chain instability. Genes that encode control of β -globin synthesis are in the $\delta\gamma\beta$ -gene “cluster” located on chromosome 11 (Fig. 7-10, p. 138). More than 150 point mutations in the β -globin gene have been described (Weatherall, 2010). Most are single-nucleotide substitutions that produce transcriptional or translational defects, RNA splicing or modification, or frameshifts that result in highly unstable hemoglobins. Thus, deletional and nondeletional mutations affect β -globin RNA. In β -thalassemia, there is decreased β -chain production, and excess α -chains precipitate to cause cell membrane damage. Other forms of β -thalassemias are caused by α -chain instability (Kihm, 2002). Because of the variety of genetic defects and their combinations with genes that code for globin chain synthesis, these are collectively referred to as thalassemia syndromes (Weatherall, 2010).

The heterozygous trait is *β -thalassemia minor*, and those most commonly encountered have elevated hemoglobin A₂ levels. This hemoglobin is composed of two α - and two δ -globin chains, and concentrations are usually more than 3.5 percent. Hemoglobin F—composed of two α - and two γ -globin chains—also usually has increased concentrations of more than 2 percent. Some patients with heterozygous β -thalassemia minor do not have anemia, and others have mild to moderate anemia characterized by hypochromia and microcytosis.

Homozygous β -thalassemia—also called *β -thalassemia major* or *Cooley anemia*—is a serious and frequently fatal disorder. There is intense hemolysis and severe anemia. Many patients become transfusion dependent, and the subsequent iron load, along with abnormally increased gastrointestinal iron absorption, leads to hemochromatosis, which is fatal in many cases. A heterozygous form of β -thalassemia that clinically manifests as *thalassemia intermedia* produces moderate anemia.

Pregnancy

There are few problems that arise during pregnancy in women with β -thalassemia minor who have mild anemia. Iron and folate supplements are given. In some women, anemia will worsen because normal plasma volume expansion may be accompanied by slightly subnormal erythropoiesis.

Thalassemia major and some of the other severe forms were uncommonly encountered during pregnancy before the advent of transfusion and iron chelation therapy. With such management, there were 63 pregnancies reported without serious complications (Aessopos, 1999; Daskalakis, 1998; Kumar, 1997). Pregnancy is considered advisable if there is normal maternal cardiac function. Transfusions are given throughout pregnancy to maintain the hemoglobin concentration at 10 g/dL. This is coupled with surveillance of fetal growth (American College of Obstetricians and Gynecologists, 2013b; Sheiner, 2004).

Prenatal Diagnosis

Because β -thalassemia major is caused by numerous mutations, prenatal diagnosis is difficult. For a given individual, targeted mutation analysis is done that requires prior identification of that familial mutation. These are done using CVS and other techniques discussed in Chapter 14 (p. 300). Noninvasive

testing of circulating fetal nucleic acids in maternal plasma for the diagnosis of β -thalassemia has been described (Galbiati, 2012; Leung, 2012).

PLATELET DISORDERS

Thrombocytopenia

Various platelet abnormalities may precede pregnancy, may develop during pregnancy coincidentally, or may be induced by pregnancy. Abnormally low platelet counts are relatively common in the pregnant woman and have various causes. These disorders may be inherited or idiopathic, acute or chronic in onset, and either primary or associated with other disorders. For example, thrombocytopenia in obstetrics is seen often with severe preeclampsia syndrome; massive hemorrhage with transfusions; consumptive coagulopathy from placental abruption, sepsis syndrome, or amniotic-fluid embolism; hemolytic anemias; systemic lupus erythematosus and antiphospholipid antibody syndrome; or hypoplastic or aplastic anemia. Other causes include viral infections, exposure to various drugs, and allergic reactions (Aster, 2007; Diz-Küçükaya, 2010). Thrombocytopenia defined as $< 150,000/\mu\text{L}$ platelets occurs in 6 to 15 percent of pregnant women, and 75 percent of these cases stem from gestational thrombocytopenia (Boehlen, 2006).

Burrows and Kelton (1993) reported that 6.6 percent of 15,471 pregnant women had a platelet count $< 150,000/\mu\text{L}$, and in 1.2 percent, it was $< 100,000/\mu\text{L}$. They reported that almost 75 percent of 1027 women whose platelet counts were $< 150,000/\mu\text{L}$ were found to have normal-variant incidental thrombocytopenia. Of the remainder, 21 percent had a hypertensive disorder of pregnancy, and 4 percent had an immunological disorder. A platelet count of $< 80,000/\mu\text{L}$ should trigger an evaluation for etiologies other than incidental or gestational thrombocytopenia, which is unlikely to have a platelet count of $< 50,000/\mu\text{L}$ (Gernsheimer, 2013).

Gestational Thrombocytopenia

Normal pregnancy may be accompanied by a physiological decrease in platelet concentration (Appendix, p. 1287). This is usually evident in the third trimester and is thought to be predominantly due to hemodilution. However, the increased splenic mass characteristic of normal pregnancy may be contributory (Maymon, 2006). Most evidence shows that platelet life span is unchanged in normal pregnancy (Kenny, 2014). Thus, some degree of *gestational thrombocytopenia* is considered normal. Obviously, the definition used for thrombocytopenia is important. In their review, Rouse and coworkers (1998) cited an incidence of 4 to 7 percent for gestational thrombocytopenia, defined by platelet counts $< 150,000/\mu\text{L}$.

Inherited Thrombocytopenias

The *Bernard-Soulier syndrome* is characterized by lack of platelet membrane glycoprotein (GPIb/IX), which causes severe dysfunction. Maternal antibodies against fetal GPIb/IX antigen can cause alloimmune fetal thrombocytopenia. Peng and colleagues (1991) described an affected woman who during four pregnancies had episodes of postpartum hemorrhage, gastrointestinal hemorrhage, and fetal thrombocytopenia. Fujimori and

associates (1999) described a similarly affected woman whose neonate died from thrombocytopenic intracranial hemorrhage. A systematic review of 30 pregnancies in 18 women reported a 33-percent rate of primary postpartum hemorrhage, and half of women with bleeding required blood transfusion. The reviewers also noted six cases of neonatal alloimmune thrombocytopenia and two perinatal deaths (Peitsidis, 2010). Close monitoring through pregnancy and 6 weeks postpartum is critical due to the possibility of life-threatening hemorrhage (Prabu, 2006).

Chatwani and coworkers (1992) reported a woman with autosomally dominant *May-Hegglin anomaly* whose infant was not affected. This condition is characterized by thrombocytopenia, giant platelets, and leukocyte inclusions. Urato and Repke (1998) also described such a woman who was delivered vaginally. Despite a platelet count of $16,000/\mu\text{L}$, she did not bleed excessively. The neonate inherited the anomaly, but also had no bleeding despite a platelet count of $35,000/\mu\text{L}$. Fayyad and colleagues (2002) managed three pregnancies in a woman with May-Hegglin anomaly. In the first, the mother had a term cesarean delivery of an unaffected infant; in the second, she had a fetal demise with multiple placental infarcts; and in the third, she received low-dose aspirin (75 mg/d) and gave birth to an unaffected infant.

Immune Thrombocytopenic Purpura

The primary form—also termed *idiopathic thrombocytopenic purpura (ITP)*—is usually caused by a cluster of IgG antibodies directed against one or more platelet glycoproteins (Schwartz, 2007). Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen. Although this is not proven, the disorder is probably mediated by auto-antibodies directed at platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA. In adults, ITP most often is a chronic disease that rarely resolves spontaneously.

Secondary forms of chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and several systemic diseases. Approximately 2 percent of thrombocytopenic patients have positive serological tests for lupus, and in some cases there are high levels of anticardiolipin antibodies. Perhaps 10 percent of HIV-positive patients will have associated thrombocytopenia (Scaradavou, 2002).

Diagnosis and Management. Only a few adults with primary ITP recover spontaneously, and for those who do not, platelet counts usually range from 10,000 to $100,000/\mu\text{L}$ (George, 2010). There is no irrefutable evidence that pregnancy increases the risk of relapse in women with previously diagnosed ITP or worsens thrombocytopenia in women with active disease. That said, it is certainly not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia has also been suggested as a cause.

Therapy is considered if the platelet count is less than $30,000$ to $50,000/\mu\text{L}$ (George, 2010). Primary treatment includes IVIG or corticosteroids (Neunert, 2011). Prednisone, 1 mg/kg daily, is given to suppress the phagocytic activity of the splenic monocyte-macrophage system. IVIG given in a total dose of 2 g/kg during 2 to 5 days is also usually effective.

In pregnant women with no response to corticosteroid or IVIG therapy, open or laparoscopic splenectomy may be effective. In late pregnancy, surgery is technically more difficult, and cesarean delivery may be necessary for exposure. Intravenous anti-D IgG, 50 to 75 $\mu\text{g/kg}$, has been described for treatment of resistant ITP in D-positive patients with a spleen (Konkle, 2008). There usually is improvement by 1 to 3 days, with a peak at approximately 8 days (Sieunarine, 2007). Cytotoxic agents are typically avoided in pregnancy due to teratogenicity risks. Azathioprine and rituximab, however, which are used in nonpregnant ITP, have been used for other conditions in pregnancy. Finally, the thrombopoietin agonist *romiplostim* has improved responses (Imbach, 2011; Kuter, 2010).

Fetal and Neonatal Effects. Platelet-associated IgG antibodies cross the placenta and may cause thrombocytopenia in the fetus-neonate. Fetal death from hemorrhage occurs occasionally (Webert, 2003). The severely thrombocytopenic fetus is at increased risk for intracranial hemorrhage with labor and delivery. This fortunately is unusual. Payne and associates (1997) reviewed studies of maternal ITP published since 1973 and added their experiences with 55 cases. Of 601 newborns, 12 percent had severe thrombocytopenia defined as a platelet count $< 50,000/\mu\text{L}$. Six infants had intracranial hemorrhage, and in three, their initial platelet count was $> 50,000/\mu\text{L}$. This is consistent with a study of 127 pregnancies in women with ITP in which 10 to 15 percent of neonates were found to have transient ITP (Koyama, 2012).

Considerable attention has been directed at identifying the fetus with potentially dangerous thrombocytopenia. All investigators have concurred that there is not a strong correlation between fetal and maternal platelet counts (George, 2009; Payne, 1997). Because of this, there have been attempts to quantify the relationships among maternal IgG free platelet antibody levels, platelet-associated antibody levels, and fetal platelet count. Again, however, there is little concurrence with these.

Investigators have also examined the association between the specific maternal cause of thrombocytopenia and risk of a thrombocytopenic fetus. Four causes investigated include gestational thrombocytopenia, hypertension-associated thrombocytopenia, ITP, and alloimmune thrombocytopenia. Burrows and Kelton (1993) reported neonatal umbilical cord platelet counts of $< 50,000/\mu\text{L}$ in 19 of 15,932 consecutive newborns (0.12 percent). Of all of these pregnancies, only one of 756 mothers with gestational thrombocytopenia had an affected infant. Of 1414 hypertensive women with thrombocytopenia, five infants had thrombocytopenia. In contrast, of 46 mothers with ITP, four infants had thrombocytopenia. Finally, alloimmune thrombocytopenia was associated with profound thrombocytopenia and cord platelet counts $< 20,000/\mu\text{L}$. One of these fetuses died, and two others had intracranial hemorrhage.

Detection of Fetal Thrombocytopenia. Because there are no clinical characteristics or laboratory tests that accurately predict fetal platelet count, direct fetal blood sampling is necessary. Scott and coworkers (1983) obtained intrapartum scalp blood samples and recommended cesarean delivery for fetuses with platelet counts $< 50,000/\mu\text{L}$. Daffos and colleagues

(1985) reported that percutaneous umbilical cord blood sampling (PUBS) had a high complication rate (Chap. 14, p. 300). Conversely, using PUBS, Berry and associates (1997) reported no complications but found a high negative predictive value of low platelet counts. Payne and coworkers (1997) summarized six studies in which fetal blood sampling was done for platelet estimation. Of the total of 195 fetuses, severe neonatal thrombocytopenia—defined as $< 50,000/\mu\text{L}$ —was found in 7 percent. However, there were serious complications from cordocentesis in 4.6 percent. Because of the low incidence of severe neonatal thrombocytopenia and morbidity, fetal platelet determinations and cesarean delivery are not recommended for women with ITP (Neunert, 2011).

Neonatal Alloimmune Thrombocytopenia (NAIT).

Disparity between maternal and fetal platelet antigens can stimulate maternal production of antiplatelet antibodies. Such platelet alloimmunization is identical to that caused by red cell antigens (Chap. 15, p. 313).

Thrombocytosis

Also called *thrombocythemia*, thrombocytosis generally is defined as persistent platelet counts $> 450,000/\mu\text{L}$. Common causes of *secondary* or *reactive thrombocytosis* are iron deficiency, infection, inflammatory diseases, and malignant tumors (Deutsch, 2013). Platelet counts seldom exceed $800,000/\mu\text{L}$ in these secondary disorders, and prognosis depends on the underlying disease. On the other hand, *primary* or *essential thrombocytosis* accounts for most cases in which platelet counts exceed 1 million/ μL . It is a clonal disorder frequently due to an acquired mutation in the *JAK2* gene (Beer, 2010). Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop (Rabinerson, 2007). These cases must be differentiated from the *sticky platelet syndrome*, which is also associated with thromboses (Rac, 2011). Cortelazzo and colleagues (1995) reported that myelosuppression with hydroxyurea for nonpregnant patients with essential thrombocytosis decreased thrombotic episodes from 24 to 4 percent compared with rates in untreated controls.

Normal pregnancies have been described in women whose mean platelet counts were > 1.25 million/ μL (Beard, 1991; Randi, 1994). Others report more adverse outcomes. Niittyvuopio and associates (2004) described 40 pregnancies in 16 women with essential thrombocythemia. Almost half had a spontaneous abortion, fetal demise, or preeclampsia. In 63 pregnancies in 36 women cared for at the Mayo Clinic, a third had a spontaneous miscarriage, but other pregnancy complications were uncommon (Gangat, 2009). In this observational study, aspirin therapy was associated with a significantly lower abortion rate than that in untreated women—1 versus 75 percent, respectively.

Suggested treatments for thrombocytosis during pregnancy include aspirin, low-molecular-weight heparin, and interferon- α (Finazzi, 2012). Interferon- α therapy during pregnancy was successful in 11 women in the review by Delage and coworkers (1996). One of these women had transient blindness at midpregnancy when her platelet count was 2.3 million/ μL . Thrombocytapheresis and interferon- α were used to maintain platelet counts at approximately 1 million/ μL until delivery.

Thrombotic Microangiopathies

Although not a proven primary platelet disorder, there almost always is some degree of thrombocytopenia with the thrombotic microangiopathies. Their similarities to the HELLP syndrome allude to their obstetrical ramifications (George, 2013). Moschowitz (1925) originally described *thrombotic thrombocytopenic purpura (TTP)* by the pentad of thrombocytopenia, fever, neurological abnormalities, renal impairment, and hemolytic anemia. Gasser and colleagues (1955) later described the similar *hemolytic uremic syndrome (HUS)*, which had more profound renal involvement and fewer neurological aberrations. Scully and associates (2012) provided guidelines for the diagnosis and management of thrombotic microangiopathic hemolytic anemias. The syndromes have an incidence of 2 to 6 per million persons per year (Miller, 2004).

Etiopathogenesis

Different causes likely account for the variable findings within these syndromes. Clinically, however, they frequently are indistinguishable in adults. Most cases of TTP are thought to be caused by a plasma deficiency of or antibodies to a von Willebrand factor-cleaving protease termed *ADAMTS-13 (ADAM metalloproteinase with thrombospondin type 1 motif, 13)* (Ganesan, 2011; Sadler, 2010). Conversely, HUS is usually due to endothelial damage incited by viral or bacterial infections and is seen primarily in children (Ardissino, 2013; George, 2013).

The general consensus is that intravascular platelet aggregation stimulates a cascade of events leading to end-organ failure. Although there is endothelial activation and damage, it is unclear whether this is a consequence or a cause. Elevated levels of unusually large multimers of von Willebrand factor are identified with active TTP. The *ADAMTS13* gene encodes the endothelium-derived protease responsible for cleaving von Willebrand factor—vWF (Sadler, 2010). Defects in this gene result in various clinical presentations of thrombotic microangiopathy (Camilleri, 2007; Moake, 2002, 2004). In another scheme, antibodies raised against ADAMTS-13 neutralize its action to cleave vWF multimers during an acute episode. The end result is microthrombi of hyaline material consisting of platelets and small amounts of fibrin develop within arterioles and capillaries. When sufficient in number or size, these aggregates produce ischemia or infarctions in various organs.

Clinical and Laboratory Manifestations

Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and variable organ dysfunction. Neurological symptoms develop in up to 50 percent and include headache, altered consciousness, convulsions, fever, or stroke. Because renal involvement is common, TTP and HUS are difficult to separate clinically. Renal failure is thought to be more severe with the HUS, and in half of the cases, dialysis is required.

Thrombocytopenia is usually severe, but fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and erythrocyte transfusions are frequently necessary. The blood smear is characterized by

erythrocyte fragmentation with schizocytosis. Reticulocytes and nucleated red blood cells are increased, lactate dehydrogenase (LDH) levels are high, and haptoglobin concentrations are decreased. Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

Treatment

The cornerstone of treatment is plasmapheresis with fresh-frozen plasma replacement. Plasma exchange removes inhibitors and replaces the ADAMTS-13 enzyme (George, 2010; Michael, 2009; Sadler, 2010). This has remarkably improved outcomes with these formerly fatal syndromes. Red cell transfusions are imperative for life-threatening anemia. If there are neurological abnormalities or rapid clinical deterioration, then plasmapheresis and plasma exchange can be performed twice daily. These are usually continued until the platelet count is $> 150,000/\mu\text{L}$. Unfortunately, relapses are common (Sadler, 2010). Additionally, there may be long-term sequelae such as renal impairment (Dashe, 1998).

Pregnancy

As shown in the Appendix (p. 1288), ADAMTS-13 enzyme activity decreases across pregnancy by as much as 50 percent (Sánchez-Luceros, 2004). Levels are decreased even further with the preeclampsia syndrome (Chap. 40, p. 731). This is consonant with prevailing opinions that TTP is more commonly seen during pregnancy. The Parkland Hospital experiences were described by Dashe and coworkers (1998), who identified 11 pregnancies complicated by these syndromes among nearly 275,000 obstetrical patients—a frequency of 1 in 25,000.

It seems likely that the disparately higher incidence in pregnancy reported by others is because of inclusion of women with severe preeclampsia and eclampsia (Hsu, 1995; Magann, 1994). There are differences that allow appropriate diagnosis (Table 56-6). For example, moderate to severe hemolysis is a rather constant feature of thrombotic microangiopathies. This is seldom severe with the preeclampsia syndrome, even when complicated by HELLP syndrome (Chap. 40, p. 742). And, although there is deposition of hyaline microthrombi within the liver with thrombotic microangiopathy, hepatocellular necrosis with elevated serum hepatic aminotransferase levels characteristic of preeclampsia is not a common feature (Ganesan, 2011; Sadler, 2010). Importantly, whereas delivery is imperative to reverse the preeclampsia syndrome in women with the HELLP syndrome, there is no evidence that thrombotic microangiopathy is improved by delivery (Dashe, 1998; Letsky, 2000). Finally, microangiopathic syndromes are usually recurrent and unassociated with pregnancy. For example, seven of 11 women described by Dashe and colleagues (1998) had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy. George (2009) reported recurrent TTP in only five of 36 subsequent pregnancies.

Unless the diagnosis is unequivocally one of these thrombotic microangiopathies, rather than severe preeclampsia, the response to pregnancy termination should be evaluated before resorting to plasmapheresis and exchange transfusion, massive-dose glucocorticoid therapy, or other therapy. Unfortunately, recall that determination of ADAMTS-13 enzyme activity may

TABLE 56-6. Some Differential Factors between HELLP Syndrome and Thrombotic Microangiopathies^a

	HELLP Syndrome	Thrombotic Microangiopathies
Thrombocytopenia	Mild/Mod.	Mod./severe
Microangiopathic hemolysis (schizocytosis)	Mild	Severe
ADAMTS13 def.	Mild/Mod.	Severe
DIC	Mild	Mild
Transaminitis (AST, ALT)	Mod./severe	None/mild
Treatment	Delivery	Plasmapheresis

^aIncludes thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS). ADAMTS13 = ADAM metalloproteinase with thrombospondin type 1 motif, 13; AST = aspartate aminotransferase; ALT = alanine aminotransferase; def. = deficiency; DIC = disseminated intravascular coagulation; HELLP = hemolysis, elevated liver enzymes, and low platelets; Mod. = moderate.

be difficult to interpret if not within the already lower range for normal pregnancy. With HELLP syndrome, enzyme activity levels are much lower and similar to those reported with microangiopathies (Franchini, 2007). It cannot be overemphasized that plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.

During the past two decades, and coincidental with plasmapheresis and plasma exchange, maternal survival rates from thrombotic microangiopathy have improved dramatically (Dashe, 1998). Although previously fatal in up to half of mothers, with such treatment, Eggerman and coworkers (1996) reported two maternal and three fetal deaths in 11 pregnancies. Hunt and associates (2013) reported that TTP accounted for 1 percent of maternal deaths in the United Kingdom from 2003 to 2008. Finally, a case of sudden maternal death from TTP has been described (Yamamoto, 2013).

Long-Term Prognosis

Women who are diagnosed with thrombotic microangiopathy during pregnancy are at risk for serious long-term complications. The Parkland experiences included a mean 9-year surveillance period (Dashe, 1998). These women had multiple recurrences; renal disease requiring dialysis, transplantation, or both; severe hypertension; and transfusion-acquired infectious diseases. Two women died remote from pregnancy—one from dialysis complications and one from transfusion-acquired HIV infection. Similar observations were reported by Eggerman and colleagues (1996).

There have been reports of persistent cognitive defects and physical disabilities in nonpregnant women who have recovered from thrombotic microangiopathies (Kennedy, 2009; Lewis, 2009). Interestingly, these cognitive defects are very similar to

those found in long-term surveillance studies of women who had eclampsia. Aukes (2009, 2012) and Wiegman (2012) and their associates from The Netherlands have documented cognitive and visual defects years following an eclamptic episode as further discussed in Chapter 40 (p. 770).

INHERITED COAGULATION DEFECTS

Hemophilias A and B

Obstetrical hemorrhage may infrequently be the consequence of an inherited defect of a protein that controls coagulation. As examples, both types of hemophilia may be involved. These are dependent on plasma factor levels and are categorized as mild—levels of 6 to 30 percent; moderate—2 to 5 percent; or severe—less than 1 percent (Mannucci, 2001).

Hemophilia A is an X-linked recessively transmitted disease characterized by a marked deficiency of small component antihemophilic factor (factor VIII). It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Heterozygous women have diminished factor VIII levels, but almost invariably, the homozygous state is the requisite for hemophilia A. In a few instances, it appears in women spontaneously from a newly mutant gene. Pregnancy-associated acquired hemophilia A from antibodies may result in severe morbidity from bleeding (Tengborn, 2012).

Christmas disease or *hemophilia B* is caused by severe deficiency of factor IX and has genetic and clinical features similar to those of hemophilia A.

Pregnancy

The obstetrical bleeding risk with these is directly related to factor VIII or factor IX levels. Affected women have a range of activity that is determined by random X-chromosome inactivation—lyonization—although activity is expected to average 50 percent (Letsky, 2000). If levels fall below 10 to 20 percent, there is a risk of hemorrhage. If levels fall to near zero, the risks are substantial. Pregnancy does afford some protection, however, because both of these clotting factors increase appreciably during normal pregnancy (Appendix, p. 1288). Treatment with desmopressin may also stimulate factor VIII release. Risks are further reduced by avoiding lacerations, minimizing episiotomy use, and maximizing postpartum uterine contractions. Operative vaginal deliveries should be avoided (Ljung, 1994).

There are few published experiences during pregnancy in women with hemophilia complications. Kadir and coworkers (1997) reported that 20 percent of carriers had postpartum hemorrhage, and in two, it was massive. Guy and associates (1992) reviewed five pregnancies in women with hemophilia B, and in all, outcomes were favorable. They recommended factor IX administration if levels are below 10 percent. Desmopressin has been shown in selected cases to reduce obstetrical bleeding complications (Trigg, 2012).

If a male fetus has hemophilia, the risk of hemorrhage increases after delivery in the neonate. This is especially true if circumcision is attempted.

Inheritance

If a mother has hemophilia A or B, all of her sons will have the disease, and all of her daughters will be carriers. If she is a carrier, half of her sons will inherit the disease, and half of her daughters will be carriers. Prenatal diagnosis of hemophilia is possible in some families using CVS (Chap. 14, p. 300). Preimplantation genetic diagnosis for hemophilia was reviewed by Lavery (2009).

Factor VIII or IX Inhibitors

Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. Patients with hemophilia A or B, because of prior treatment with factor VIII or IX, more commonly develop such antibodies. In contrast, acquisition of these antibodies in non-hemophiliacs is extraordinary. That said, this phenomenon has been identified rarely in women during the puerperium (Santoro, 2009). The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Reece, 1988). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple transfusions of whole blood and plasma; huge doses of cryoprecipitate; large volumes of an admixture of activated coagulation factors, including porcine factor VIII; immunosuppressive therapy; and attempts at various surgical procedures, especially curettage and hysterectomy. Another treatment involves bypassing factor VIII or IX by the use of activated forms of factors VII, IX, and X. A recombinant activated factor VII (NovoSeven) stops bleeding in up to 75 percent of patients with these inhibitors (Mannucci, 2001). As discussed in Chapter 41 (p. 817), NovoSeven has also been used in nonhemophiliac patients in cases of intractable obstetrical hemorrhage caused by uterine atony and by dilutional effects of multiple transfusions.

Von Willebrand Disease

There are at least 20 heterogeneous clinical disorders involving aberrations of factor VIII complex and platelet dysfunction—collectively termed *von Willebrand disease (vWD)*. These abnormalities are the most commonly inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Mannucci, 2004; Pacheco, 2010). Most von Willebrand variants are inherited as autosomal dominant traits, and types I and II are the most common. Type III, which is the most severe, is a recessive trait (Nichols, 2008).

Although far less common than inherited von Willebrand disease, acquired disorders have been described. These are stimulated by underlying conditions such as benign and malignant hematological diseases, solid tumors, autoimmune disorders, and medications such as ciprofloxacin (Shau, 2002). Although most cases of acquired vWD develop after age 50 years, some have been reported in pregnant women (Lipkind, 2005).

Pathogenesis

The *von Willebrand factor* is a series of large plasma multimeric glycoproteins that form part of the factor VIII complex. It is

essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug at the site of blood vessel injury. It also plays a major role in stabilizing the coagulant properties of factor VIII. The procoagulant component is the antihemophilic factor or factor VIII, which is a glycoprotein synthesized by the liver. Conversely, von Willebrand precursor, which is present in platelets and plasma, is synthesized by endothelium and megakaryocytes under the control of autosomal genes on chromosome 12. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

Clinical Presentation

Symptomatic patients usually present with bleeding suggestive of a chronic coagulation disorder. The classic autosomal dominant form usually causes symptoms in the heterozygous state. The less common but clinically more severe autosomal recessive form is manifest when inherited from both parents, who typically demonstrate little or no disease. Type I, which accounts for 75 percent of von Willebrand variants, is characterized by easy bruising; epistaxis; mucosal hemorrhage; and excessive bleeding with trauma, including surgery. Its laboratory features are usually a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen levels, decreased factor VIII immunological and coagulation-promoting activity, and inability of platelets from an affected person to react to various stimuli.

Pregnancy

During normal pregnancy, maternal levels of both factor VIII and vWF antigen increase substantively (Appendix, p. 1288). Because of this, pregnant women with vWD often develop normal levels of factor VIII coagulant activity and vWF antigen, although the bleeding time still may be prolonged. If factor VIII activity is very low or if there is bleeding, treatment is recommended. Desmopressin by infusion may transiently increase factor VIII and vWF levels, especially in patients with type I disease (Kujovich, 2005; Mannucci, 2004). With significant bleeding, 15 or 20 units of cryoprecipitate are given every 12 hours. Alternatively, factor VIII concentrates may be given that contain high-molecular-weight vWF multimers (Alfanate, Hemate-P). These concentrates are highly purified and are heat treated to destroy HIV. Lubetsky and colleagues (1999) described continuous infusion with Hemate-P in a woman during a vaginal delivery. According to Chi and coworkers (2009), conduction analgesia can be given safely if coagulation defects have normalized or if hemostatic agents are given prophylactically.

Pregnancy outcomes in women with von Willebrand disease are generally good, but postpartum hemorrhage is encountered in up to 50 percent of cases. Of 38 cases summarized by Conti and associates (1986), bleeding was reported with abortion, with delivery, or in the puerperium in a fourth. Greer and colleagues (1991) noted that eight of 14 pregnancies were complicated by postpartum hemorrhage. Kadir and coworkers (1998) reported their experiences with 84 pregnancies. They described a 20-percent incidence of immediate postpartum hemorrhage and another 20-percent incidence of late hemorrhage. Most

cases were associated with low vWF levels in untreated women, and none given treatment peripartum had hemorrhage. In our experiences, levels of coagulant factors within the normal range do not always protect against such bleeding.

Inheritance

Although most patients with von Willebrand disease have heterozygous variants and associated minor bleeding complications, the disease can be severe. Moreover, homozygous offspring develop a serious clotting dysfunction. CVS with DNA analysis to detect the missing genes has been described. Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.

Other Factor Deficiencies

In general, the activity of most procoagulant factors increases across pregnancy (Appendix, p. 1288). In addition to the hemophilias, there are other inherited deficiencies of these factors that may cause a coagulopathy.

Factor VII deficiency is a rare autosomal recessive disorder. Levels of this factor normally increase during pregnancy, but these may rise only mildly in women with factor VII deficiency (Fadel, 1989). A systematic review of 94 births found no difference in postpartum hemorrhage rates with or without prophylaxis with recombinant factor VIIa (Baumann Kreuziger, 2013).

Factor X or Stuart-Prower factor deficiency is rare and is inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Konje and colleagues (1994) described a woman who had 2-percent factor activity. She was given prophylactic treatment with plasma-derived factor X, which raised her plasma levels to 37 percent. Despite this, she suffered an intrapartum placental abruption. Bofill and coworkers (1996) gave intrapartum fresh-frozen plasma to a woman with less than 1-percent factor X activity. She delivered spontaneously without incident. Beksaç and associates (2010) described a woman with severe factor X deficiency who was successfully managed with prophylactic prothrombin complex concentrate. Nance and colleagues (2012) reported on 24 pregnancies, of which 18 resulted in a healthy baby. However, the authors found a 2.5-fold increased risk of preterm birth.

Factor XI—plasma thromboplastin antecedent—deficiency is inherited as an autosomal trait. It is manifest as severe disease in homozygotes but only as a minor defect in heterozygotes. It is most prevalent in Ashkenazi Jews and is rarely seen in pregnancy. Musclow and coworkers (1987) reported 41 deliveries in 17 affected women, and none required transfusion. They also described a woman who developed a spontaneous hemarthrosis at 39 weeks. Kadir and associates (1998) analyzed 29 pregnancies in 11 affected women. None of these had factor XI level increases; 15 percent had immediate postpartum hemorrhage; and another 25 percent had delayed hemorrhage. In 105 pregnancies from 33 affected women, Myers and colleagues (2007) reported an uneventful pregnancy and delivery in 70 percent. They recommended peripartum treatment with factor XI concentrate if cesarean delivery is performed and advised against

epidural analgesia unless factor XI is given. From their review, Martin-Salces and associates (2010) found that there was poor correlation between factor XI levels and bleeding in women with severe deficiency.

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. An increased incidence of thromboembolism is encountered in nonpregnant patients with this deficiency. Lao and coworkers (1991) reported an affected pregnant woman in whom placental abruption developed at 26 weeks' gestation.

Factor XIII deficiency is an autosomal recessive trait and may be associated with maternal intracranial hemorrhage (Letsky, 2000). In their review, Kadir and associates (2009) cited an increased risk of recurrent miscarriage and placental abruption. It has also been reported to cause umbilical cord bleeding (Odame, 2014). Treatment is fresh frozen plasma. Naderi and colleagues (2012) described 17 successful pregnancies in women receiving weekly prophylaxis with FXIII concentrate.

Fibrinogen abnormalities—either qualitative or quantitative—also may cause coagulation abnormalities. Autosomally inherited abnormalities usually involve the formation of a functionally defective fibrinogen—commonly referred to as *dysfibrinogenemia* (Edwards, 2000). Familial *hypofibrinogenemia* and sometimes *afibrinogenemia* are infrequent recessive disorders. In some cases, both are found—*hypodysfibrinogenemia* (Deering, 2003). Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state. Typically, the thrombin-clottable protein level in these patients ranges from 80 to 110 mg/dL when nonpregnant, and this increases by 40 or 50 percent in normal pregnancy. Those pregnancy complications that give rise to acquired hypofibrinogenemia, for example, placental abruption, are more common with fibrinogen deficiency. Trehan and Fergusson (1991) and Funai and coworkers (1997) described successful outcomes in two affected women in whom fibrinogen or plasma infusions were given weekly or biweekly throughout pregnancy.

Conduction Analgesia with Bleeding Disorders

Most serious bleeding disorders would logically preclude the use of epidural or spinal analgesia for labor or delivery. If the bleeding disorder is controlled, however, conduction analgesia may be considered. Chi and colleagues (2009) reviewed intrapartum outcomes in 80 pregnancies in 63 women with an inherited bleeding disorder. These included those with factor XI deficiency, hemophilia carrier status, von Willebrand disease, platelet disorders, or a deficiency of factor VII, XI, or X. Regional block was used in 41. Of these, 35 had spontaneously normalized hemostatic dysfunction, and others were given prophylactic replacement therapy. The reviewers encountered no unusual complications and concluded that such practices were safe. Singh and associates (2009) reviewed 13 women with factor XI deficiency. Nine received neuraxial analgesia without complications, but only after fresh-frozen plasma was given to most to correct the activated partial thromboplastin time.

THROMBOPHILIAS

Several important regulatory proteins inhibit clotting. There are physiological antithrombotic proteins that act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity. Inherited deficiencies of these inhibitory proteins are caused by gene mutations. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias*. Because these deficiencies may be associated with thromboembolism, they are discussed in Chapter 52 (p. 1029), and they have been recently reviewed by the American College of Obstetricians and Gynecologists (2013d).

CHAPTER 57

Diabetes Mellitus

TYPES OF DIABETES	1125
PREGESTATIONAL DIABETES	1127
DIAGNOSIS	1127
FETAL EFFECTS	1128
MATERNAL EFFECTS	1131
MANAGEMENT OF DIABETES IN PREGNANCY	1134
GESTATIONAL DIABETES	1136
SCREENING AND DIAGNOSIS	1136
MATERNAL AND FETAL EFFECTS	1139
MANAGEMENT	1140

According to the National Center for Health Statistics (2013), the number of adults diagnosed with diabetes in the United States has tripled from 6.9 million in 1991 to 20.9 million in 2011. Astoundingly, the Centers for Disease Control and Prevention (2010) have estimated that the number of Americans with diabetes will range from 1 in 3 to 1 in 5 by 2050. Reasons for this rise include an aging population more likely to develop type 2 diabetes, increases in minority groups at particular risk for type 2 diabetes, and dramatic increases in obesity—also referred to as diabetes. This term reflects the strong relationship of diabetes with the current obesity epidemic in the United States and underlines the critical need for diet and lifestyle interventions to change the trajectory of both.

There is keen interest in events that precede diabetes, and this includes the uterine environment, where early imprinting is believed to have effects later in life (Saudek, 2002). For

example, in utero exposure to maternal hyperglycemia leads to fetal hyperinsulinemia, causing an increase in fetal fat cells. This leads to obesity and insulin resistance in childhood (Feig, 2002). This in turn leads to impaired glucose tolerance and diabetes in adulthood. This cycle of fetal exposure to diabetes leading to childhood obesity and glucose intolerance has been reported in Pima Indians and a heterogeneous Chicago population (Silverman, 1995).

TYPES OF DIABETES

In nonpregnant individuals, the type of diabetes is based on its presumed etiopathogenesis and its pathophysiological manifestations. Absolute insulin deficiency characterizes *type 1 diabetes*. In contrast, defective insulin secretion, insulin resistance, or increased glucose production characterizes *type 2 diabetes* (Table 57-1). Both types are generally preceded by a period of abnormal glucose homeostasis. The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) are now obsolete. Pancreatic β -cell destruction can begin at any age, but type 1 diabetes is clinically apparent most often before age 30. Type 2 diabetes usually develops with advancing age but is increasingly identified in younger obese adolescents.

Classification During Pregnancy

Diabetes is the most common medical complication of pregnancy. Women can be separated into those who were known to have diabetes before pregnancy—*pregestational* or *overt*, and those diagnosed during pregnancy—*gestational diabetes*. The incidence of diabetes complicating pregnancy increased approximately 40 percent between 1989 and 2004 (Getahun, 2008). In 2006, slightly more than 179,000—4.2 percent—of American women had pregnancies coexistent with some form of diabetes (Martin, 2009). African American, Native

TABLE 57-1. Etiological Classification of Diabetes Mellitus

Type 1: β -Cell destruction, usually absolute insulin deficiency Immune-mediated Idiopathic
Type 2: Ranges from predominantly insulin resistance to predominantly an insulin secretory defect with insulin resistance
Other types Genetic mutations of β -cell function—MODY 1–6, others Genetic defects in insulin action Genetic syndromes—Down, Klinefelter, Turner Diseases of the exocrine pancreas—pancreatitis, cystic fibrosis Endocrinopathies—Cushing syndrome, pheochromocytoma, others Drug or chemical induced—glucocorticosteroids, thiazides, β -adrenergic agonists, others Infections—congenital rubella, cytomegalovirus, coxsackievirus
Gestational diabetes

MODY = maturity-onset diabetes of the young.
Modified from Powers, 2012.

American, Asian, and Hispanic women are at higher risk for gestational diabetes compared with white women (Ferrara, 2007). The increasing incidence of gestational diabetes during the past 15 years, shown in Figure 57-1, is reminiscent of similar statistics for obesity (Chap. 48, p. 961).

White Classification in Pregnancy

Until the mid-1990s, the classification by Priscilla White for diabetic pregnant women was the linchpin of management. Today, the White classification is used less frequently, but its

FIGURE 57-1 Age-specific incidence of gestational diabetes from National Hospital Discharge Survey Data of nearly 59 million births in the United States from 1989 to 2004. (Redrawn from Getahun, 2008.)

role remains important. And because most currently cited literature contains data from these older classifications, the one previously recommended by the American College of Obstetricians and Gynecologists (1986) is provided in Table 57-2.

Beginning several years ago, the American College of Obstetricians and Gynecologists (2012, 2013) no longer recommended the White classification. Instead, the current focus is whether diabetes antedates pregnancy or is first diagnosed during pregnancy. Many now recommend adoption of the classification proposed by the American Diabetes Association (ADA), as shown in Table 57-3.

TABLE 57-2. Classification Scheme Used from 1986 through 1994 for Diabetes Complicating Pregnancy

Class	Onset	Plasma Glucose Level		Therapy
		Fasting	2-Hour Postprandial	
A ₁	Gestational	< 105 mg/dL	< 120 mg/dL	Diet
A ₂	Gestational	> 105 mg/dL	> 120 mg/dL	Insulin
Class	Age of Onset (yr)	Duration (yr)	Vascular Disease	Therapy
B	Over 20	< 10	None	Insulin
C	10 to 19	10 to 19	None	Insulin
D	Before 10	> 20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy ^a	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart	Insulin

^aWhen diagnosed during pregnancy: proteinuria \geq 500 mg/24 hr before 20 weeks' gestation.

TABLE 57-3. Proposed Classification System for Diabetes in Pregnancy

Gestational diabetes: diabetes diagnosed during pregnancy that is not clearly overt (type 1 or type 2) diabetes

Type 1 Diabetes:

Diabetes resulting from β -cell destruction, usually leading to absolute insulin deficiency

- a. Without vascular complications
- b. With vascular complications (specify which)

Type 2 Diabetes:

Diabetes from inadequate insulin secretion in the face of increased insulin resistance

- a. Without vascular complications
- b. With vascular complications (specify which)

Other types of diabetes: genetic in origin, associated with pancreatic disease, drug-induced, or chemically induced

Data from American Diabetes Association, 2012.

PREGESTATIONAL DIABETES

The increasing prevalence of type 2 diabetes in general, and in younger people in particular, has led to an increasing number of affected pregnancies (Ferrara, 2007). In Los Angeles County, Baraban and coworkers (2008) reported that the age-adjusted prevalence tripled from 14.5 cases per 1000 women in 1991 to 47.9 cases per 1000 in 2003. Thus, the number of pregnant women with diabetes that was undiagnosed before pregnancy is increasing. Many women found to have gestational diabetes are likely to have type 2 diabetes that has previously gone undiagnosed (Feig, 2002). In fact, 5 to 10 percent of women with gestational diabetes are found to have diabetes immediately after pregnancy.

Diagnosis

Women with high plasma glucose levels, glucosuria, and ketoacidosis present no problem in diagnosis. Similarly, women with a random plasma glucose level > 200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss or those with a fasting glucose level exceeding 125 mg/dL are considered by the ADA (2012) to have overt diabetes. Women with only minimal metabolic derangement may be more difficult to identify. To diagnose overt diabetes

in pregnancy, The International Association of Diabetes and Pregnancy Study Groups (IADPSG) Consensus Panel (2010) recommends threshold values for fasting or random plasma glucose and glycosylated hemoglobin (A_{1c}) levels at prenatal care initiation (Table 57-4). There was no consensus on whether such testing should be universal or limited to those women classified as high risk. Regardless, the tentative diagnosis of overt diabetes during pregnancy based on these thresholds should be confirmed postpartum. Risk factors for impaired carbohydrate metabolism in pregnant women include a strong familial history of diabetes, prior delivery of a large newborn, persistent glucosuria, or unexplained fetal losses.

Impact on Pregnancy

With pregestational—or overt—diabetes, the embryo, fetus, and mother frequently experience serious complications directly attributable to diabetes. The likelihood of successful outcomes with overt diabetes is related somewhat to the degree of glycemic control, but more importantly, to the degree of underlying cardiovascular or renal disease. Thus, advancing stages of the White classification, seen in Table 57-2, are inversely related to favorable pregnancy outcomes. As an example shown in Table 57-5, data from Yang and associates (2006) chronicles the deleterious pregnancy outcomes of overt

TABLE 57-4. Diagnosis of Overt Diabetes in Pregnancy^a

Measure of Glycemia	Threshold
Fasting plasma glucose	At least 7.0 mmol/L (126 mg/dL)
Hemoglobin A_{1c}	At least 6.5%
Random plasma glucose	At least 11.1 mmol/L (200 mg/dL) plus confirmation

^aApply to women without known diabetes antedating pregnancy. The decision to perform blood testing for evaluation of glycemia on all pregnant women or only on women with characteristics indicating a high risk for diabetes is based on the background frequency of abnormal glucose metabolism in the population and on local circumstances.

Modified from International Association of Diabetes and Pregnancy Study Groups Consensus Panel, 2010.

TABLE 57-5. Pregnancy Outcomes of Births in Nova Scotia from 1988 to 2002 in Women with and without Pregestational Diabetes

diabetes. These maternal and fetal complications are described in the following sections.

Fetal Effects

Spontaneous Abortion. Several studies have shown that early miscarriage is associated with poor glycemic control. In 215 women with type 1 diabetes enrolled for prenatal care before 9 weeks' gestation, 24 percent had an early pregnancy loss (Rosenn, 1994). Only those whose initial glycohemoglobin A_{1c} concentrations were > 12 percent or whose preprandial glucose concentrations were persistently > 120 mg/dL were at increased risk. In another analysis of 127 Spanish women with pregestational diabetes, poor glycemic control, defined by glycohemoglobin A_{1c} concentrations > 7 percent, was associated with a threefold increase in the spontaneous abortion rate (Galindo, 2006).

Preterm Delivery. Overt diabetes is an undisputed risk factor for preterm birth. Eidem and associates (2011) analyzed 1307 births in women with pregestational type 1 diabetes from the Norwegian Medical Birth Registry. More than 26 percent were delivered preterm compared with 6.8 percent in the general obstetrical population. Moreover, almost 60 percent were indicated preterm births, that is, due to obstetrical or medical complications. In the Canadian study shown in Table 57-5, the incidence of preterm birth was 28 percent—a fivefold increase compared with that of their normal population.

Malformations. The incidence of major malformations in women with type 1 diabetes is doubled and approximates 5 percent (Eidem, 2010; Sheffield, 2002). These account for almost half of perinatal deaths in diabetic pregnancies. A twofold increased risk of major congenital defects in Norwegian women with pregestational type 1 diabetes included cardiovascular malformations that accounted for more than half of the anomalies (Table 57-6). In the National Birth Defects Prevention Study, the risk of an isolated cardiac defect was fourfold higher in women with pregestational diabetes compared with the twofold increased risk of noncardiac defects (Correa, 2008). The caudal regression

sequence is a rare malformation frequently associated with maternal diabetes (Garne, 2012).

Poorly controlled diabetes, both preconceptionally and early in pregnancy, is thought to underlie this increased severe-malformation risk. As shown in Figure 57-2, Galindo and colleagues (2006) demonstrated a clear correlation between increased maternal glycohemoglobin A_{1c} at first prenatal visit and major malformations. Eriksson (2009) concluded that the etiology was multifactorial. At least three interrelated molecular chain reactions have been linked to maternal hyperglycemia

and can potentially explain the mechanism behind poor glycemic control and increased risk for major malformations (Reece, 2012). These include alterations in cellular lipid metabolism, excess production of toxic superoxide radicals, and activation of programmed cell death. For example, Morgan and associates (2008) demonstrated that hyperglycemia-induced oxidative stress inhibited migration of cardiac neural-crest cells in embryos of diabetic mice.

Altered Fetal Growth. Diminished growth may result from congenital malformations or from substrate deprivation due to advanced maternal vascular disease. However, fetal overgrowth is more typical of pregestational diabetes. Maternal hyperglycemia prompts fetal hyperinsulinemia, particularly during the second half of gestation. This in turn stimulates excessive somatic growth or macrosomia. Except for the brain, most fetal organs are affected by the macrosomia that characterizes the fetus of a diabetic woman. Such infants are described as being anthropometrically different from other large-for-gestational age (LGA) infants (Durnwald, 2004; McFarland, 2000). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk, which predisposes to shoulder dystocia or cesarean delivery (Fig. 57-3).

The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations chronically exceed 130 mg/dL (Hay, 2012). Hammoud and coworkers (2013) reported that the macrosomia rates for Nordic women with type 1, type 2, or gestational diabetes were 35 percent, 28 percent, and 24 percent, respectively. As shown in Figure 57-4, the birthweight distribution of neonates of diabetic mothers is skewed toward consistently heavier birthweights compared with that of normal pregnancies.

In the study by Hammoud and colleagues (2013), fetal growth profiles from 897 sonographic examinations in 244 women with diabetes were compared with 843 examinations

in 145 control women. The abdominal circumference evolved differently in the diabetic groups. Analysis of head circumference/abdominal circumference (HC/AC) ratios shows that this disproportionate growth occurs mainly in diabetic pregnancies that ultimately yield macrosomic newborns (Fig. 57-5). These findings comport with the observation that virtually all neonates of diabetic mothers are growth promoted. Ben-Haroush and associates (2007) analyzed fetal sonographic measurements between 29 and 34 weeks' gestation in 423 diabetic pregnancies and found that accelerated fetal growth was particularly evident in women with poor glycemic control.

Unexplained Fetal Demise. The risk of fetal death is three to four times higher in women with type 1 diabetes compared with that of the general obstetrical population (Eidem, 2011). Stillbirth without an identifiable cause is a phenomenon relatively limited to pregnancies complicated by overt diabetes. These stillbirths are "unexplained" because common factors such as obvious placental insufficiency, abruption, fetal-growth restriction, or oligohydramnios are not identified. These infants are typically LGA and die before labor, usually after 35 weeks' gestation or later (Garner, 1995).

FIGURE 57-4 Distribution of birthweight standard deviation from the normal mean for gestational age in 280 infants of diabetic mothers and in 3959 infants of nondiabetic mothers. (From Bradley, 1988, with permission.)

FIGURE 57-5 Comparison of sonographic fetal anatomic measurements by gestational age and subdivided according to presence or absence of macrosomia among women with various types of diabetes types and controls. **A.** Abdominal circumference measurements. **B.** Head circumference (HC)/Abdominal circumference (AC) ratio. DM = diabetes mellitus; GDM = gestational diabetes mellitus. (Redrawn from Hammoud, 2013, with permission.)

These unexplained stillbirths are associated with poor glycemic control. Lauenborg and coworkers (2003) identified suboptimal glycemic control in two thirds of unexplained stillbirths between 1990 and 2000. Also, fetuses of diabetic mothers often have elevated lactic acid levels. Salvesen and colleagues (1992, 1993) analyzed fetal blood samples and reported that mean umbilical venous blood pH was lower in diabetic pregnancies and was significantly related to fetal insulin levels. Such findings support the hypothesis that hyperglycemia-mediated chronic aberrations in oxygen and fetal metabolite transport may underlie these unexplained fetal deaths (Pedersen, 1977). However, the exact mechanisms by which uncontrolled hyperglycemia leads to elevated lactic acid levels and fetal acidosis remain unclear.

Explicable stillbirths due to placental insufficiency also occur with increased frequency in women with overt diabetes, usually in association with severe preeclampsia. In a retrospective analysis of more than 500,000 singleton deliveries, Yanit and associates (2012) found that the fetal death risk was sevenfold higher in women with hypertension and pregestational diabetes compared with the threefold increased risk associated with diabetes alone. Stillbirth is also increased in women with advanced diabetes and vascular complications. Maternal ketoacidosis can also cause fetal death.

Hydramnios. Diabetic pregnancies are often complicated by excess amniotic fluid. According to Idris and coworkers (2010), 18 percent of 314 women with pregestational diabetes were identified with hydramnios, defined as an amniotic fluid index (AFI) greater than 24 cm in the third trimester. A likely—albeit unproven—explanation is that fetal hyperglycemia causes polyuria (Chap. 11, p. 234). In a study from Parkland Hospital, Dashe and colleagues (2000) found that the AFI parallels the amniotic fluid glucose level among women with diabetes. This finding suggests that the hydramnios associated with diabetes is a result of increased amniotic fluid glucose concentration. Further support for this hypothesis was provided by Vink and associates (2006), who linked poor maternal glucose control to macrosomia and hydramnios. In their retrospective analysis of diabetic pregnancies, Idris and coworkers (2010) also found that women with elevated glycohemoglobin A_{1c} values in the third trimester were more likely to have hydramnios.

Neonatal Effects. Before tests of fetal health and maturity became available, delivery before term was deliberately selected for women with diabetes to avoid unexplained fetal death. Although this practice has been abandoned, there is still an increased frequency of preterm delivery in women with diabetes. Most are due to advanced diabetes with superimposed preeclampsia. Thankfully, modern neonatal care has largely eliminated neonatal deaths due to immaturity. Conversely, neonatal *morbidity* due to preterm birth continues to be a serious consequence.

Respiratory Distress Syndrome. Historically, newborns of diabetic mothers were thought to be at increased risk for respiratory distress from delayed lung maturation. Subsequent

observations challenged this concept, and gestational age rather than overt diabetes is likely the most significant factor associated with respiratory distress syndrome. Indeed, in their analysis of 19,399 very-low-birthweight neonates delivered between 24 and 33 weeks' gestation, Bental and colleagues (2011) were unable to demonstrate an increased rate of respiratory distress syndrome in newborns of diabetic mothers. This is discussed further in Chapter 33 (p. 637).

Hypoglycemia. Newborns of a diabetic mother experience a rapid drop in plasma glucose concentration after delivery. This is attributed to hyperplasia of the fetal β -islet cells induced by chronic maternal hyperglycemia. Low glucose concentrations—defined as < 45 mg/dL—are particularly common in newborns of women with unstable glucose concentrations during labor (Persson, 2009). In a recent analysis of prenatal outcomes during a 20-year period in Finnish women with type 1 diabetes, the incidence of neonatal hypoglycemia declined significantly over time (Klemetti, 2012). The authors attributed this to frequent blood glucose measurements and active early feeding practices in such neonates. Prompt recognition and treatment of the hypoglycemic newborn minimizes adverse sequelae.

Hypocalcemia. Defined as a total serum calcium concentration < 8 mg/dL in term newborns, hypocalcemia is one of the potential metabolic derangements in neonates of diabetic mothers. Its cause has not been explained. Theories include aberrations in magnesium–calcium economy, asphyxia, and preterm birth. In a randomized study by DeMarini and associates (1994), 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control. Almost a third of neonates in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict control group.

Hyperbilirubinemia and Polycythemia. The pathogenesis of hyperbilirubinemia in neonates of diabetic mothers is uncertain. A major contributing factor is newborn polycythemia, which increases the bilirubin load (Chap. 33, p. 643). Polycythemia is thought to be a fetal response to relative hypoxia. According to Hay (2012), the sources of this fetal hypoxia are hyperglycemia-mediated increases in maternal affinity for oxygen and fetal oxygen consumption. Together with insulin-like growth factors, this hypoxia leads to increased fetal erythropoietin levels and red cell production. Venous hematocrits of 65 to 70 volume percent have been observed in up to 40 percent of these newborns (Salvesen, 1992). Renal vein thrombosis is reported to result from polycythemia.

Cardiomyopathy. Infants of diabetic pregnancies may have hypertrophic cardiomyopathy that primarily affects the interventricular septum (Rolo, 2011). In severe cases, this cardiomyopathy may lead to obstructive cardiac failure. Russell and coworkers (2008) performed serial echocardiograms on fetuses of 26 women with pregestational diabetes. In the first trimester, fetal diastolic dysfunction was evident compared with that of nondiabetic controls. In the third trimester, the fetal interventricular septum and right ventricular

wall were thicker in fetuses of diabetic mothers. The authors concluded that cardiac dysfunction precedes these structural changes. Fortunately, most affected newborns are asymptomatic following birth, and hypertrophy resolves in the months after delivery. Relief from maternal hyperglycemia is presumed to promote this resolution (Hornberger, 2006). Conversely, fetal cardiomyopathy may progress to adult cardiac disease.

Long-Term Cognitive Development. Intrauterine metabolic conditions have long been linked to neurodevelopment in offspring. This may also be true in children of diabetic mothers. Despite rigorous antepartum management, Rizzo and colleagues (1995) found numerous correlations between maternal glycemia and intellectual performance in children up to age 11 years in 139 offspring of diabetic women. In a study of more than 700,000 Swedish-born men, the intelligence quotient of those whose mothers had diabetes during pregnancy averaged 1 to 2 points lower (Fraser, 2014). DeBoer and associates (2005) demonstrated impaired memory performance in infants of diabetic mothers at age 1 year. Finally, results from the Childhood Autism Risks from Genetics and the Environment (CHARGE) study indicated that autism spectrum disorders or developmental delay were more common in children of diabetic women (Krakowiak, 2012). Although interpreting effects of the intrauterine environment on neurodevelopment is certainly confounded by postnatal events, emerging data at least support a link between maternal diabetes, glycemic control, and neurocognitive outcome.

Inheritance of Diabetes. The risk of developing type 1 diabetes if either parent is affected is 3 to 4 percent. Type 2 diabetes has a much stronger genetic component. If both parents have type 2 diabetes, the risk of developing it approaches 40 percent. McKinney and coworkers (1999) studied 196 children with type 1 diabetes and found that older maternal age and maternal type 1 diabetes are important risk factors. Plagemann and colleagues (2002) have implicated breast feeding by diabetic mothers in the genesis of childhood diabetes. Conversely, breast feeding has also been associated with a reduced risk of type 2 diabetes (Owen, 2006). The Trial to Reduce Insulin-dependent Diabetes Mellitus in the Genetically At Risk (TRIGR) was designed to analyze hydrolyzed formula use, rather than breast milk, to reduce rates of type 1 diabetes in at-risk children by age 10. This study will be complete in 2017 (Knip, 2011).

Maternal Effects

Diabetes and pregnancy interact significantly such that maternal welfare can be seriously jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes is not affected by pregnancy.

Maternal death is uncommon, but rates in women with diabetes are still increased. In an analysis of 972 women with type 1 diabetes, Leinonen and associates (2001) reported a maternal mortality rate of 0.5 percent. Deaths resulted from diabetic ketoacidosis, hypoglycemia, hypertension, and infection. Especially morbid is ischemic heart disease. Pombar and coworkers (1995) reviewed

17 women with coronary artery disease—class H diabetes—and reported that only half survived pregnancy.

Preeclampsia. Hypertension that is induced or exacerbated by pregnancy is the complication that most often forces preterm delivery in diabetic women. The incidence of chronic and gestational hypertension—and especially preeclampsia—is remarkably increased in diabetic mothers. In the study cited earlier by Yanit and colleagues (2012), preeclampsia developed three to four times more often in women with overt diabetes. Moreover, those diabetics with coexistent chronic hypertension were almost 12 times more likely to develop preeclampsia. Special risk factors for preeclampsia include any vascular complication and preexisting proteinuria, with or without chronic hypertension. As shown in [Figure 57-6](#), women with type 1 diabetes who are in more advanced White classes of overt diabetes increasingly developed preeclampsia. This increasing risk with duration of diabetes may be related to oxidative stress, which plays a key role in the pathogenesis of diabetic complications and preeclampsia. With this in mind, the Diabetes and Preeclampsia Intervention Trial (DAPIT) randomly assigned 762 women with type 1 diabetes to antioxidant vitamin C and E supplementation or placebo in the first half of pregnancy (McCance, 2010). There were no differences in preeclampsia rates except in a few women with a low antioxidant status at baseline. Temple and coworkers (2006) prospectively studied hemoglobin A_{1c} levels at 24 weeks' gestation in 290 women with type 1 diabetes and found that preeclampsia was related to glucose control. Management of preeclampsia is discussed in Chapter 40 (p. 749).

Diabetic Nephropathy. Diabetes is the leading cause of end-stage renal disease in the United States (Chap. 53, p. 1060). Clinically detectable nephropathy begins with microalbuminuria—30 to 300 mg/24 hours. This may manifest as early as 5 years after diabetes onset. Macroalbuminuria—more than 300 mg/24 hours—develops in patients destined to have end-stage renal disease. Hypertension almost invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years. The incidence of overt proteinuria is nearly 30 percent in individuals with type 1 diabetes and ranges

FIGURE 57-6 Incidence of preeclampsia in 491 type 1 diabetic women in Sweden and the United States. (Data from Hanson^a, 1993; Sibai^b, 2000.)

from 4 to 20 percent in those with type 2 diabetes (Reutens, 2013). Progression from microalbuminuria is not inexorable, and regression is common. Presumably from improved glucose control, the incidence of nephropathy in individuals with type 1 diabetes has declined in the past few decades. Investigators for the Diabetes Control and Complications Trial (2002) reported that there was a 25-percent decrease in the rate of nephropathy for each 10-percent decrease in hemoglobin A_{1c} levels.

Approximately 5 percent of pregnant women with diabetes already have renal involvement. Approximately 40 percent of these will develop preeclampsia (Vidaeff, 2008). High rates are also illustrated in Figure 57-6. However, this may not be the case with microproteinuria. In one analysis of 460 women, How and colleagues (2004) found no association between preeclampsia and microproteinuria. Nevertheless, they found that chronic hypertension with overt diabetic nephropathy increased the risk of preeclampsia to 60 percent.

In general, pregnancy does not appear to worsen diabetic nephropathy. In their prospective study of 43 women with diabetes, Young and associates (2012) could not demonstrate diabetic nephropathy progression through 12 months after delivery. Most of these women had only mild renal impairment. Conversely, pregnancy in women with moderate to severe renal impairment may accelerate progression of their disease (Vidaeff, 2008). As in women with glomerulopathies, hypertension or substantial proteinuria before or during pregnancy is a major predictive factor for progression to renal failure in women with diabetic nephropathy (Chap. 53, p. 1062).

Diabetic Retinopathy. Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. In the United States, diabetic retinopathy is the most important cause of visual impairment in persons younger than age 60 years (Frank, 2004). The first and most common visible lesions are small microaneurysms followed by blot hemorrhages that form when erythrocytes escape from the aneurysms. These areas leak serous fluid that creates hard exudates. Such features are termed *benign* or *background* or *nonproliferative retinopathy*. With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded, leading to retinal ischemia and infarctions that appear as *cotton wool exudates*. These are considered *preproliferative retinopathy*. In response to ischemia, there is neovascularization on the retinal surface and out into the vitreous cavity. Vision is obscured when there is hemorrhage. Laser photocoagulation before hemorrhage, as shown in Figure 57-7, reduces the rate of visual loss progression and blindness by half. The procedure is performed during pregnancy when indicated.

Vestgaard and coworkers (2010) reported that almost two thirds of 102 pregnant women with type 1 diabetes examined by 8 weeks' gestation had background retinal changes, proliferative retinopathy, or macular edema. A fourth of these women developed progression of retinopathy in at least one eye. The same group of investigators evaluated 80 type 2 diabetics and identified retinopathy, mostly mild, in 14 percent during early pregnancy. Progression was identified in only 14 percent (Rasmussen, 2010). This complication is believed

FIGURE 57-7 Retinal photographs from a 30-year-old diabetic woman. **A.** Optic nerve head showing severe proliferative retinopathy characterized by extensive networks of new vessels surrounding the optic disc. **B.** A portion of the acute photocoagulation full “scatter” pattern following argon laser treatment. (From Elman, 1990, with permission.)

to be a rare example of a long-term adverse effect of pregnancy. However, in a prospective postpartum 5-year surveillance of 59 type 1 diabetic women, Arun and Taylor (2008) found that baseline retinopathy was the only independent risk factor for progression.

Other risk factors that have been associated with progression of retinopathy include hypertension, higher levels of insulin-like growth factor-I, and macular edema identified in early pregnancy (Bargiota, 2011; Mathiesen, 2012; Ringholm, 2011; Vestgaard, 2010). The National Institute for Health and Clinical Excellence (2008) established guidelines recommending that pregnant women with preexisting diabetes should routinely be offered retinal assessment after the first prenatal visit. Currently, most agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy.

Ironically, “acute” rigorous metabolic control during pregnancy has been linked to acute worsening of retinopathy. In a study of 201 women with retinopathy, McElvy and associates (2001) found that almost 30 percent suffered eye disease progression during pregnancy despite intensive glucose control. That said, Wang and coworkers (1993) have observed that

retinopathy worsened during the critical months of rigorous glucose control, but long term, deterioration of eye disease slowed. In their study mentioned above, Arun and Taylor (2008) found that only four women required laser photocoagulation during pregnancy, and none required laser in the next 5 years.

Diabetic Neuropathy. Peripheral symmetrical sensorimotor diabetic neuropathy is uncommon in pregnant women. But a form of this, known as *diabetic gastropathy*, is troublesome during pregnancy. It causes nausea and vomiting, nutritional problems, and difficulty with glucose control. Women with gastroparesis should be advised that this complication is associated with a high risk of morbidity and poor perinatal outcome (Kitzmler, 2008). Treatment with metoclopramide and H₂-receptor antagonists is sometimes successful. *Hyperemesis gravidarum* is further discussed in Chapter 54 (p. 1070).

Diabetic Ketoacidosis. This serious complication develops in approximately 1 percent of diabetic pregnancies (Hawthorne, 2011). It is most often encountered in women with type 1 diabetes. It is increasingly being reported in women with type 2 or even those with gestational diabetes (Sibai, 2014). Diabetic ketoacidosis (DKA) may develop with hyperemesis gravidarum, β -mimetic drugs given for tocolysis, infection, and corticosteroids given to induce fetal lung maturation. DKA results from an insulin deficiency combined with an excess in counter-regulatory hormones such as glucagon. This leads to

gluconeogenesis and ketone body formation. The ketone body β -hydroxybutyrate is synthesized at a much greater rate than acetoacetate, which is preferentially detected by commonly used ketosis detection methodologies. Therefore, serum or plasma assays for β -hydroxybutyrate more accurately reflect true ketone body levels.

The incidence of fetal loss can be as high as 20 percent with DKA. Noncompliance is a prominent factor, and this and ketoacidosis were historically considered prognostically bad signs in pregnancy (Pedersen, 1974). Pregnant women usually develop ketoacidosis at lower blood glucose thresholds than when nonpregnant. In a study from China, the mean glucose level for pregnant women with DKA was 293 mg/dL compared with 495 mg/dL for nonpregnant women (Guo, 2008). Chico and associates (2008) reported ketoacidosis in a pregnant woman whose plasma glucose was only 87 mg/dL.

One management protocol for diabetic ketoacidosis is shown in Table 57-7. An important cornerstone of management is vigorous rehydration with crystalloid solutions of normal saline or Ringer lactate.

Infections. Almost all types of infections are increased in diabetic pregnancies. Stamler and coworkers (1990) reported that almost 80 percent of women with type 1 diabetes develop at least one infection during pregnancy compared with only 25 percent in those without diabetes. Common infections include *Candida* vulvovaginitis, urinary and respiratory tract

TABLE 57-7. Protocol Recommended by the American College of Obstetricians and Gynecologists (2012) for Management of Diabetic Ketoacidosis During Pregnancy

Laboratory assessment

Obtain arterial blood gases to document degree of acidosis present; measure glucose, ketones, and electrolyte levels at 1- to 2-hour intervals

Insulin

Low-dose, intravenous
Loading dose: 0.2–0.4 U/kg
Maintenance: 2–10 U/hr

Fluids

Isotonic sodium chloride
Total replacement in first 12 hours of 4–6 L
1 L in first hour
500–1000 mL/hr for 2–4 hours
250 mL/hr until 80 percent replaced

Glucose

Begin 5-percent dextrose in normal saline when glucose plasma level reaches 250 mg/dL (14 mmol/L)

Potassium

If initially normal or reduced, an infusion rate up to 15–20 mEq/hr may be required; if elevated, wait until levels decrease into the normal range, then add to intravenous solution in a concentration of 20–30 mEq/L

Bicarbonate

Add one ampule (44 mEq) to 1 L of 0.45 normal saline if pH is < 7.1

From Landon, 2007, with permission.

infections, and puerperal pelvic sepsis. In their population-based study of almost 200,000 pregnancies, Sheiner and colleagues (2009) found a twofold increased risk of asymptomatic bacteruria in women with diabetes. Similarly, Alvarez and associates (2010) reported positive urine cultures in a fourth of diabetic women compared with 10 percent of nondiabetic pregnant women. In a 2-year analysis of pyelonephritis at Parkland Hospital, 5 percent of women with diabetes developed pyelonephritis compared with 1.3 percent of the nondiabetic population (Hill, 2005). Fortunately, these latter infections can be minimized by screening and eradication of asymptomatic bacteriuria (Chap. 53, p. 1053). Takoudes and colleagues (2004) found that pregestational diabetes is associated with a two- to threefold increase in wound complications after cesarean delivery.

Management of Diabetes in Pregnancy

Because of the relationship between pregnancy complications and maternal glycemic control, efforts to achieve glucose targets are typically more aggressive during pregnancy. Management preferably should begin before pregnancy and include specific goals during each trimester.

Preconceptional Care

To minimize early pregnancy loss and congenital malformations in offspring of diabetic mothers, optimal medical care and education are recommended before conception (Chap. 8, p. 157). Unfortunately, nearly half of pregnancies in the United States are unplanned, and many diabetic women frequently begin pregnancy with suboptimal glucose control (Finer, 2011; Kim, 2005).

The ADA has defined optimal preconceptional glucose control using insulin to include self-monitored preprandial glucose levels of 70 to 100 mg/dL, peak postprandial values of 100 to 129 mg/dL, and mean daily glucose concentrations < 110 mg/dL (Kitzmiller, 2008). Glycosylated hemoglobin measurement, which reflects an average of circulating glucose for the past 4 to 8 weeks, is useful to assess early metabolic control. The ADA (2012) defines optimal values to be < 7 percent. In their prospective population-based study of 933 pregnant women with type 1 diabetes, Jensen and colleagues (2010) found the risk of congenital malformations was not demonstrably higher with glycosylated hemoglobin levels < 6.9 percent compared with that in more than 70,000 nondiabetic controls. They also identified a substantial fourfold increased risk for malformations at levels > 10 percent.

If indicated, evaluation and treatment for diabetic complications such as retinopathy or nephropathy should also be instituted before pregnancy. Finally, folate, 400 µg/day orally is given periconceptionally and during early pregnancy to decrease the risk of neural-tube defects.

First Trimester

Careful monitoring of glucose control is essential. For this reason, many clinicians hospitalize overtly diabetic women during early pregnancy to initiate an individualized glucose control program and offer education. It also provides an opportunity

TABLE 57-8. Action Profiles of Commonly Used Insulins

Insulin Type	Onset	Peak (hr)	Duration (hr)
Short-acting (SC)			
Lispro	< 15 min	0.5–1.5	3–4
Glulisine	< 15 min	0.5–1.5	3–4
Aspart	< 15 min	0.5–1.5	3–4
Regular	30–60 min	2–3	4–6
Long-acting (SC)			
Detemir	1–4 hr	Minimal ^a	Up to 24
Glargine	1–4 hr	Minimal ^a	Up to 24
NPH	1–4 hr	6–10	10–16

^aMinimal peak activity.

NPH = neutral protamine Hagedorn; SC = subcutaneous. Modified from Powers, 2012.

to assess the extent of diabetic vascular complications and precisely establish gestational age.

Insulin Treatment

The overtly diabetic pregnant woman is best treated with insulin. Although oral hypoglycemic agents have been used successfully for gestational diabetes (p. 1141), these agents are not currently recommended for overt diabetes except for limited and individualized use (American College of Obstetricians and Gynecologists, 2012). Maternal glycemic control can usually be achieved with multiple daily insulin injections and adjustment of dietary intake. The action profiles of commonly used short- and long-term insulins are shown in Table 57-8.

Subcutaneous insulin infusion by a calibrated pump may be used during pregnancy. However, as demonstrated in a Cochrane Database review by Farrar and associates (2007), there is scarce robust evidence for specific salutary pregnancy effects. In a metaanalysis of six small randomized trials comparing insulin pumps to multiple daily injections of insulin, there were no significant differences in LGA birthweight, maternal hypoglycemia, or retinopathy progression (Mukhopadhyay, 2007). Notably, more women using insulin pumps developed ketoacidosis. Roeder and colleagues (2012) noted with insulin pump use in women with type 1 diabetes that total daily doses declined in the first trimester but later increased by more than threefold. Postprandial glucose excursions accounted for most increases. Women who use an insulin pump must be highly motivated and compliant to minimize the risk of nocturnal hypoglycemia (Gabbe, 2003).

Monitoring. Self-monitoring of capillary glucose levels using a glucometer is recommended because this involves the woman in her own care. Glucose goals recommended during pregnancy are shown in Table 57-9. Advances in noninvasive glucose monitoring will undoubtedly render intermittent capillary glucose monitoring obsolete. Subcutaneous continuous glucose monitoring devices reveal that pregnant women with

TABLE 57-9. Self-Monitored Capillary Blood Glucose Goals

Specimen	Level (mg/dL)
Fasting	≤ 95
Premeal	≤ 100
1-hr postprandial	≤ 140
2-hr postprandial	≤ 120
0200–0600	≥ 60
Mean (average)	100
Hemoglobin A _{1c}	≤ 6%

diabetes experience significant periods of daytime hyperglycemia and nocturnal hypoglycemia that are undetected by traditional monitoring (Combs, 2012). In one randomized trial of 71 women, those with periodic supplemental access to continuous glucose data had lower glycosylated hemoglobin levels—5.8 versus 6.4 percent—and delivered fewer overgrown newborns (Murphy, 2008). To date however, there have been no trials evaluating the impact of *personal* continuous monitoring devices that give immediate feedback to pregnant women. Such glucose monitoring systems, coupled with a continuous insulin pump, offer the potential of an “artificial pancreas” to avoid undetected hypo- or hyperglycemia during pregnancy.
