Diet. Nutritional planning includes appropriate weight gain through carbohydrate and caloric modifications based on height, weight, and degree of glucose intolerance (American Diabetes Association, 2012; Bantle, 2008). The mix of carbohydrate, protein, and fat is adjusted to meet the metabolic goals and individual patient preferences, but a 175-g minimum of carbohydrate per day should be provided. Carbohydrate should be distributed throughout the day in three small- to moderate-sized meals and two to four snacks (Bantle, 2008). Weight loss is not recommended, but modest caloric restriction may be appropriate for overweight or obese women. An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat, of which < 10 percent is saturated fat.

Hypoglycemia. Diabetes tends to be unstable in the first trimester. Hellmuth and associates (2000) reported that 37 percent of 43 women with type 1 diabetes had maternal hypoglycemia during the first trimester, and the average duration was more than 2 hours. Similarly, Chen and coworkers (2007) identified hypoglycemic events—blood glucose < 40 mg/dL—in 37 of 60 women with type 1 diabetes. A fourth of these were considered severe because the women were unable to treat their own symptoms. Rosenn and colleagues (1994) noted that maternal hypoglycemia had a peak incidence between 10 and 15 weeks’ gestation. Caution is recommended when attempting euglycemia in women with recurrent episodes of hypoglycemia.

We have reported that good pregnancy outcomes can be achieved in women with mean preprandial plasma glucose values up to 143 mg/dL (Leveno, 1979). In women with diabetes who are not pregnant, the Diabetes Control and Complications Trial Research Group (1993) found that

similar glucose values delayed and slowed diabetic retinopathy, nephropathy, and neuropathy. Thus, women with overt diabetes who have glucose values considerably above those defined as normal both during and after pregnancy can expect good outcomes.

Second Trimester

Maternal serum alpha-fetoprotein determination at 16 to 20 weeks’ gestation is used in association with targeted sonographic examination at 18 to 20 weeks to detect neural-tube defects and other anomalies (Chap. 14, p. 284). Maternal alpha-fetoprotein levels may be lower in diabetic pregnancies, and interpretation is altered accordingly. Because the incidence of congenital cardiac anomalies is five times greater in mothers with diabetes, fetal echocardiography is an important part of second-trimester sonographic evaluation (Fouda, 2013). Despite advances in ultrasound technology, however, Dashe and associates (2009) cautioned that detection of fetal anomalies in obese diabetic women is more difficult than in similarly sized women without diabetes.

Regarding second-trimester glucose control, euglycemia with self-monitoring continues to be the goal in management. After the first-trimester instability, a stable period ensues. This is followed by an increased insulin requirement. Recall that Roeder and coworkers (2012) identified a threefold increase in total daily insulin after the first trimester in women using an insulin pump. This is due to the increased peripheral resistance to insulin described in Chapter 4 (p. 53).

Third Trimester and Delivery

During the last several decades, the threat of late-pregnancy fetal death in women with diabetes has prompted recommendations for various fetal surveillance programs beginning in the third trimester. Such protocols include fetal movement counting, periodic fetal heart rate monitoring, intermittent biophysical profile evaluation, and contraction stress testing (Chap. 17, p. 335). None of these techniques has been subjected to prospective randomized clinical trials, and their primary value seems related to their low false-negative rates. The American College of Obstetricians and Gynecologists (2012) suggests initiating such testing at 32 to 34 weeks’ gestation.

At Parkland Hospital, women with diabetes are seen in a specialized obstetrical complications clinic every 2 weeks. During these visits, glycemic control is evaluated and insulin adjusted. They are routinely instructed to perform fetal kick counts beginning early in the third trimester. At 34 weeks, admission is offered to all insulin-treated women. While in the hospital, they continue daily fetal movement counts and undergo fetal heart rate monitoring three times a week. Delivery is planned for 38 weeks.

Labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (Chap. 26, p. 523). Cesarean delivery at or near term has frequently been used to avoid traumatic birth of a large infant in a woman with diabetes. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successful labor induction remote from term has also contributed to an

TABLE 57-10. Insulin Management During Labor and Delivery

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
- Once active labor begins or glucose levels decrease to < 70 mg/dL, the infusion is changed from saline to 5-percent dextrose and delivered at a rate of 100–150 mL/hr (2.5 mg/kg/min) to achieve a glucose level of approximately 100 mg/dL.
- Glucose levels are checked hourly using a bedside meter allowing for adjustment in the insulin or glucose infusion rate.
- Regular (short-acting) insulin is administered by intravenous infusion at a rate of 1.25 U/hr if glucose levels exceed 100 mg/dL.

Data from Coustan DR. Delivery: timing, mode, and management. In: Reece EA, Coustan DR, Gabbe SG, editors. *Diabetes in women: adolescence, pregnancy, and menopause*. 3rd ed. Philadelphia (PA): Lippincott Williams & Wilkins; 2004; and Jovanovic L, Peterson CM. Management of the pregnant, insulin-dependent diabetic woman. *Diabetes Care* 1980;3:63–8. From Pregestational diabetes mellitus. ACOG Practice Bulletin No. 60. American College of Obstetricians and Gynecologists. *Obstet Gynecol* 2005;105:675–85; reaffirmed 2012.

increased cesarean delivery rate. In a nested case-control study of 209 women with type 1 diabetes, Lepercq and colleagues (2010) reported a 70-percent cesarean delivery rate overall. Two thirds of these were delivered without labor. Both maternal body mass index (BMI) > 25 kg/m² and low Bishop score were independently associated with cesarean delivery for those in labor. In another study, a glycohemoglobin level > 6.4 percent at delivery was independently associated with urgent cesarean delivery. This suggests that tighter glycemic control during the third trimester might reduce late fetal compromise and cesarean delivery for fetal indications (Miaillhe, 2013). The cesarean delivery rate for women with overt diabetes has remained at approximately 80 percent for the past 35 years at Parkland Hospital.

Reducing or withholding the dose of long-acting insulin given on the day of delivery is recommended. Regular insulin should be used to meet most or all of the insulin needs of the mother during this time, because insulin requirements typically drop markedly after delivery. We have found that continuous insulin infusion by calibrated intravenous pump is most satisfactory (Table 57-10). Throughout labor and after delivery, the woman should be adequately hydrated intravenously and given glucose in sufficient amounts to maintain normoglycemia. Capillary or plasma glucose levels should be checked frequently, especially during active labor, and regular insulin should be administered accordingly.

Puerperium

Often, women may require virtually no insulin for the first 24 hours or so postpartum. Subsequently, insulin requirements may fluctuate markedly during the next few days. Infection must be promptly detected and treated.

Counseling in the puerperium should include a discussion of birth control. Available options are discussed in Chapter 38 (p. 695). Effective contraception is especially important in women with overt diabetes to allow optimal glucose control before subsequent conceptions.

GESTATIONAL DIABETES

In the United States, 5 to 6 percent of pregnancies—almost 250,000 women—are affected annually by various forms of gestational diabetes. Worldwide, its prevalence differs according to

race, ethnicity, age, and body composition and by screening and diagnostic criteria. There continue to be several controversies pertaining to the diagnosis and treatment of gestational diabetes. Accordingly, a National Institutes of Health (NIH) Consensus Development Conference (2013) was convened. Coincidental with publication of the Conference findings, the American College of Obstetricians and Gynecologists (2013) also updated its recommendations. These two authoritative sources provide an up-to-date analysis of the issues surrounding this diagnosis and bolster the approach to identifying and treating women with gestational diabetes, as described subsequently.

The word *gestational* implies that diabetes is induced by pregnancy—ostensibly because of exaggerated physiological changes in glucose metabolism (Chap. 4, p. 53). Gestational diabetes is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy (American College of Obstetricians and Gynecologists, 2013). This definition applies whether or not insulin is used for treatment and undoubtedly includes some women with previously unrecognized overt diabetes. In their analysis of more than 1500 nonpregnant adults as part of National Health and Nutrition Examinations Survey (NHANES) IV, Karve and Hayward (2010) estimated that only 4.8 percent of individuals with impaired fasting glucose or glucose intolerance were aware of their diagnosis.

Use of the term *gestational diabetes* has been encouraged to communicate the need for increased surveillance and to stimulate women to seek further testing postpartum. The most important perinatal correlate is excessive fetal growth, which may result in both maternal and fetal birth trauma. The likelihood of fetal death with appropriately treated gestational diabetes is not different from that in the general population. Importantly, more than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years. And, as discussed on page 1125, evidence is mounting for long-range complications that include obesity and diabetes in their offspring.

Screening and Diagnosis

Despite more than 40 years of research, there is still no agreement regarding optimal gestational diabetes screening. The difficulty in achieving consensus is underscored by the controversy following publication of the single-step approach espoused by

TABLE 57-11. Threshold Values for Diagnosis of Gestational Diabetes

Plasma Glucose	Glucose Concentration Threshold ^a		Above Threshold (%) Cumulative
	mmol/L	mg/dL	
Fasting	5.1	92	8.3
1-hr OGTT	10.0	180	14.0
2-hr OGTT	8.5	153	16.1 ^b

^aOne or more of these values from a 75-g OGTT must be equaled or exceeded for the diagnosis of gestational diabetes.

^bIn addition, 1.7% of participants in the initial cohort were unblinded because of fasting plasma glucose levels > 5.8 mmol/L (105 mg/dL) or 2-hr OGTT values > 11.1 mmol/L (200 mg/dL), bringing the total to 17.8%. OGTT = oral glucose tolerance test.

the IADPSG Consensus Panel (2010) (Table 57-11). This strategy was greatly influenced by results of the Hypoglycemia and Pregnancy Outcomes (HAPO) Study described later. Although the ADA adopted this new scheme, the American College of Obstetricians and Gynecologists (2013) declined to endorse the single 75-gram oral glucose tolerance test. Instead, the College continues to recommend a two-step approach to screen and diagnose gestational diabetes. Similarly, the NIH

Consensus Development Conference in 2013 concluded that evidence is insufficient to adopt a one-step approach.

The recommended two-step approach begins with either universal or risk-based selective screening using a 50-g, 1-hour oral glucose challenge test. Participants in the Fifth International Workshop Conferences on Gestational Diabetes endorsed use of *selective screening* criteria shown in Table 57-12. *Universal screening* is also acceptable. Gabbe and associates (2004) surveyed practicing obstetricians and reported that 96 percent used universal screening. Screening should be performed between 24 and 28 weeks' gestation in those women not known to have glucose intolerance earlier in pregnancy. This *50-g screening test* is followed by a *diagnostic 100-g, 3-hour oral glucose tolerance test (OGTT)* if screening results meet or exceed a predetermined plasma glucose concentration.

For the 50-g screen, the plasma glucose level is measured 1 hour after a 50-g oral glucose load without regard to the time of day or time of last meal. In a recent review, the pooled sensitivity for a threshold of 140 mg/dL ranged from 74 to 83 percent depending on 100-g thresholds used for diagnosis (van Leeuwen, 2012). Sensitivity estimates for a 50-g screen threshold of 135 mg/dL improved only slightly to 78 to 85 percent. Importantly, specificity dropped from a range of 72 to 85 percent for 140 mg/dL to 65 to 81 percent for a threshold of 135 mg/dL. That said, the American College of Obstetricians and Gynecologists (2013) recommends using either 135 or 140 mg/dL as the 50-g screen threshold. At Parkland Hospital, we continue to use 140 mg/dL.

TABLE 57-12. Fifth International Workshop-Conference on Gestational Diabetes: Recommended Screening Strategy Based on Risk Assessment for Detecting Gestational Diabetes (GDM)

GDM risk assessment: should be ascertained at the first prenatal visit

Low Risk: Blood glucose testing not routinely required if all the following are present:

- Member of an ethnic group with a low prevalence of GDM
- No known diabetes in first-degree relatives
- Age < 25 years
- Weight normal before pregnancy
- Weight normal at birth
- No history of abnormal glucose metabolism
- No history of poor obstetrical outcome

Average Risk: Perform blood glucose testing at 24 to 28 weeks using either:

- Two-step procedure: 50-g oral glucose challenge test (GCT), followed by a diagnostic 100-g OGTT for those meeting the threshold value in the GCT
- One-step procedure: diagnostic 100-g OGTT performed on all subjects

High Risk: Perform blood glucose testing as soon as feasible, using the procedures described above, if one or more of these are present:

- Severe obesity
- Strong family history of type 2 diabetes
- Previous history of GDM, impaired glucose metabolism, or glucosuria
- If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks' gestation or at any time symptoms or signs suggest hyperglycemia

OGTT = oral glucose tolerance test.

Modified from Metzger, 2007.

TABLE 57-13. Fifth International Workshop Conference on Gestational Diabetes: Diagnostic Criteria of Gestational Diabetes by Oral Glucose Tolerance Testing

Time	Oral Glucose Load ^a			
	100-g Glucose ^b		75-g Glucose ^b	
Fasting	95 mg/dL	5.3 mmol/L	95 mg/dL	5.3 mmol/L
1-hr	180 mg/dL	10.0 mmol/L	180 mg/dL	10.0 mmol/L
2-hr	155 mg/dL	8.6 mmol/L	155 mg/dL	8.6 mmol/L
3-hr	140 mg/dL	7.8 mmol/L	—	—

^aThe test should be performed in the morning after an overnight fast of at least 8 hr but not more than 14 hr and after at least 3 days of unrestricted diet (≥ 150 g/d) and physical activity. The subject should remain seated and should not smoke during the test.

^bTwo or more of the venous plasma glucose concentrations listed must be met or exceeded for a positive diagnosis.

Data from Metzger, 2007.

Justification for screening and treatment of women with gestational diabetes was strengthened by the study by Crowther and coworkers (2005). They assigned 1000 women with gestational diabetes between 24 and 34 weeks' gestation to receive dietary advice with blood glucose monitoring plus insulin therapy—the intervention group—or to undergo routine prenatal care. Women were diagnosed as having gestational diabetes if their blood glucose was < 100 mg/dL after an overnight fast and was between 140 and 198 mg/dL 2 hours after ingesting a 75-g glucose solution. Women in the intervention group had a significantly reduced risk of a composite adverse outcome that included perinatal death, shoulder dystocia, fetal bone fracture, and fetal nerve palsy. Macrosomia defined by birthweight ≥ 4000 g complicated 10 percent of deliveries in the intervention group compared with 21 percent in the routine prenatal care group. Cesarean delivery rates were almost identical in the two study groups.

Slightly different results were reported by the Maternal-Fetal Medicine Units Network randomized trial of 958 women (Landon, 2009). Dietary counseling plus glucose monitoring was compared with standard obstetrical care in women with mild gestational diabetes to reduce perinatal morbidity rates. Mild gestational diabetes was identified in women with fasting glucose levels < 95 mg/dL. They reported no differences in rates of composite morbidity that included stillbirth; neonatal hypoglycemia, hyperinsulinemia, and hyperbilirubinemia; and birth trauma. Importantly, secondary analyses demonstrated a 50-percent reduction in macrosomia, fewer cesarean deliveries, and a significant decrease in shoulder dystocia rates—1.5 versus 4 percent—in treated versus control women.

Based largely on these two studies, the U.S. Preventive Services Task Force (2013) now recommends universal screening in low-risk women after 24 weeks' gestation. However, the Task Force concluded that evidence is insufficient to assess the balance of benefits versus harms of screening before 24 weeks. From the foregoing, there obviously is not international agreement as to the optimal glucose tolerance test to identify gesta-

tional diabetes. The World Health Organization (1998) and now the American Diabetes Association (2013) recommend the 75-g 2-hour oral glucose tolerance test. In the United States, however, the 100-g, 3-hour OGTT test performed after an overnight fast is recommended by the American College of Obstetricians and Gynecologists (2013). Criteria for interpretation of the 100-g diagnostic glucose tolerance test are shown in Table 57-13. Also shown are the criteria for the 75-g test most often used outside the United States.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study

This was a 7-year international epidemiological study of 23,325 pregnant women at 15 centers in nine countries (HAPO Study Cooperative Research Group, 2008). The investigation analyzed the association of various levels of glucose intolerance during the third trimester with adverse infant outcomes in women with gestational diabetes. Between 24 and 32 weeks' gestation, the general population of pregnant women underwent 75-g oral glucose tolerance testing after overnight fasting. Blood glucose levels were measured fasting and then 1 and 2 hours after glucose ingestion. Caregivers were blinded to results except for women whose glucose levels exceeded values that required treatment and removal from the study. Glucose values at each of these three time posts were stratified into seven categories (Fig. 57-8). Values were then correlated with rates for birthweight > 90th percentile (LGA), primary cesarean delivery, clinical neonatal hypoglycemia, and cord-serum C-peptide levels > 90th percentile. C-peptide is a measurable by-product created during insulin production. Odds of each outcome were calculated using the lowest category—for example, fasting plasma glucose < 75 mg/dL—as the referent group. Their findings in general supported the supposition that increasing plasma glucose levels at each epoch were associated with increasing adverse outcomes.

In an editorial accompanying publication of the HAPO trial, Ecker and Greene (2008) posed the question: “Given

FIGURE 57-8 Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study. The frequency of newborn birthweight \geq 90th percentile for gestational age plotted against glucose levels (mg/dL) fasting and at 1- and 2-hr intervals following a 75-g oral glucose load. LGA = large for gestational age. (Adapted from The HAPO Study Cooperative Research Group, 2008.)

the results of the HAPO study, should we lower our threshold for the diagnosis and treatment of gestational diabetes?" It was adjudged that it will be difficult to show that treating lesser degrees of carbohydrate intolerance—as suggested in the HAPO study—would provide any meaningful improvements in clinical outcomes. Thus Ecker and Greene (2008) concluded, and we agree, that changes in criteria are not justified until clinical trials prove benefits. Most recently, this position was endorsed by the 2013 NIH Consensus Development Conference.

International Association of Diabetes and Pregnancy Study Group

The IADPSG sponsored a workshop conference on the diagnosis and classification of gestational diabetes in 2008. After reviewing the results of the HAPO study, a panel was appointed to develop recommendations for the diagnosis and classification of hyperglycemia during pregnancy. This panel allowed for the diagnosis of overt diabetes during pregnancy as shown in Table 57-4. It also recommended a single-step approach to the diagnosis of gestational diabetes using the 75-g, 2-hour OGTT. Thresholds for fasting, 1-, and 2-hour values based on mean glucose concentrations from the entire HAPO study cohort were considered. These thresholds were derived using an arbitrary 1.75 odds ratio of outcomes such as LGA birthweight and cord serum C-peptide levels $>$ 90th percentile. Only one of these thresholds would need to be met or exceeded to make the diagnosis of gestational diabetes (see Table 57-11).

It is estimated that implementation of these recommendations would increase the prevalence of gestational diabetes in the United States to 17.8 percent! Said another way, the number of women with mild gestational diabetes would increase almost threefold with no evidence of treatment benefit (Cundy, 2012). Despite these significant drawbacks, the ADA (2013) recommended

adopting this new approach based on benefits inferred from trials in women identified using a two-step approach described on page 1138 (Crowther, 2005; Landon, 2009).

National Institutes of Health Consensus Development Conference on Diagnosing Gestational Diabetes Mellitus

Prompted by the IADPSG recommendations (2010) and their adoption by the ADA (2013), an NIH Consensus Development Conference (2013) was convened. This conference included input from a multidisciplinary planning committee, a systematic evidence review by the Agency for Healthcare Research and Quality (AHRQ) Evidence-Based Practice Center, expert testimony, and a nonbiased panel to produce the overall report. The panel concluded that there were potential benefits to worldwide standardization. However, it found insufficient evidence to adopt

a one-step diagnostic process such as the one proposed by the IADPSG. Moreover, as mentioned previously, after consideration of these findings, the American College of Obstetricians and Gynecologists (2013) continues to recommend a two-step screening and diagnostic approach to gestational diabetes diagnosis. It noted no significant improvements in maternal or perinatal outcomes that would offset the tripling of gestational diabetes incidence that would derive from the one-step approach. We applaud this decision.

Maternal and Fetal Effects

Adverse consequences of gestational diabetes differ from those of pregestational diabetes. Unlike in women with overt diabetes, rates of fetal anomalies do not appear to be substantially increased (Sheffield, 2002). In a study of more than 1 million women from the Swedish Medical Birth Registry, major malformation rates were marginally increased—2.3 versus 1.8 percent (Fadl, 2010). The stillbirth rate was not increased in this study or in an analysis of 130 perinatal deaths in the HAPO study (2008). In contrast, and not unexpectedly, women with *elevated* fasting glucose levels have increased rates of unexplained stillbirths similar to women with overt diabetes. The ADA (2003) concluded that fasting hyperglycemia $>$ 105 mg/dL may be associated with an increased risk of fetal death during the final 4 to 8 weeks. This increasing risk with progressive maternal hyperglycemia prompted the IADPSG (2010) to emphasize the importance of identifying women with evidence of preexisting diabetes early in pregnancy (see Table 57-4). Similar to women with overt diabetes, adverse maternal effects associated with gestational diabetes include an increased frequency of hypertension and cesarean delivery.

Fetal Macrosomia

The primary effect attributed to gestational diabetes is excessive fetal size or macrosomia that is variably defined and discussed further in Chapter 44 (p. 884). Maternal hyperglycemia prompts fetal hyperinsulinemia, particularly during the second half of pregnancy. This in turn stimulates excessive somatic growth. The perinatal goal is to avoid difficult delivery from macrosomia and concomitant birth trauma associated with shoulder dystocia. In a retrospective analysis of more than 80,000 vaginal deliveries in Chinese women, Cheng and associates (2013) calculated a 76-fold increased risk for shoulder dystocia in newborns weighing ≥ 4200 g compared with the risk in those weighing < 3500 g. Importantly, however, the odds ratio for shoulder dystocia in women with diabetes was less than 2. Although gestational diabetes is certainly a risk factor, it accounts for only a small number of pregnancies complicated by shoulder dystocia.

The excessive shoulder and trunk fat that commonly characterizes the macrosomic infant of a diabetic mother theoretically predisposes such infants to shoulder dystocia or cesarean delivery (Durnwald, 2004; McFarland, 2000). Landon and colleagues (2011) identified shoulder dystocia in approximately 4 percent of women with mild gestational diabetes compared with < 1 percent of women with a 50-g glucose screen result < 120 mg/dL. In a prospective study of fetal adipose measurements, however, Buhling and coworkers (2012) demonstrated no differences between measurements in 630 offspring of women with gestational diabetes and 142 without diabetes. The authors attributed this negative finding to successful treatment of gestational diabetes.

There is extensive evidence that insulin-like growth factors also play a role fetal-growth regulation (Chap. 44, p. 872). These proinsulin-like polypeptides are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Luo and coworkers (2012) reported that insulin-like growth factor-I strongly correlated with birthweight. The HAPO study investigators also reported dramatic increases of cord-serum C-peptide levels with increasing maternal glucose levels following a 75-g OGTT. C-peptide levels > 90 th percentile were found in almost a third of newborns in the highest glucose categories. Other factors implicated in macrosomia include epidermal growth factor, fibroblast growth factor, platelet-derived growth factor, leptin, and adiponectin (Grissa, 2011; Loukovaara, 2004; Mazaki-Tovi, 2005).

Neonatal Hypoglycemia

Neonatal hyperinsulinemia may provoke hypoglycemia within minutes of birth. The incidence varies depending on the threshold definition. Cornblath and associates (2000) established a threshold of 35 mg/dL in term newborns. An NIH workshop conference on neonatal hypoglycemia supported use of such operational thresholds but cautioned that these are not strictly evidence-based (Hay, 2009). Newborns described by the HAPO study (2008) had an incidence of clinical neonatal hypoglycemia that increased with increasing maternal OGTT values defined in Figure 57-8. The frequency varied from 1 to 2 percent, but it was as high as 4.6 percent in women with fasting glucose levels ≥ 100 mg/dL. Likewise,

cord-blood insulin levels are related to maternal glucose control (Leipold, 2004).

Maternal Obesity

In women with gestational diabetes, maternal BMI is an independent and more substantial risk factor for fetal macrosomia than is glucose intolerance (Ehrenberg, 2004; Mission, 2013). Stuebe and colleagues (2012) completed a secondary analysis of women with either untreated mild gestational diabetes or normal glucose tolerance testing results. They found that higher BMI levels were associated with increasing birthweight, regardless of glucose levels. Also, maternal obesity is an important confounding factor in the diagnosis of gestational diabetes. In their metaanalysis, Torloni and coworkers (2009) estimated that the gestational diabetes prevalence increases by approximately 1 percent for every 1 kg/m² increase in BMI. Weight distribution also seems to play a role because the risk of gestational diabetes is increased with truncal obesity. Suresh and colleagues (2012) verified that increased maternal abdominal subcutaneous fat thickness as measured by sonography at 18 to 22 weeks' gestation correlated with BMI and was a better predictor of gestational diabetes. Martin and associates (2009) reported similar findings for sonographically measured maternal visceral adipose depth. Importantly, excessive gestational weight gain is commonly identified in women with gestational diabetes and also confers an additive risk for fetal macrosomia (Egan, 2014).

Management

Women with gestational diabetes can be divided into two functional classes using fasting glucose levels. Pharmacological methods are usually recommended if diet modification does not consistently maintain the fasting plasma glucose levels < 95 mg/dL or the 2-hour postprandial plasma glucose < 120 mg/dL (American College of Obstetricians and Gynecologists, 2013). Whether pharmacological treatment should be used in women with lesser degrees of fasting hyperglycemia—105 mg/dL or less before dietary intervention—is unclear. There have been no controlled trials to identify ideal glucose targets for fetal risk prevention. On the other hand, the HAPO study (2008) did demonstrate increased fetal risk at glucose levels below the threshold used for diagnosis of diabetes. The Fifth International Workshop Conference recommended that fasting capillary glucose levels be kept ≤ 95 mg/dL (Metzger, 2007).

In a systematic review, Hartling and colleagues (2013) concluded that treating gestational diabetes resulted in a significantly lower incidence of preeclampsia, shoulder dystocia, and macrosomia. For example, the calculated risk ratio for delivering an infant > 4000 g after treatment was 0.50. These investigators caution that the attributed risk for these outcomes is low, especially when glucose values are only moderately elevated. Importantly, they were unable to demonstrate an effect on neonatal hypoglycemia or future metabolic outcomes in the offspring.

Diabetic Diet

As discussed previously, reports by Crowther (2005) and Landon (2009) and their colleagues describe the benefits

of dietary counseling and monitoring in women with gestational diabetes. The ADA recommends individualized nutritional counseling based on height and weight (Bantle, 2008). Nutritional instructions generally include a carbohydrate-controlled diet sufficient to maintain normoglycemia and avoid ketosis. On average, this includes a daily caloric intake of 30 to 35 kcal/kg. Moreno-Castilla and associates (2013) randomly assigned 152 women with gestational diabetes to either a 40- or a 55-percent daily carbohydrate diet and found no difference in insulin levels and pregnancy outcomes. The American College of Obstetricians and Gynecologists (2013) suggests that carbohydrate intake be limited to 40 percent of total calories. The remaining calories are apportioned to give 20 percent as protein and 40 percent as fat.

Although the most appropriate diet for women with gestational diabetes has not been established, the ADA (2003) has suggested that obese women with a BMI > 30 kg/m² may benefit from a 30-percent caloric restriction, which approximates 25 kcal/kg/d. This should be monitored with weekly assessment for ketonuria, which has been linked with impaired psychomotor development in offspring (Rizzo, 1995; Scholte, 2012). That said, Most and Langer (2012) found that insulin was necessary to reduce excess birthweight in offspring of obese women with gestational diabetes.

Exercise

The American College of Obstetricians and Gynecologists (2009) reviewed three randomized trials of exercise in women with gestational diabetes (Avery, 1997; Bung, 1993; Jovanovic-Peterson, 1989). The results suggest that exercise improved cardiorespiratory fitness without improving pregnancy outcome. Importantly, these trials were small and had limited power to show improvement in outcomes. Dempsey and coworkers (2004) found that physical activity during pregnancy reduced the risk of gestational diabetes. Brankston and associates (2004) reported that resistance exercise diminished the need for insulin therapy in overweight women with gestational diabetes. Conversely, Stafne and colleagues (2012), in a randomized controlled trial in 855 women, observed that a 1-week exercise program during the second half of pregnancy did not prevent gestational diabetes or improve insulin resistance. Importantly, the average BMI at enrollment was 24.8 ± 3.2 . The American College of Obstetricians and Gynecologists (2013) recommends a moderate exercise program as part of the treatment plan for women with gestational diabetes.

Glucose Monitoring

Hawkins and colleagues (2008) compared outcomes in 315 women with diet-treated gestational diabetes who used personal glucose monitors with those of 615 gestational diabetics who were also diet-treated but who underwent intermittent fasting glucose evaluation during semi-weekly obstetrical visits. Women using daily blood-glucose self-monitoring had significantly fewer macrosomic infants and gained less weight after diagnosis than women evaluated during clinic visits only. These findings support the common practice of blood-glucose self-monitors for women with diet-treated gestational diabetes.

Postprandial surveillance for gestational diabetes has been shown to be superior to preprandial surveillance. DeVeciana and coworkers (1995) studied 66 pregnant women with gestational diabetes in whom insulin was initiated for fasting hyperglycemia. The women were randomly assigned to glucose surveillance using either preprandial or 1-hour postprandial capillary blood-glucose concentrations. Postprandial surveillance was shown to be superior in that blood-glucose control was significantly improved and was associated with fewer cases of neonatal hypoglycemia—3 versus 21 percent; less macrosomia—12 versus 42 percent; and fewer cesarean deliveries for dystocia—24 versus 39 percent. At Parkland Hospital, we were unable to demonstrate similar findings when we reviewed the impact of changing to postprandial monitoring in women with diet-treated gestational diabetes. We did, however, demonstrate a significant reduction in maternal weight gain per week—0.63 lb/week to 0.45 lb/week—in women managed with a postprandial monitoring schema. The American College of Obstetricians and Gynecologists (2013) recommends four-times daily glucose monitoring performed fasting and either 1 or 2 hours after each meal.

Insulin Treatment

Historically, insulin has been considered standard therapy in women with gestational diabetes when target glucose levels cannot be consistently achieved through nutrition and exercise. It does not cross the placenta, and tight glycemic control can typically be achieved. In a report prepared for the AHRQ, Nicholson and associates (2009) were unable to determine a threshold above which insulin should be initiated. Pharmacological therapy—in this case insulin—is typically added if fasting levels persistently exceed 95 mg/dL in women with gestational diabetes. The American College of Obstetricians and Gynecologists (2013) also recommends that insulin be considered in women with 1-hour postprandial levels that persistently exceed 140 mg/dL or those with 2-hour levels above 120 mg/dL. Importantly, all of these thresholds are extrapolated from recommendations for managing women with overt diabetes.

If insulin is initiated, the starting dose is typically 0.7–1.0 units/kg/day given in divided doses (American College of Obstetricians and Gynecologists, 2013). A combination of intermediate-acting and short-acting insulin may be used, and dose adjustments are based on glucose levels at particular times of the day. At Parkland Hospital, insulin instruction for these women is accomplished either in a specialized outpatient clinic or during a short hospital stay. As shown in Table 57-8, insulin analogues such as insulin aspart and insulin lispro have a more rapid onset of action than regular insulin and theoretically could be helpful in postprandial glucose management. Experience with these analogues with gestational diabetes is limited, and Singh and coworkers (2008) were unable to demonstrate a benefit compared with conventional insulins.

Oral Hypoglycemic Agents

Several studies have attested to the safety and efficacy of gestational diabetes treatment with either glyburide (Micronase) or metformin (Glucophage) (Langer, 2000; Nicholson, 2009;

Rowan, 2008). In one study, Langer and colleagues (2000, 2005) randomly assigned 404 women to insulin or glyburide therapy. Near normoglycemic levels were achieved with either regimen, and there were no apparent neonatal complications attributable to glyburide. In a follow-up study, Conway and coworkers (2004) reported that women with fasting glucose levels > 110 mg/dL did not adequately respond to glyburide therapy. Similar results were reported by Chmait (2004) and Kahn (2006) and their associates. At one time, glyburide was thought not to cross the placenta. However, Hebert and colleagues (2008, 2009) sampled 20 paired maternal-cord specimens and found the latter to have glyburide concentrations approximately half that of maternal levels.

Metformin treatment for polycystic ovarian disease throughout pregnancy reduced the incidence of gestational diabetes (Glueck, 2004). Because metformin crosses to the fetus, there was reticence to use it in pregnant women (Harborne, 2003). Subsequent studies have helped allay these concerns. Rowan and associates (2008) randomly assigned 751 women with gestational diabetes to metformin or insulin treatment. The primary outcome was a composite of neonatal hypoglycemia, respiratory distress syndrome, phototherapy, birth trauma, 5-minute Apgar score ≤ 7 , and preterm birth. Similarities in the composite outcome between metformin and insulin led investigators to conclude that metformin was not associated with adverse perinatal outcomes. It is noteworthy that 46 percent of women in the metformin trial required supplemental insulin compared with only 4 percent of women treated with glyburide (Langer, 2000).

In their systematic review and metaanalysis of oral hypoglycemic agents for gestational diabetes, Nicholson and coworkers (2009) found no evidence of increased adverse maternal or neonatal outcomes with glyburide or metformin compared with insulin. Moore and associates (2010) randomly assigned 149 women with gestational diabetes who did not achieve glycemic control on diet therapy to either glyburide or metformin treatment. More than a third of women in the metformin group required supplemental insulin compared with 16 percent of those treated with glyburide.

Oral hypoglycemic agents are being increasingly used for gestational diabetes, although they have not been approved by the Food and Drug Administration for this indication. A survey of almost 1400 fellows of the American College of Obstetricians and Gynecologists found that 13 percent of respondents were using glyburide as first-line therapy for diet failure in women with gestational diabetes (Gabbe, 2004). The American College of Obstetricians and Gynecologists (2013) acknowledges that both glyburide and metformin are appropriate, as is insulin, for first-line glycemic control in women with gestational diabetes. Because long-term outcomes have not been studied, the committee recommends appropriate counseling when hypoglycemic agents are used.

■ Obstetrical Management

In general, for women with gestational diabetes who do not require insulin, early delivery or other interventions are seldom required. There is no consensus regarding the value or timing

of antepartum fetal testing. It is typically reserved for women with pregestational diabetes because of the increased stillbirth risk. The American College of Obstetricians and Gynecologists (2013) endorses fetal surveillance in women with gestational diabetes and poor glycemic control. At Parkland Hospital, women with gestational diabetes are routinely instructed to perform daily fetal kick counts in the third trimester (Chap. 17, p. 335). Insulin-treated women are offered inpatient admission after 34 weeks' gestation, and fetal heart rate monitoring is performed three times each week.

Women with gestational diabetes and adequate glycemic control are managed expectantly. Elective labor induction to prevent shoulder dystocia compared with spontaneous labor remains controversial. One randomized trial evaluated induction at 38 weeks in 200 women with insulin-treated diabetes—187 of whom had gestational diabetes. Investigators reported a significantly lower proportion of newborns with a birthweight > 90th percentile in the active induction group—10 versus 23 percent (Kjos, 1993). However, there were no differences in rates of cesarean delivery or shoulder dystocia or in neonatal outcomes. Witkop and colleagues (2009) performed a systematic review and concluded that, in the aggregate, a reduction in fetal macrosomia is likely in women with gestational diabetes who undergo an elective labor induction at term. They also found a limited ability to draw definite conclusions based on available evidence. The American College of Obstetricians and Gynecologists (2013) also has concluded that no evidence-based recommendation can be made regarding delivery timing in women with gestational diabetes. To study this, a large multicenter trial (NCT01058772) expected to enroll 1760 women with gestational diabetes is currently recruiting participants (Maso, 2011).

Elective cesarean delivery to avoid brachial plexus injuries in overgrown fetuses is also an important issue. The American College of Obstetricians and Gynecologists (2013) has suggested that cesarean delivery should be considered in women with gestational diabetes whose fetuses have a sonographically estimated weight ≥ 4500 g. From their systematic review, Garabedian and coworkers (2010) estimated that as many as 588 cesarean deliveries in women with gestational diabetes and an estimated fetal weight of ≥ 4500 g would be necessary to avoid one case of permanent brachial plexus palsy. Effects of such a policy were retrospectively analyzed by Gonen and associates (2000) in a general obstetrical population of more than 16,000 women. Elective cesarean delivery had no significant effect on the incidence of brachial plexus injury.

■ Postpartum Evaluation

Recommendations for postpartum evaluation are based on the 50-percent likelihood of women with gestational diabetes developing overt diabetes within 20 years (O'Sullivan, 1982). The Fifth International Workshop Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo evaluation with a 75-g oral glucose tolerance test at 6 to 12 weeks postpartum and other intervals thereafter (Metzger, 2007). These recommendations are shown in [Table 57-14](#) along with the classification scheme of the ADA

TABLE 57-14. Fifth International Workshop-Conference: Metabolic Assessments Recommended after Pregnancy with Gestational Diabetes

Time	Test	Purpose
Postdelivery (1–3 d)	Fasting or random plasma glucose	Detect persistent, overt diabetes
Early postpartum (6–12 wk)	75-g, 2-hr OGTT	Postpartum classification of glucose metabolism
1-yr postpartum	75-g, 2-hr OGTT	Assess glucose metabolism
Annually	Fasting plasma glucose	Assess glucose metabolism
Triannually	75-g, 2-hr OGTT	Assess glucose metabolism
Prepregnancy	75-g, 2-hr OGTT	Classify glucose metabolism

Classification of the American Diabetes Association (2013)		
Normal Values	Impaired Fasting Glucose or Impaired Glucose Tolerance	Diabetes Mellitus
Fasting < 100 mg/dL	100–125 mg/dL	≥ 126 mg/dL
2 hr < 140 mg/dL	2 hr ≥ 140–199 mg/dL	2 hr ≥ 200 mg/dL
Hemoglobin A _{1c} < 5.7%	5.7–6.4%	≥ 6.5%

OGTT = oral glucose tolerance test.

From American Diabetes Association, 2013; Metzger, 2007.

(2013). Hunt and colleagues (2010) reviewed performance rates of postpartum glucose screening and found that anywhere between 23 and 58 percent of women actually undergo 75-g glucose testing. The American College of Obstetricians and Gynecologists (2013) recommends either a fasting glucose or the 75-g, 2-hour OGTT for the diagnosis of overt diabetes. The ADA (2011) recommends testing at least every 3 years in women with a history of gestational diabetes but normal postpartum glucose screening.

Women with a history of gestational diabetes are also at risk for cardiovascular complications associated with dyslipidemia, hypertension, and abdominal obesity—the *metabolic syndrome* (Chap. 48, p. 962). In a study of 47,909 parous women, Kessous and coworkers (2013) evaluated subsequent hospitalizations due to cardiovascular morbidity. They found that almost 5000 women with gestational diabetes were 2.6 times more likely to be hospitalized for cardiovascular morbidity. Shah and coworkers (2008) also documented excessive cardiovascular disease by 10 years in women with gestational diabetes. Akinci and associates (2009) reported that a fasting glucose level ≥ 100 mg/dL in the index OGTT was an independent predictor of the metabolic syndrome.

Recurrent Gestational Diabetes

In subsequent pregnancies, recurrence was documented in 40 percent of 344 primiparous women with gestational diabetes (Holmes, 2010). Obese women were more likely to have impaired glucose tolerance in subsequent pregnancies. Thus, lifestyle behavioral changes, including weight control and exercise between pregnancies, likely would prevent gestational diabetes recurrence (Kim, 2008). Ehrlich and colleagues (2011) found that the loss of at least two BMI units was associated with a lower risk of gestational diabetes in women who were overweight or obese in the first pregnancy. Getahun and coworkers (2010) found that only 4.2 percent of women with-

out gestational diabetes in their first pregnancy were diagnosed with gestational diabetes when screened in a second pregnancy. This compared with 41.3 percent in women with a history of gestational diabetes.

Contraception

Low-dose hormonal contraceptives may be used safely by women with recent gestational diabetes (Chap. 38, p. 709). The rate of subsequent diabetes in oral contraceptive users is not significantly different from that in those who did not use hormonal contraception (Kerlan, 2010). Importantly, comorbid obesity, hypertension, or dyslipidemia should direct the choice for contraception toward a method without potential cardiovascular consequences. In these instances, the intrauterine device is a good alternative.

CHAPTER 58

Endocrine Disorders

THYROID PHYSIOLOGY AND PREGNANCY	1147
HYPERTHYROIDISM	1148
HYPOTHYROIDISM	1152
SUBCLINICAL HYPOTHYROIDISM	1154
IODINE DEFICIENCY	1155
CONGENITAL HYPOTHYROIDISM	1156
POSTPARTUM THYROIDITIS	1156
NODULAR THYROID DISEASE	1157
PARATHYROID DISEASES	1157
ADRENAL GLAND DISORDERS	1159
PITUITARY DISEASES	1162

There are no endocrine disorders that are unique to pregnancy. However, endocrinopathies seem particularly closely related to pregnancy due to their proclivity for hormone secretion. Indeed, some hormones are secreted in prodigious quantities. This is probably best illustrated by placental lactogen in diabetes, the most common endocrinopathy encountered in pregnancy (Chap. 57, p. 1125). Pregnancy is also interrelated with some endocrinopathies that are at least partially due to autoimmune dysregulation. Clinical manifestations of this result from complex interplay among genetic, environmental, and endogenous factors that activate the immune system against targeted cells within endocrine organs. An extraordinary example of these interactions comes from studies that implicate maternal organ engraftment by fetal cells that were transferred during pregnancy. These cells later provoke antibody production, tissue destruction, and autoimmune endocrinopathies.

THYROID DISORDERS

Taken in aggregate, these are common in young women and thus frequently managed in pregnancy. There is an intimate relationship between maternal and fetal thyroid function, and drugs that affect the maternal thyroid also affect the fetal gland. Moreover, thyroid autoantibodies have been associated with increased early pregnancy wastage, and uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Finally, there is evidence that autoimmune thyroid disorder severity may be ameliorated during pregnancy, only to be exacerbated postpartum.

Thyroid Physiology and Pregnancy

Maternal thyroid changes are substantial, and normally altered gland structure and function are sometimes confused with thyroid abnormalities. These alterations are discussed in detail in Chapter 4 (p. 68), and normal hormone level values are found in the Appendix (p. 1290). First, maternal serum concentrations of thyroid-binding globulin are increased concomitantly with total or bound thyroid hormone levels (Fig. 4-17, p. 69). Second, *thyrotropin*, also called *thyroid-stimulating hormone (TSH)*, currently plays a central role in screening and diagnosis of many thyroid disorders. Serum TSH levels in early pregnancy decline because of weak TSH-receptor stimulation from massive quantities of human chorionic gonadotropin (hCG) secreted by placental trophoblast. Because TSH does not cross the placenta, it has no direct fetal effects. During the first 12 weeks of gestation, when hCG serum levels are maximal, thyroid hormone secretion is stimulated. The resulting increased serum free thyroxine levels act to suppress hypothalamic *thyrotropin-releasing hormone (TRH)* and in turn limit pituitary TSH secretion (Fig. 58-1). Accordingly, TRH is undetectable in maternal serum. Conversely, beginning at midpregnancy,

FIGURE 58-1 Gestational age-specific values for serum thyroid-stimulating hormone (TSH) levels (black lines) and free thyroxine (T_4) levels (blue lines). Data were derived from 17,298 women tested during pregnancy. For each color, the dark solid lines represent the 50th percentile, whereas the upper and lower light lines represent the 2.5th and 97.5th percentiles, respectively. (Data from Casey, 2005; Dashe, 2005.)

TRH becomes detectable in fetal serum, but levels are static and do not increase with advancing gestation.

Throughout pregnancy, maternal thyroxine is transferred to the fetus (Calvo, 2002). Maternal thyroxine is important for normal fetal brain development, especially before development of fetal thyroid gland function (Bernal, 2007). And even though the fetal gland begins concentrating iodine and synthesizing thyroid hormone after 12 weeks' gestation, maternal thyroxine contribution remains important. In fact, maternal sources account for 30 percent of thyroxine in fetal serum at term (Thorpe-Beeston, 1991; Vulsma, 1989). Developmental risks associated with maternal hypothyroidism after midpregnancy, however, remain poorly understood (Morreale de Escobar, 2004).

■ Autoimmunity and Thyroid Disease

Most thyroid disorders are inextricably linked to autoantibodies against various cell components. Several of these antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to follicular cell destruction. Often, these effects overlap or even coexist.

Thyroid-stimulating autoantibodies, also called *thyroid-stimulating immunoglobulins (TSIs)*, bind to the TSH receptor and activate it, causing thyroid hyperfunction and growth. Although these antibodies are identified in most patients with classic Graves disease, simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Weetman, 2000). *Thyroid peroxidase (TPO)* is a thyroid gland enzyme that normally functions in the production of thyroid hormones. *Thyroid peroxidase antibodies*, previously called *thyroid microsomal autoantibodies*, are directed against TPO and have been identified in 5 to 15 percent of all pregnant women (Fig. 58-2) (Abbassi-Ghanavati, 2010; Kuijpers, 2001). These antibodies have been associated in some studies with early pregnancy loss and preterm birth (Abramson, 2001; Negro, 2006; Thangaratnam,

FIGURE 58-2 Incidence in percent of antithyroid peroxidase antibodies in 16,407 women who are normal or euthyroid, in 233 with isolated maternal hypothyroxinemia (IMH), in 598 with subclinical hypothyroidism (SCH), and in 134 with overt hypothyroidism. (Data from Casey, 2007.)

2011). Conversely, in a study with more than 1000 TPO antibody-positive pregnant women, there was no increased risk for preterm birth, however, there was an increased risk for placental abruption (Abbassi-Ghanavati, 2010). These women are also at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Premawardhana, 2000; Stagnaro-Green, 2011b).

Fetal Microchimerism

Autoimmune thyroid disease is much more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking (Greer, 2011). When fetal lymphocytes enter the maternal circulation, they can live for more than 20 years. Stem cell interchange also occurs with engraftment in several maternal tissues including the thyroid (Bianchi, 2003; Khosrotehrani, 2004). A high prevalence of Y-chromosome-positive cells has been identified using fluorescence in situ hybridization (FISH) in thyroid glands of women with Hashimoto thyroiditis—60 percent, or Graves disease—40 percent (Renné, 2004). In another study of women giving birth to a male fetus, Lepez and colleagues (2011) identified significantly more circulating male mononuclear cells in those with Hashimoto thyroiditis.

■ Hyperthyroidism

The incidence of thyrotoxicosis or hyperthyroidism in pregnancy is varied and complicates between 2 and 17 per 1000 births when gestational-age appropriate TSH threshold values are used (Table 58-1). Because normal pregnancy simulates some clinical findings similar to thyroxine (T_4) excess, clinically mild thyrotoxicosis may be difficult to diagnose. Suggestive findings include tachycardia that exceeds that usually seen with normal pregnancy, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory confirmation is by a markedly depressed TSH level along with an elevated

TABLE 58-1. Incidence of Overt Hyperthyroidism in Pregnancy

Study	Country	Overt Hypothyroidism
Wang (2011) ^a	China	1%
Vaidya (2007) ^a	United Kingdom	0.7%

^aScreened in the first trimester.^bScreened at 9–15 weeks.^cScreened at < 20 weeks.

serum free T_4 (fT_4) level. Rarely, hyperthyroidism is caused by abnormally high serum triiodothyronine (T_3) levels—so-called T_3 -toxicosis.

Thyrototoxicosis and Pregnancy

The overwhelming cause of thyrototoxicosis in pregnancy is *Graves disease*, an organ-specific autoimmune process associated with thyroid-stimulating TSH-receptor antibodies as previously discussed. Because these antibodies are specific to Graves hyperthyroidism, such assays have been proposed for diagnosis, management, and prognosis in pregnancies complicated by hyperthyroidism (Barbesino, 2013). At Parkland Hospital, these receptor antibody assays are generally reserved for cases in which fetal thyrototoxicosis is suspected. With Graves disease, during the course of pregnancy, hyperthyroid symptoms may initially worsen because of chorionic gonadotropin stimulation, but then subsequently diminish with decreases in receptor antibody titers in the second half of pregnancy (Mestman, 2012; Stagnaro-Green, 2011a). Amino and coworkers (2003) have found that levels of blocking antibodies are also decreased during pregnancy.

Treatment. Thyrototoxicosis during pregnancy can nearly always be controlled by thionamide drugs. *Propylthiouracil* (PTU) has been historically preferred because it partially inhibits the conversion of T_4 to T_3 and crosses the placenta less readily than *methimazole*. The latter has also been associated with a rare methimazole embryopathy characterized by *esophageal* or *choanal atresia* as well as *aplasia cutis*, a congenital skin defect. Yoshihara and associates (2012) analyzed more than 5000 Japanese women with first-trimester hyperthyroidism and found a twofold increased risk of major fetal malformations in pregnancies exposed to methimazole compared with the risk from PTU. Specifically, seven of nine cases with aplasia cutis and the only case of esophageal atresia were in the group of methimazole-exposed infants.

Until recently, PTU has been the preferred thionamide in the United States (Brent, 2008). In 2009, however, the Food and Drug Administration issued a safety alert on PTU-associated hepatotoxicity. This warning prompted the American Thyroid Association and the American Association of Clinical Endocrinologists (2011) to recommend PTU therapy during the first trimester followed by methimazole beginning in the second trimester. The obvious disadvantage is that this might

lead to poorly controlled thyroid function. Accordingly, at Parkland Hospital we continue to prescribe PTU treatment throughout pregnancy.

Transient leukopenia can be documented in up to 10 percent of women taking antithyroid drugs, but this does not require therapy cessation. In 0.3 to 0.4 percent, however, *agranulocytosis* develops suddenly and mandates drug discontinuance. It is not dose related, and because of its acute onset, serial leukocyte counts during therapy are not helpful. Thus, if fever or sore throat develops, women are instructed to discontinue medication immediately and report for a complete blood count (Brent, 2008).

As mentioned above, hepatotoxicity is another potentially serious side effect that develops in 0.1 to 0.2 percent. Serial measurement of hepatic enzymes has not been shown to prevent fulminant PTU-related hepatotoxicity. Also, approximately 20 percent of patients treated with PTU develop *antineutrophil cytoplasmic antibodies* (ANCA). However, only a small percentage of these subsequently develop serious vasculitis (Helfgott, 2002; Kimura, 2013). Finally, although thionamides have the potential to cause fetal complications, these are uncommon. In some cases, thionamides may even be therapeutic, because TSH-receptor antibodies cross the placenta and can stimulate the fetal thyroid gland to cause thyrototoxicosis and goiter.

The initial thionamide dose is empirical. For nonpregnant patients, the American Thyroid Association recommends that methimazole be used at an initial higher daily dose of 10 to 20 mg orally followed by a lower maintenance dose of 5 to 10 mg. If PTU is selected, a dose of 50 to 150 mg orally three times daily may be initiated depending on clinical severity (Bahn, 2011). At Parkland Hospital, we usually initially give 300 or 450 mg of PTU daily in three divided doses for pregnant women. Occasionally, daily doses of 600 mg are necessary. As discussed, we generally do not transition women to methimazole during the second trimester. The goal is treatment with the lowest possible thionamide dose to maintain thyroid hormone levels slightly above or in the high normal range while TSH levels remains suppressed (Bahn, 2011). Serum free T_4 concentrations are measured every 4 to 6 weeks (National Academy of Clinical Biochemistry, 2002).

Subtotal thyroidectomy can be performed after thyrototoxicosis is medically controlled. This seldom is done during pregnancy but may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Davison, 2001; Stagnaro-Green, 2012a). Surgery is best accomplished in the second trimester. Potential drawbacks of thyroidectomy during pregnancy include inadvertent resection of parathyroid glands and injury to the recurrent laryngeal nerve (Fitzpatrick, 2010).

Thyroid ablation with therapeutic radioactive iodine is contraindicated during pregnancy. These doses may also cause fetal thyroid gland destruction. Thus, when given unintentionally, many clinicians recommend abortion. Any exposed fetus must be carefully evaluated, and the incidence of fetal hypothyroidism depends on gestational age and radioiodine dose (Berlin, 2001). Tran and colleagues (2010) describe a case in which a relatively high dose (19.8 mCi) of radioiodine early in the first trimester

resulted in a normal euthyroid male infant assessed at 6 months. The authors hypothesized that the exposure occurred well before thyroid embryogenesis. There is no evidence that radioiodine given before pregnancy causes fetal anomalies if enough time has passed to allow radiation effects to dissipate and if the woman is euthyroid (Ayala, 1998). The International Commission on Radiological Protection has recommended that women avoid pregnancy for 6 months after radioablative therapy (Brent, 2008). Moreover, during lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to ¹³¹I-containing milk ingestion and maternal risk from significant breast irradiation. To limit maternal exposure and her cancer risks, a delay of 3 months between lactation and ablation will more reliably ensure complete breast involution (Sisson, 2011).

Pregnancy Outcome. Women with thyrotoxicosis have pregnancy outcomes that largely depend on whether metabolic control is achieved. For example, as discussed in Chapter 18 (p. 353), excess thyroxine may cause miscarriage (Anselmo, 2004). In untreated women or in those who remain hyperthyroid despite therapy, there is a higher incidence of preeclampsia, heart failure, and adverse perinatal outcomes (Table 58-2). A prospective cohort study from China reported that women with clinical hyperthyroidism had a 12-fold increased risk of delivering an infant with hearing loss (Su, 2011). Perinatal mortality rates varied from 6 to 12 percent in several studies.

Fetal and Neonatal Effects

In most cases, the perinate is euthyroid. In some, however, hyper- or hypothyroidism can develop with or without a goiter (Fig. 58-3). Clinical hyperthyroidism develops in approximately 1 percent of neonates born to women with Graves disease (Barbesino, 2013; Fitzpatrick, 2010; Luton, 2005). If fetal thyroid disease is suspected, nomograms are available for

FIGURE 58-3 Term neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks’ gestation. The mother was given methimazole 30 mg orally daily and was euthyroid at delivery. Laboratory studies showed that the infant was hypothyroid.

sonographically measured thyroid volume (Gietka-Czernel, 2012; Ranzini, 2001).

The fetus or neonate who was exposed to excessive maternal thyroxine may have any of several clinical presentations. First, *goitrous thyrotoxicosis* is caused by placental transfer of thyroid-stimulating immunoglobulins. *Nonimmune hydrops* and fetal demise have been reported with fetal thyrotoxicosis (Nachum, 2003; Stulberg, 2000). The best predictor of perinatal thyrotoxicosis is presence of thyroid-stimulating TSH-receptor antibodies in women with Graves disease. This is especially true if their levels are more than threefold higher than the upper normal limit (Barbesino, 2013). In a study of 72 pregnant women with Graves disease, Luton and associates (2005) reported that none of the fetuses in 31 low-risk mothers had a goiter, and all were euthyroid at delivery. Low risk was defined by no antithyroid medications during the third trimester or absence of antithyroid antibodies. Conversely, in a group of 41 women who either were taking antithyroid medication at delivery or had thyroid receptor antibodies, 11 fetuses—27 percent—had sonographic evidence of a goiter at 32 weeks’ gestation. Seven of these 11 were determined to be hypothyroid, and the remaining fetuses were hyperthyroid. In response to such results, the American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend routine evaluation of TSH-receptor antibodies between 22 and 26 weeks’ gestation in women with Graves disease. The American College of Obstetricians and Gynecologists (2013), however, does not recommend such testing because management is rarely changed by the results. If the fetus is thyrotoxic, treatment is by adjustment of maternal thionamide drugs even though maternal thyroid function may be within the targeted range (Duncombe, 2001; Mestman, 2012). Occasionally, neonatal thyrotoxicosis may also require short-course antithyroid drug treatment.

TABLE 58-2. Pregnancy Outcomes in 239 Women with Overt Thyrotoxicosis		
Factor	Treated and Euthyroid ^a n = 149	Uncontrolled Thyrotoxicosis ^a n = 90
Maternal outcome

Thyrotoxicosis	1	2
Hypothyroidism	4	0
Goiter	2	0

^aData presented as n (%).
Data from Davis, 1989; Kriplani, 1994; Millar, 1994.

A second presentation is *goitrous hypothyroidism* caused by fetal exposure to maternally administered thionamides (see Fig. 58-3). Although there are theoretical neurological implications, reports of adverse fetal effects seem to have been exaggerated. Available data indicate that thionamides carry an extremely small risk for causing neonatal hypothyroidism (Momotani, 1997; O'Doherty, 1999). For example, of the 239 treated thyrotoxic women shown in Table 58-1, there was evidence of hypothyroidism in only four infants despite relatively high maternal PTU doses. Furthermore, at least four long-term studies report no abnormal intellectual and physical development of these children (Mestman, 1998). If hypothyroidism is identified, the fetus can be treated by a reduced maternal antithyroid medication dose and injection of intraamniotic thyroxine if necessary.

A third presentation, *nongoitrous hypothyroidism*, may develop from transplacental passage of maternal TSH-receptor blocking antibodies (Fitzpatrick, 2010; Gallagher, 2001). And finally, *fetal thyrotoxicosis* after maternal thyroid gland ablation, usually with ^{131}I radioiodine, may result from transplacental thyroid-stimulating antibodies. In the previously described case of early fetal exposure to radioiodine, neonatal thyroid studies indicated transient hyperthyroidism from maternal transfer of stimulating antibodies (Tran, 2010).

Fetal Diagnosis. Evaluation of fetal thyroid function is somewhat controversial. Although fetal thyroid sonographic assessment has been reported in women taking thionamide drugs or those with thyroid-stimulating antibodies, most investigators do not currently recommend this routinely (Cohen, 2003; Luton, 2005). Kilpatrick (2003) recommends umbilical blood sampling and fetal antibody testing only if the mother has previously undergone radioiodine ablation. Because fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, fetal blood sampling may be appropriate if these are identified (Brand, 2005). The Endocrine Society Clinical Practice Guidelines recommend umbilical blood sampling only when the diagnosis of fetal thyroid disease cannot be reasonably ascertained based on clinical and sonographic data (Garber, 2012). Diagnosis and treatment are considered further in Chapter 16 (p. 324).

Thyroid Storm and Heart Failure

Both are acute and life-threatening in pregnancy. Thyroid storm is a hypermetabolic state and is rare in pregnancy. In contrast, pulmonary hypertension and heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine is common in pregnant women (Sheffield, 2004). As shown in Table 58-2, heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In these women, cardiomyopathy is characterized by a high-output state, which may lead to a dilated cardiomyopathy (Fadel, 2000; Klein, 1998). The pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is usually precipitated by preeclampsia, anemia, sepsis, or a combination of these. Fortunately, thyroxine-induced cardiomyopathy and pulmonary hypertension are frequently reversible (Sheffield, 2004; Siu, 2007; Vydut, 2006).

Management. Treatment for thyroid storm or heart failure is similar and should be carried out in an intensive care area that may include special-care units within labor and delivery (Fitzpatrick, 2010; Zeeman, 2003). Shown in Figure 58-4 is our stepwise approach to medical management of thyroid storm or thyrotoxic heart failure. An hour or two after initial thionamide administration, iodide is given to inhibit thyroidal release of T_3 and T_4 . It can be given intravenously as sodium iodide or orally as either saturated solution of potassium iodide (SSKI) or Lugol solution. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead. Most authorities recommend dexamethasone, 2 mg intravenously every 6 hours for four doses, to further block peripheral conversion of T_4 to T_3 . If a β -blocker drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol have all been used successfully. Coexisting severe preeclampsia, infection, or anemia should be aggressively managed before delivery is considered.

Hyperemesis Gravidarum and Gestational Transient Thyrotoxicosis

Transient biochemical features of hyperthyroidism may be observed in 2 to 15 percent of women in early pregnancy (Fitzpatrick, 2010). Many women with hyperemesis gravidarum have abnormally high serum thyroxine levels and low TSH levels (Chap. 54, p. 1070). This results from TSH-receptor stimulation from massive—but normal for pregnancy—concentrations of hCG. This transient condition is also termed *gestational transient thyrotoxicosis*. Even if associated with hyperemesis, antithyroid drugs are not warranted (American College of Obstetricians and Gynecologists, 2013). Serum thyroxine and TSH values become more normal by midpregnancy (Fitzpatrick, 2010).

Thyrotoxicosis and Gestational Trophoblastic Disease

The prevalence of increased thyroxine levels in women with molar pregnancy has been reported to be between 25 and 65 percent (Hershman, 2004). As discussed, abnormally high hCG levels lead to overstimulation of the TSH receptor. Because these tumors are now usually diagnosed early, clinically apparent hyperthyroidism has become less common. With definitive treatment, serum free- T_4 levels usually normalize rapidly in parallel with the decline in hCG concentrations. This is discussed further in Chapter 20 (p. 399).

Subclinical Hyperthyroidism

Third-generation TSH assays with an analytical sensitivity of 0.002 mU/mL permit identification of subclinical thyroid disorders. These biochemically defined extremes usually represent normal biological variations but may herald the earliest stages of thyroid dysfunction. *Subclinical hyperthyroidism* is characterized by an abnormally low serum TSH concentration in concert with thyroxine hormone levels within the normal reference range (Surks, 2004). Long-term effects of persistent subclinical thyrotoxicosis include osteoporosis,

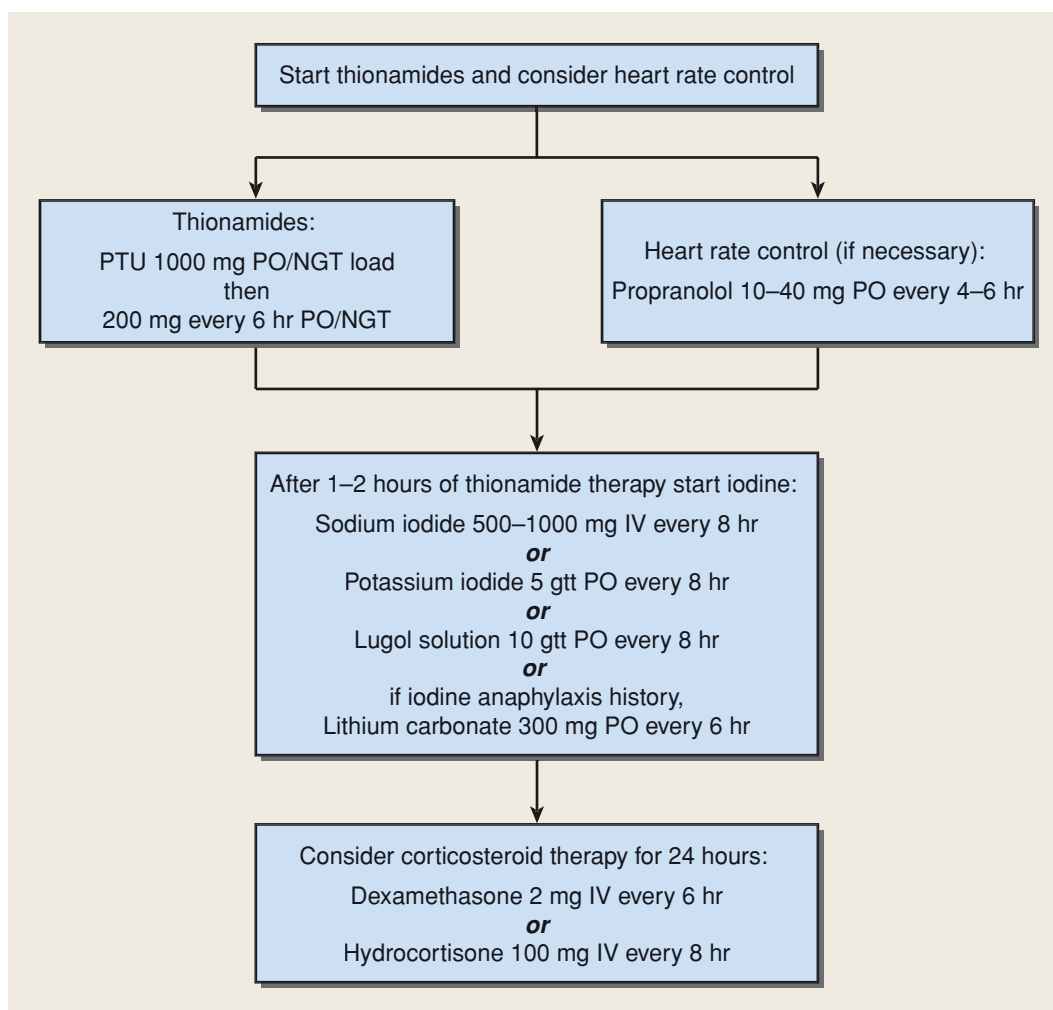

FIGURE 58-4 One management method for thyroid storm or thyrotoxic heart failure. gtt = drops; NGT = nasogastric tube; PO = orally.

cardiovascular morbidity, and progression to overt thyrotoxicosis or thyroid failure. Casey and Leveno (2006b) identified subclinical hyperthyroidism in 1.7 percent of pregnant women. Importantly, these investigators showed that subclinical hyperthyroidism was not associated with adverse pregnancy outcomes. In separate retrospective analyses of almost 25,000 women who underwent thyroid screening throughout pregnancy, Wilson and colleagues (2012) and Tudela and coworkers (2012) confirmed no relationship between subclinical hyperthyroidism and preeclampsia or gestational diabetes.

The American Thyroid Association and American Association of Clinical Endocrinologists guidelines recommend consideration for treatment of subclinical hyperthyroidism in individuals 65 years or older and in postmenopausal women to improve cardiovascular health and bone mineral density. There is, however, no convincing evidence that subclinical hyperthyroidism should be treated in younger nonpregnant individuals. Thus, treatment seems especially unwarranted in pregnancy because antithyroid drugs may affect the fetus. Women identified with subclinical hyperthyroidism may benefit from periodic surveillance, and approximately half eventually have normal TSH concentrations.

Hypothyroidism

Overt or symptomatic hypothyroidism, as shown in Table 58-3, has been reported to complicate between 2 and 10 pregnancies per 1000. It is characterized by insidious nonspecific clinical findings that include fatigue, constipation, cold intolerance, muscle cramps, and weight gain. A pathologically enlarged thyroid gland depends on the etiology

TABLE 58-3. Frequency of Overt Hypothyroidism in Pregnancy

Casey (2005) ^b	United States	0.2%

^aScreened during first trimester.

^bScreened at < 20 weeks' gestation.

of hypothyroidism and is more likely in women in areas of endemic iodine deficiency or those with Hashimoto thyroiditis. Other findings include edema, dry skin, hair loss, and prolonged relaxation phase of deep tendon reflexes. *Clinical* or *overt hypothyroidism* is confirmed when an abnormally high serum TSH level is accompanied by an abnormally low thyroxine level. *Subclinical hypothyroidism* is defined by an elevated serum TSH level and *normal* serum thyroxine concentration (Surks, 2004). Included in the spectrum of subclinical thyroid disease are asymptomatic individuals with measurable antithyroid peroxidase or antithyroglobulin antibodies. Euthyroid autoimmune thyroid disease represents a new investigative frontier in screening and treatment of thyroid dysfunction during pregnancy.

Overt Hypothyroidism and Pregnancy

The most common cause of hypothyroidism in pregnancy is Hashimoto thyroiditis, characterized by glandular destruction from autoantibodies, particularly antithyroid peroxidase antibodies. Clinical identification of hypothyroidism is especially difficult during pregnancy because many of the signs or symptoms are also common to pregnancy itself. Thyroid analyte testing should be performed on symptomatic women or those with a history of thyroid disease (American College of Obstetricians and Gynecologists, 2013). As discussed in Chapter 18 (p. 353), *severe hypothyroidism* during pregnancy is uncommon, probably because it is often associated with infertility and increased spontaneous abortion rates (Abalovich, 2002; De Groot, 2012). Even women with treated hypothyroidism undergoing in vitro fertilization have a significantly decreased chance of achieving pregnancy (Scoccia, 2012).

Treatment. The American Thyroid Association and American Association of Clinical Endocrinologists (2011) recommend replacement therapy for hypothyroidism beginning with levothyroxine in doses of 1 to 2 µg/kg/day or approximately 100 µg daily. Women who are athyreotic after thyroidectomy or radioiodine therapy may require higher doses. Surveillance is with TSH levels measured at 4- to 6-week intervals, and the thyroxine dose is adjusted by 25- to 50-µg increments until TSH values become normal. Pregnancy is associated with an increased thyroxine requirement in approximately a third of supplemented women (Abalovich, 2010; Alexander, 2004). Because a similar increased requirement is seen in women with postmenopausal hypothyroidism after estrogen replacement, the increased demand in pregnancy is believed to be related to increased estrogen production (Arafah, 2001).

Increased thyroxine requirements begin as early as 5 weeks. In a randomized trial that provided an increased levothyroxine dose at pregnancy confirmation in 60 mothers, Yassa and coworkers (2010) found that a 29- to 43-percent increase in the weekly dose maintained serum TSH values < 5.0 mU/L during the first trimester in all women. Importantly, however, this increase caused TSH suppression in more than a third of women. Significant hypothyroidism may develop early in women without thyroid reserve such as those with a previous thyroidectomy, those with prior radioiodine ablation, or those undergoing assisted reproductive techniques

TABLE 58-4. Pregnancy Complications in 440 Women with Hypothyroidism

Complications	Hypothyroidism (%)	
	Overt n = 112	Subclinical n = 328
Preeclampsia	32	8

Cardiac dysfunction	3	2
Birthweight < 2000 g ^{a,b}	33	32
Stillbirths ^c	9	3 ^c

^aPreterm or term deliveries were the only outcomes reported by Abalovich, 2002.

^bLow birthweight and stillbirth were outcomes reported by Su, 2011.

^cOne infant died from syphilis.

Data from Abalovich, 2002; Davis, 1988; Leung, 1993; Männistö, 2009; Su, 2011.

(Alexander, 2004; Loh, 2009; Rotondi, 2004). Anticipatory 25-percent increases in thyroxine replacement at pregnancy confirmation will reduce this likelihood. All other women with hypothyroidism should undergo TSH testing at initiation of prenatal care.

Pregnancy Outcome with Overt Hypothyroidism.

Observational studies, although limited, indicate that there are excessive adverse perinatal outcomes associated with overt thyroxine deficiency (Table 58-4). With appropriate replacement therapy, however, adverse effects are not increased in most reports (Matalon, 2006; Tan, 2006; Wolfberg, 2005). In one dissenting study, however, there was an increased risk for some pregnancy complications even in women taking replacement therapy (Wikner, 2008). Most experts agree that adequate hormone replacement during pregnancy minimizes the risk of adverse outcomes and most complications (Abalovich, 2002; Fitzpatrick, 2010).

Fetal and Neonatal Effects. There is no doubt that maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodide intake, and its deficiency early in pregnancy can cause both maternal and fetal hypothyroidism. And as discussed, maternal TSH-receptor-blocking antibodies can cross the placenta and cause fetal thyroid dysfunction. Rovelli and colleagues (2010) evaluated 129 neonates born to women with autoimmune thyroiditis. They found that 28 percent had an elevated TSH level on the third or fourth day of life, and 47 percent of these had TPO antibodies on day 15. Still, autoantibodies were undetectable at 6 months of age. It seems paradoxical that despite these transient laboratory findings in the *neonate*, TPO and antithyroglobulin (TG) antibodies have little or no effect on *fetal* thyroid function (Fisher, 1997). Indeed, prevalence of fetal hypothyroidism in women with Hashimoto thyroiditis is estimated to be only 1 in 180,000 neonates (Brown, 1996).

Subclinical Hypothyroidism

This thyroid condition is common in women, but its incidence can be variable depending on age, race, dietary iodine intake, and serum TSH thresholds used to establish the diagnosis (Cooper, 2012). According to Fitzpatrick and Russell (2010), its prevalence in pregnancy has been estimated to be between 2 and 5 percent. In two large studies totaling more than 25,000 pregnant women screened in the first half of pregnancy, subclinical hypothyroidism was identified in 2.3 percent of women (Casey, 2005; Cleary-Goldman, 2008). The rate of progression to overt thyroid failure is affected by TSH level, age, other disorders such as diabetes, and presence and concentration of antithyroid antibodies. Diez and Iglesias (2004) prospectively followed 93 nonpregnant women with subclinical hypothyroidism for 5 years and reported that in a third, TSH values became normal. In the other two thirds, those women whose TSH levels were 10 to 15 mU/L developed overt disease at a rate of 19 per 100 patient-years. Those women whose TSH levels were < 10 mU/L developed overt hypothyroidism at a rate of 2 per 100 patient-years. The U.S. Preventative Services Task Force on screening for subclinical hypothyroidism also reported that nearly all patients who develop overt hypothyroidism within 5 years have an initial TSH level > 10 mU/L (Helfand, 2004; Karmisholt, 2008). In a 20-year follow-up study of 5805 women who were screened in early pregnancy, only 3 percent developed thyroid disease. Of the 224 women identified with subclinical hypothyroidism during pregnancy, 36 (17 percent) developed thyroid disease in the next 20 years, and most of these had either TPO or TG antibodies during pregnancy (Männistö, 2010). Consequently, the likelihood of progression to overt hypothyroidism *during* pregnancy in otherwise healthy women with subclinical hypothyroidism seems unlikely.

Subclinical Hypothyroidism and Pregnancy

Observational studies spanning almost 25 years and shown in Table 58-4 suggest that subclinical hypothyroidism is

likely associated with some adverse pregnancy outcomes. In 1999, interest was heightened by two studies that suggested that undiagnosed maternal thyroid hypofunction may impair fetal neuropsychological development. In one study, Pop and associates (1999) described 22 women who had free T₄ levels < 10th percentile in early pregnancy whose offspring were at increased risk for impaired psychomotor development. In the other study, Haddow and coworkers (1999) retrospectively evaluated children born to 48 untreated women whose serum TSH values were > 98th percentile. Some had diminished school performance, reading recognition, and intelligent quotient (IQ) scores. Although described as “subclinically hypothyroid,” these women had an abnormally low mean serum free thyroxine level, and thus, many had overt hypothyroidism.

To further evaluate any adverse effects, Casey and colleagues (2005) identified subclinical hypothyroidism in 2.3 percent of 17,298 women screened before midpregnancy. As shown in Table 58-5, these women had higher incidences of preterm birth, placental abruption, and admission of infants to the intensive care nursery compared with euthyroid women. In the study of 10,990 participants in the First- and Second-Trimester Evaluation of Risk (FASTER) Trial, Cleary-Goldman and associates (2008) did not find such a link with these adverse obstetrical outcomes.

In a study of 24,883 women screened throughout pregnancy, Wilson and coworkers (2012) found that women identified with subclinical hypothyroidism had an almost twofold increased risk of severe preeclampsia. The authors hypothesized that this was related to endothelial cell dysfunction that has been linked to subclinical hypothyroidism in older patients. In their analysis of the same cohort, Tudela and associates (2012) identified a consistent relationship between increasing TSH level and risk for gestational diabetes. More specifically, 6.3 percent of women with subclinical hypothyroidism were diagnosed with gestational diabetes compared with 4.2 percent in euthyroid women. Nelson and colleagues (2014) evaluated 230 women diagnosed with subclinical hypothyroidism during a prior pregnancy. These women were at increased risk for

TABLE 58-5. Pregnancy Outcomes in Women with Untreated Subclinical Hypothyroidism and Isolated Maternal Hypothyroxinemia Compared with Euthyroid Pregnant Women

Data from Casey, 2007.

diabetes and stillbirth in subsequent pregnancies. Although these findings are intriguing, there is currently no evidence that identification and treatment of subclinical hypothyroidism during pregnancy improves these outcomes.

TSH Level Screening in Pregnancy. Because of the findings from the 1999 studies cited above, some professional organizations recommend routine prenatal screening and treatment for subclinical hypothyroidism (Gharib, 2005). The American College of Obstetricians and Gynecologists (2013) has reaffirmed that although observational data were consistent with the *possibility* that subclinical hypothyroidism was associated with adverse neuropsychological development, there have been no interventional trials to demonstrate improvement. The College thus has consistently recommended against implementation of screening until further studies are done to validate or refute these findings (American College of Obstetricians and Gynecologists, 2012).

Lazarus and colleagues (2012) reported the findings of the international multicenter Controlled Antenatal Thyroid Screening (CATS) study of thyroid screening and treatment of subclinical hypothyroidism and isolated maternal hypothyroxinemia during pregnancy. The primary outcome was offspring IQ scores at 3 years of age. Cognitive function in the children was not improved with screening and treatment. A second comparable study is being conducted by the Maternal-Fetal Medicine Units Network, and the results are anticipated in 2016.

Consequent to the Lazarus study, clinical practice guidelines from the Endocrine Society, The American Thyroid Association, and the American Association of Clinical Endocrinologists now uniformly recommend screening only those at increased risk during pregnancy (De Groot, 2012; Garber, 2012). Furthermore, previous cost-effectiveness analyses that favored a universal screening strategy are no longer valid since they were based on assumptions of improved neurodevelopmental outcomes in offspring (Dosiou, 2008; Thung, 2009).

■ Isolated Maternal Hypothyroxinemia

Women with low serum free T_4 values but a normal range TSH level are considered to have *isolated maternal hypothyroxinemia*. This was identified by Casey and colleagues (2007) in 1.3 percent of more than 17,000 pregnant women screened at Parkland Hospital before 20 weeks. Cleary-Goldman and associates (2008) found a 2.1-percent incidence in the FASTER Trial cohort described earlier. As discussed previously, offspring of women with isolated hypothyroxinemia have been reported to have neurodevelopmental difficulties at age 3 weeks, 10 months, and 2 years (Kooistra, 2006; Pop, 1999, 2003). These findings have not stimulated recommendations for prenatal serum thyroxine screening. Importantly, free T_4 estimates by currently available immunoassays may not be accurate during pregnancy because of sensitivity to alterations in binding proteins (Lee, 2009).

In a study of 233 women with isolated maternal hypothyroxinemia, Casey and colleagues (2007) reported that there were no increased adverse perinatal outcomes compared with

those of euthyroid women (see Table 58-5). And, as shown in Figure 58-2, unlike subclinical hypothyroidism, these women had a low prevalence of antithyroid antibodies. The only other finding was from Cleary-Goldman and coworkers (2008), who reported a twofold incidence of fetal macrosomia. Taken together, these findings indicate that isolated maternal hypothyroxinemia has no apparent serious adverse effects on pregnancy outcome. Finally, the aforementioned CATS study did not find improved neurodevelopmental outcomes in women with isolated hypothyroxinemia who were then treated with thyroxine (Lazarus, 2012). Because of this, routine screening for isolated hypothyroxinemia is not recommended.

■ Euthyroid Autoimmune Thyroid Disease

Autoantibodies to TPO and TG have been identified in 6 to 20 percent of reproductive-aged women (Thangaratinam, 2011). Most who test positive for such antibodies, however, are euthyroid. That said, such women are at a two- to fivefold increased risk for early pregnancy loss (Stagnaro-Green, 2004; Thangaratinam, 2011). The presence of thyroid antibodies has also been associated with preterm birth (Stagnaro-Green, 2009). In a randomized treatment trial of 115 euthyroid women with TPO antibodies, Negro and coworkers (2006) reported that treatment with levothyroxine astoundingly reduced the preterm birth rate from 22 to 7 percent. Contrarily, Abbassi-Ghanavati and associates (2010) evaluated pregnancy outcomes in more than 1000 untreated women with TPO antibodies and did not find an increased risk for preterm birth compared with the risk in 16,000 euthyroid women without antibodies. These investigators, however, found a threefold increased risk of placental abruption in these women. As with nonpregnant subjects with TPO antibodies, these women are also at increased risk for progression of thyroid disease and postpartum thyroiditis (Stagnaro-Green, 2012a).

This group of euthyroid women with abnormally high thyroid autoantibody levels represents a new focus of thyroid research. Dosiou and colleagues (2012) performed a cost-effectiveness analysis of universal screening for autoimmune thyroid disease during pregnancy. Their results favored universal screening. There is, however, a paucity of studies that show benefit to identifying and treating euthyroid women with thyroid autoantibodies. Thus, calls for routine antibody screening seem premature. Currently, universal screening for the thyroid autoantibodies is not recommended by any professional organizations (De Groot, 2012; Stagnaro-Green, 2011a, 2012a).

■ Iodine Deficiency

Decreasing iodide fortification of table salt and bread products in the United States during the past 25 years has led to occasional iodide deficiency (Caldwell, 2005; Hollowell, 1998). Importantly, the most recent National Health and Nutrition Examination survey indicated that, overall, the United States population remains iodine sufficient (Caldwell, 2011). Even so, experts agree that iodine nutrition in vulnerable populations such as pregnant women requires continued monitoring.

In 2011 the Office of Dietary Supplements of the National Institutes of Health sponsored a workshop to prioritize iodine research. Participants emphasized the decline in median urinary iodine to 125 µg/L in pregnant women and the serious potential impact on the developing fetus (Swanson, 2012).

Dietary iodine requirements are increased during pregnancy due to increased thyroid hormone production, increased renal losses, and fetal iodine requirements. Adequate iodine is requisite for fetal neurological development beginning soon after conception, and abnormalities are dependent on the degree of deficiency. The World Health Organization (WHO) has estimated that at least 50 million people worldwide have varying degrees of preventable brain damage due to iodine deficiency (Brundtland, 2002). Although it is doubtful that *mild deficiency* causes intellectual impairment, supplementation does prevent fetal goiter (Stagnaro-Green, 2012b). *Severe deficiency*, on the other hand, is frequently associated with damage typically encountered with *endemic cretinism* (Delange, 2001). It is presumed that *moderate deficiency* has intermediate and variable effects. Berbel and associates (2009) began daily supplementation in more than 300 pregnant women with moderate deficiency at three time periods—4 to 6 weeks, 12 to 14 weeks, and after delivery. They found improved neurobehavioral development scores in offspring of women supplemented with 200 µg potassium iodide very early in pregnancy. Similarly, Velasco and coworkers (2009) found improved Bayley Psychomotor Development scores in offspring of women supplemented with 300 µg of iodide in the first trimester. In contrast, Murcia and colleagues (2011) identified lower psychomotor scores in 1-year-old infants whose mothers reported daily supplementation of more than 150 µg. There are two ongoing randomized controlled trials of iodine supplementation in mildly to moderately iodine-deficient pregnant women in India and Thailand. These studies should provide needed answers as to whether iodine supplementation in these women is beneficial (Pearce, 2013).

The Institute of Medicine (2001) recommends daily iodine intake during pregnancy of 220 µg/day, and 290 µg/day for lactating women (Chap. 9, p. 180). The Endocrine Society (De Groot, 2012) recommends an average iodine intake of 150 µg per day in childbearing-aged women, and this should be increased to 250 µg during pregnancy and breast feeding. The American Thyroid Association has recommended that 150 µg of iodine be added to prenatal vitamins to achieve this average daily intake (Becker, 2006). According to Leung and coworkers (2011), however, only 51 percent of the prenatal multivitamins in the United States contain iodine. It has even been suggested that because most cases of maternal hypothyroxinemia worldwide are related to relative iodine deficiency, supplementation may obviate the need to consider thyroxine treatment in such women (Gyamfi, 2009).

On the other hand, experts caution against oversupplementation. Teng and associates (2006) contend that excessive iodine intake—defined as > 300 µg/day—may lead to subclinical hypothyroidism and autoimmune thyroiditis. And the Endocrine Society, in accordance with the WHO, advises against exceeding twice the daily recommended intake of iodine, or 500 µg/day (De Groot, 2012; Leung, 2011).

Congenital Hypothyroidism

Because the clinical diagnosis of hypothyroidism in neonates is usually missed, universal newborn screening was introduced in 1974 and is now required by law in all states. Congenital hypothyroidism develops in approximately 1 in 3000 newborns and is one of the most preventable causes of mental retardation (LaFranchi, 2011). Developmental disorders of the thyroid gland such as agenesis and hypoplasia account for 80 to 90 percent of these cases (LaFranchi, 2011; Topaloglu, 2006). The exact underlying etiology of thyroid dysgenesis remains unknown. The remaining primary congenital hypothyroidism cases are caused by hereditary defects in thyroid hormone production. The list of identified gene mutations that cause hypothyroidism continues to grow rapidly (Moreno, 2008).

Early and aggressive thyroxine replacement is critical for infants with congenital hypothyroidism. Still, some infants identified by screening programs with severe congenital hypothyroidism who were treated promptly will exhibit cognitive deficits into adolescence (Song, 2001). Therefore, in addition to timing of treatment, the severity of congenital hypothyroidism is an important factor in long-term cognitive outcomes (Kempers, 2006). Accordingly, in infants with screening results suggestive of severe hypothyroidism, therapy should be started immediately without waiting for confirmatory results (Abduljabbar, 2012). Olivieri and colleagues (2002) reported that 8 percent of 1420 infants with congenital hypothyroidism also had other major congenital malformations.

Postpartum Thyroiditis

Transient autoimmune thyroiditis is consistently found in approximately 5 to 10 percent of women during the first year after childbirth (Amino, 2000; Stagnaro-Green, 2011b, 2012a). Postpartum thyroid dysfunction with an onset within 12 months includes hyperthyroidism, hypothyroidism, or both. The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Up to 50 percent of women who are thyroid-antibody positive in the first trimester will develop postpartum thyroiditis (Stagnaro-Green, 2012a). In a Dutch study of 82 women with type 1 diabetes, postpartum thyroiditis developed in 16 percent and was threefold higher than in the general population (Gallas, 2002). Importantly, 46 percent of those identified with overt postpartum thyroiditis had TPO antibodies in the first trimester.

Clinical Manifestations

In clinical practice, postpartum thyroiditis is diagnosed infrequently because it typically develops months after delivery and causes vague and nonspecific symptoms that often are thought to be stresses of motherhood (Stagnaro-Green, 2004). The clinical presentation varies, and classically there are two recognized clinical phases that may develop in succession. The first and earliest is *destruction-induced thyrotoxicosis* with symptoms from excessive release of hormone from glandular disruption. The onset is abrupt, and a small, painless goiter is commonly found. Although there may be many symptoms, only fatigue and

palpitations are more frequent in thyrotoxic women compared with normal controls. This thyrotoxic phase usually lasts only a few months. Thionamides are ineffective, and if symptoms are severe, a β -blocker agent may be given. The second and usually later phase is clinical *hypothyroidism* from thyroiditis between 4 and 8 months postpartum. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Thyroxine replacement with 25 to 75 $\mu\text{g}/\text{day}$ is typically given for 6 to 12 months.

Stagnaro-Green and associates (2011b) reported postpartum follow-up from 4562 Italian pregnant women who had been screened for thyroid disease in pregnancy. Serum TSH and anti-TPO antibody levels were measured again at 6 and 12 months. Overall, two thirds of 169 women (3.9 percent) with postpartum thyroiditis were identified to have hypothyroidism only. The other third were diagnosed with hyperthyroidism, but only 14 percent of all women demonstrated the “classic” biphasic progression described above. These findings are consistent with data compiled from 20 other studies between 1982 and 2008 (Stagnaro-Green, 2012a).

Importantly, women who experience either type of postpartum thyroiditis have an approximately 30-percent risk of eventually developing permanent hypothyroidism, and the annual progression rate is 3.6 percent (Lucas, 2005; Muller, 2001; Premawardhana, 2000). Women at increased risk for developing hypothyroidism are those with higher titers of thyroid antibodies and higher TSH levels during the initial hypothyroid phase. Others may develop subclinical disease, but half of those with thyroiditis who are positive for TPO antibodies develop permanent hypothyroidism by 6 to 7 years (Stagnaro-Green, 2012a).

An association between postpartum thyroiditis and postpartum depression has been proposed but remains unresolved. Lucas and coworkers (2001) found a 1.7-percent incidence of postpartum depression at 6 months in women with thyroiditis as well as in controls. Pederson and colleagues (2007) found a significant correlation between abnormal scores on the Edinburgh Postnatal Depression Scale and total thyroxine values in the low normal range during pregnancy in 31 women. Similarly unsettled is the link between depression and thyroid antibodies. Kuijpers and associates (2001) reported that TPO antibodies were a marker for postpartum depression in euthyroid women. In a randomized trial, Harris and coworkers (2002) reported no difference in postpartum depression in 342 women with TPO antibodies who were given either levothyroxine or placebo.

Nodular Thyroid Disease

Thyroid nodules can be found in 1 to 2 percent of reproductive-aged women (Fitzpatrick, 2010). Management of a palpable thyroid nodule during pregnancy depends on gestational age and mass size. Small nodules detected by sensitive sonographic methods are more common during pregnancy in some populations. For example, Kung and associates (2002) used high-resolution sonography and found that 15 percent of Chinese women had nodules larger than 2 mm in diameter. Almost half were multiple, and the nodules usually enlarged modestly

across pregnancy and did not regress postpartum. Biopsy of those $> 5 \text{ mm}^3$ that persisted at 3 months usually showed nodular hyperplasia, and none was malignant. In some studies, however, up to 40 percent of solitary nodules were malignant (Doherty, 1995; Rosen, 1986). Even so, most were low-grade neoplasms.

Evaluation of thyroid nodules during pregnancy should be similar to that for nonpregnant patients. As discussed in Chapter 46 (p. 934), most recommend against *radioiodine scanning* in pregnancy despite the fact that tracer doses used are associated with minimal fetal irradiation (Popoveniuc, 2012). *Sonographic* examination reliably detects nodules larger than 0.5 cm, and their solid or cystic structure also is determined. According to the American Association of Clinical Endocrinologists, sonographic characteristics associated with malignancy include hypoechogenic pattern, irregular margins, and microcalcifications (Gharib, 2005). *Fine-needle aspiration (FNA)* is an excellent assessment method, and histological tumor markers and immunostaining are reliable to evaluate for malignancy (Bartolazzi, 2001; Hegedüs, 2004). If the FNA biopsy shows a follicular lesion, surgery may be deferred until after delivery.

Evaluation of thyroid cancer involves a multidisciplinary approach (American College of Obstetricians and Gynecologists, 2013). Most thyroid carcinomas are well differentiated and pursue an indolent course. When thyroid malignancy is diagnosed during the first or second trimester, thyroidectomy may be performed before the third trimester (Chap. 63, p. 1231). In women without evidence of an aggressive thyroid cancer, or in those diagnosed in the third trimester, surgical treatment can be deferred to the immediate postpartum period (Gharib, 2010).

PARATHYROID DISEASES

The function of *parathyroid hormone (PTH)* is to maintain extracellular fluid calcium concentration. This 115-amino acid hormone acts directly on bone and kidney and indirectly on small intestine through its effects on synthesis of vitamin D ($1,25[\text{OH}_2]\text{-D}$) to increase serum calcium. Secretion is regulated by serum ionized calcium concentration through a negative feedback system. *Calcitonin* is a potent parathyroid hormone that acts as a physiological parathyroid hormone antagonist. The interrelationships between these hormones, calcium metabolism, and *PTH-related protein* produced by fetal tissue are discussed in Chapter 4 (p. 70).

Fetal calcium needs—300 mg/day in late pregnancy and a total of 30 g—as well as increased renal calcium loss from augmented glomerular filtration, substantively increase maternal calcium demands. Pregnancy is associated with a twofold rise in serum concentrations of $1,25\text{-dihydroxyvitamin D}$, which increases gastrointestinal calcium absorption. The effectuating hormone is probably of placental and decidual origin because maternal PTH levels are low normal or decreased during pregnancy (Cooper, 2011; Molitch, 2000). Total serum calcium levels decline with serum albumin concentrations, but ionized calcium levels remain unchanged. Vargas Zapata (2004), and others, have suggested a role for insulin-like growth factor-1

(IGF-1) in maternal calcium homeostasis and bone turnover, especially in mothers with low calcium intake.

■ Hyperparathyroidism

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases. Primary hyperparathyroidism is reported most often in women older than 50 (Miller, 2008). Because many automated laboratory systems include serum calcium measurement, hyperparathyroidism has changed from being a condition defined by symptoms to one that is discovered on routine screening (Pallan, 2012). It has a reported prevalence of 2 to 3 per 1000 women, but some have estimated the rate to be as high as 14 per 1000 when asymptomatic cases are included (Farford, 2007; Schnatz, 2005). Almost 80 percent are caused by a solitary adenoma, and another 15 percent by hyperfunction of all four glands. In the remainder, a malignancy and the cause of increased serum calcium levels are obvious. Of note, PTH produced by tumors is not identical to the natural hormone and may not be detected by routine assays.

In most patients, the serum calcium level is only elevated to within 1 to 1.5 mg/dL above the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic (Bilezikian, 2004). In a fourth, however, symptoms become apparent when the serum calcium level continues to rise. *Hypercalcemic crisis* manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

All women with symptomatic hyperparathyroidism should be surgically treated. Guidelines for management in nonpregnant patients were revised after the Third International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism (Bilezikian, 2009). Indications for parathyroidectomy include a serum calcium level 1.0 mg/dL above the upper normal range, a calculated creatinine clearance less than 60 mL/min, reduced bone density, or age < 50 years. Those not meeting these criteria should undergo annual calcium and creatinine level measurement and bone density assessment every 1 to 2 years (Pallan, 2012).

Hyperparathyroidism in Pregnancy

In their review, Schnatz and Thaxton (2005) found fewer than 200 reported cases complicating pregnancy. As in nonpregnant patients, hyperparathyroidism is usually caused by a parathyroid adenoma. Gravidas with ectopic parathyroid hormone production and rare cases of parathyroid carcinoma have been reported (Montoro, 2000). Symptoms include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally, pancreatitis is the presenting finding (Cooper, 2011; Dahan, 2001).

Pregnancy theoretically improves hyperparathyroidism because of significant calcium shunting to the fetus and augmented renal excretion (Power, 1999). When the “protective effects” of pregnancy are withdrawn, however, there is significant danger of postpartum hypercalcemic crisis. This life-threatening complication can be seen with serum calcium levels greater than 14 mg/dL and is characterized by nausea, vomiting, tremors, dehydration, and mental status changes (Malekar-Raikar, 2011). Early reports described excessive stillbirths and

preterm deliveries in pregnancies complicated by hyperparathyroidism (Shangold, 1982). More recent reports, however, described lower rates of stillbirth, neonatal death, and neonatal tetany (Kovacs, 2011). Other fetal complications include miscarriage, fetal-growth restriction, and low birthweight (Chamarthi, 2011). Schnatz (2005) reported a 25-percent incidence of preeclampsia.

Management in Pregnancy. Surgical removal of a symptomatic parathyroid adenoma is preferable. This should prevent fetal and neonatal morbidities, as well as postpartum parathyroid crises (Kovacs, 2011). Elective neck exploration during pregnancy is usually well tolerated, even in the third trimester (Graham, 1998; Kort, 1999; Schnatz, 2005). In one woman, a mediastinal adenoma was removed at 23 weeks (Rooney, 1998).

None of the three International Workshop Conferences on Asymptomatic Hyperparathyroidism have addressed its management during pregnancy (Bilezikian, 2009). Medical management may be appropriate in asymptomatic pregnant women with mild hypercalcemia. If so, patients are carefully monitored in the postpartum period for hypercalcemic crisis (Kovacs, 2011). Initial medical management might include *calcitonin* to decrease skeletal calcium release, or oral phosphate, 1 to 1.5 g daily in divided doses to bind excess calcium. For women with dangerously elevated serum calcium levels or those who are mentally obtunded with *hypercalcemic crisis*, emergency treatment is instituted. Diuresis with intravenous normal saline is begun so that urine flow exceeds 150 mL/hr. *Furosemide* is given in conventional doses to block tubular calcium reabsorption. Importantly, hypokalemia and hypomagnesemia should be prevented. Adjunctive therapy includes *mithramycin*, which inhibits bone resorption.

Neonatal Effects. Normally, cord blood calcium levels are higher than maternal levels (Chap. 7, p. 135). With maternal hyperparathyroidism, abnormally elevated maternal and thence fetal levels further suppress fetal parathyroid function. Because of this, after birth, there is a rapidly decreasing newborn calcium level, and 15 to 25 percent of these infants develop severe hypocalcemia with or without tetany (Molitch, 2000). Neonatal hypoparathyroidism caused by maternal hyperparathyroidism is usually transient and should be treated with calcium and calcitriol. Calcitriol will not be effective in preterm infants, however, because the intestinal vitamin D receptor is not sufficiently expressed (Kovacs, 2011). Neonatal tetany or seizures should stimulate an evaluation for maternal hyperparathyroidism (Beattie, 2000; Ip, 2003; Jaafar, 2004).

■ Hypoparathyroidism

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. Hypoparathyroidism is estimated to follow up to 7 percent of total thyroidectomies (Shoback, 2008). It is rare and characterized by facial muscle spasms, muscle cramps, and paresthesias of the lips, tongue, fingers, and feet. This can progress to tetany and seizures. Chronically, hypocalcemic pregnant

women may also have a fetus with skeletal demineralization resulting in multiple bone fractures in the neonatal period (Alikasifoglu, 2005).

Maternal treatment includes 1,25-dihydroxyvitamin D₃ (calcitriol), dihydrotachysterol, or large vitamin D doses of 50,000 to 150,000 U/day; calcium gluconate or calcium lactate in doses of 3 to 5 g/day; and a low-phosphate diet. The therapeutic challenge in women with known hypoparathyroidism is management of blood calcium levels. The goal during pregnancy is maintenance of the corrected calcium level in the low normal range. It is possible that the increased calcium absorption typical of pregnancy will result in lower calcium requirements or that the fetal demand for calcium will result in increased need. Since both scenarios are possible, it is best to carefully monitor the corrected serum calcium on a frequent, perhaps monthly, basis throughout pregnancy (Cooper, 2011; Kovacs, 2011). The fetal risks from large doses of vitamin D have not been established.

■ Pregnancy-Associated Osteoporosis

Even with remarkably increased calcium requirements, it is uncertain whether pregnancy causes osteopenia in most women (Kaur, 2003; To, 2003). In one study of 200 pregnant women in which bone mass was measured using quantitative ultrasonometry of the calcaneus, Kraemer and colleagues (2011) demonstrated a decline in bone density during pregnancy. Women who breast fed, carried twin pregnancies, or had a low body mass index (BMI) were at higher risk of bone loss. From their review, Thomas and Weisman (2006) cite a 3- to 4-percent average reduction in bone-mineral density during pregnancy. Lactation also represents a period of negative calcium balance that is corrected through maternal skeletal resorption. Feigenberg and coworkers (2008) found cortical bone mass reductions using ultrasound in young primiparas in the puerperium compared with nulligravid controls. Rarely, some women develop idiopathic osteoporosis while pregnant or lactating. Its incidence is estimated to be 4 per million women (Hellmeyer, 2007).

The most common symptom of osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing until nearly immobilized (Maliha, 2012). In more than half of women, no apparent reason for osteopenia is found. Some known causes include heparin, prolonged bed rest, and corticosteroid therapy (Cunningham, 2005; von Mandach, 2003). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Treatment is problematical and includes calcium and vitamin D supplementation as well as standard pain management. Shown in Figure 58-5 is a hip radiograph from a woman treated at Parkland Hospital during the third trimester for transient osteoporosis of pregnancy.

For women with pregnancy-associated osteopenia, long-term surveillance indicates that although bone density improves, these women and their offspring may have chronic osteopenia (Carbone, 1995). There is an ongoing randomized, placebo-controlled trial of vitamin D supplementation

FIGURE 58-5 Anteroposterior plain radiograph with abdominal shielding of a 25-year-old patient's hips at 26-weeks' gestation. She complained of left hip and knee pain and progressive weakness. Her transient osteoporosis of the left femur responded over 3 months to physical therapy combined with vitamin D and calcium supplementation.

in pregnant women to determine its effect on neonatal bone mineral content as assessed by dual-energy x-ray absorptiometry (DEXA) (Harvey, 2012).

ADRENAL GLAND DISORDERS

Pregnancy has profound effects on adrenal cortical secretion and its control or stimulation. These interrelationships were reviewed by Lekarev and New (2011) and are discussed in detail in Chapter 4 (p. 70).

■ Pheochromocytoma

These tumors are clinically uncommon and complicate approximately 1 per 10,000 pregnancies. Notably, they are found in 0.1 percent of hypertensive patients (Abdelmannan, 2011). However, they are more commonly found at autopsy with infrequent clinical recognition. Pheochromocytomas are chromaffin tumors that secrete catecholamines and usually are located in the adrenal medulla, although 10 percent are located in sympathetic ganglia. They are called the *10-percent tumor* because approximately 10 percent are bilateral, 10 percent are extraadrenal, and 10 percent are malignant. These tumors can be associated with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive *multiple endocrine neoplasia syndromes*, as well as in neurofibromatosis and von Hippel-Lindau disease.

Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizure disorders, or anxiety attacks. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises. Other symptoms during paroxysmal attacks are headaches, profuse sweating, palpitations, chest pain, nausea and vomiting, and pallor or flushing.

The standard screening test is quantification of catecholamine metabolites in a 24-hour urine specimen (Abdelmannan, 2011). Diagnosis is established by measurement of a 24-hour

urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine levels may be accurate but is associated with technical difficulties (Conlin, 2001; Lenders, 2002). Boyle and colleagues (2007) determined that measurement of urinary free metanephrine was superior to assessment of a VMA or urinary or plasma catecholamine level. In nonpregnant patients, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance (MR) imaging. For most cases, preferred treatment is laparoscopic adrenalectomy (Lal, 2003).

Pheochromocytoma Complicating Pregnancy

These tumors are rare but result in dangerous pregnancy complications. Geelhoed (1983) provided an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. As seen in Table 58-6, maternal mortality rates are now lower but still formidable. In their review of 60 cases, Sarathi and associates (2010) confirmed that antepartum diagnosis is the most important determinant of maternal mortality risk. Maternal death was rare if the diagnosis is made antepartum.

Diagnosis of pheochromocytoma in pregnancy is similar to that for nonpregnant patients. MR imaging is the preferred imaging technique because it almost always locates adrenal and extraadrenal pheochromocytomas (Fig. 58-6) (Manger, 2005). In many cases, the principal challenge is to differentiate preeclampsia from the hypertensive crisis caused by pheochromocytoma. Desai and coworkers (2009) describe a woman who was initially treated for severe preeclampsia, suffered an intrapartum fetal death, and was then treated for presumed peripartum cardiomyopathy. When she returned 1 week later with paroxysmal hypertension, pheochromocytoma was diagnosed and her blood pressure and ventricular function returned to normal after tumor resection. Grimbert and colleagues (1999) diagnosed two pheochromocytomas during 56 pregnancies in 30 women with von Hippel-Lindau disease.

**FIGURE 58-6** Coronal magnetic resonance image taken in a 32-week pregnant woman shows a right-sided pheochromocytoma (arrow) and its position relative to the liver above it.

Management

Immediate control of hypertension and symptoms with an α -adrenergic blocker such as *phenoxybenzamine* is imperative. The dose is 10 to 30 mg, two to four times daily. After α -blockade is achieved, β -blockers may be given for tachycardia. In many cases, surgical exploration and tumor removal are performed during pregnancy, preferably during the second trimester (Dong, 2014; Miller, 2005). Successful laparoscopic removal of adrenal tumors has become the norm (Junglee, 2007; Kim, 2006; Miller, 2012; Zuluaga-Gómez, 2012). If diagnosed later in pregnancy, either planned cesarean delivery with tumor excision or postpartum resection is appropriate.

Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two infants were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, tumor was resected postpartum.

Cushing Syndrome

This syndrome is rare and has an annual incidence of 2 to 3 per million. The female:male ratio is 3:1 (Steffenson, 2010). Most cases are iatrogenic from long-term corticosteroid treatment. However, endogenous Cushing syndrome is typically due to *Cushing disease*, which is bilateral adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas. Most are small microadenomas < 1 cm, and half measure ≤ 5 mm. Rarely,

abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotrophic hyperplasia. Such hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. Less than a fourth of cases of Cushing syndrome are corticotropin independent, and most of these are caused by an adrenal adenoma. Tumors are usually bilateral, and half are malignant. Occasionally, associated androgen excess may lead to severe virilization (Danilowicz, 2002).

The typical cushingoid body habitus is caused by adipose tissue deposition that characteristically results in *moon facies*, a *buffalo hump*, and *truncal obesity*. Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Hatipoglu, 2012; Williams, 2001). Personality changes, easy bruisability, and cutaneous striae are common. Up to 60 percent may have impaired glucose tolerance. Diagnosis is verified by elevated plasma cortisol levels that cannot be suppressed by dexamethasone or by elevated 24-hour urine free cortisol excretion (Boscaro, 2001). Neither test is totally accurate, and both are more difficult to interpret in obese patients. CT and MR imaging are used to localize pituitary and adrenal tumors or hyperplasia.

Cushing Syndrome and Pregnancy

Because most women have corticotropin-dependent Cushing syndrome, associated androgen excess may cause anovulation, and pregnancy is rare. In their review, Lekarev and New (2011) identified fewer than 140 reported cases of Cushing syndrome in pregnancy. These differ compared with nonpregnant women in that half are caused by corticotropin-independent adrenal adenomas (Abdelmannan, 2011; Klibanski, 2006). Approximately 30 percent of cases are from a pituitary adenoma, and 10 percent from adrenal carcinomas (Lekarev, 2011; Lindsay, 2005). All reports stress difficulties in diagnosis because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor levels. Measurement of 24-hour urinary free cortisol excretion is recommended, with consideration for normal elevation in pregnancy.

Pregnancy outcomes in women with Cushing syndrome are listed in Table 58-7. Heart failure is common during pregnancy and is a major cause of maternal mortality (Buescher, 1992). Hypercortisolism in pregnancy may also cause poor wound healing, osteoporotic fracture, and psychiatric complications (Kamoun, 2014).

Long-term medical therapy for Cushing syndrome usually is ineffective, and definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia (Lekarev, 2011; Motivala, 2011). During pregnancy, management of hypertension in mild cases may suffice until delivery. In their review, Lindsay and associates (2005) described primary medical therapy in 20 women with Cushing syndrome. Most were successfully treated with *metyrapone* as an interim treatment until definitive surgery after delivery. A few cases were treated with oral *ketokonazole*. However, because this drug also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. *Mifepristone*, the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease but should not be used in pregnancy for

TABLE 58-7. Maternal and Perinatal Complications in Pregnancies Complicated by Cushing Syndrome

Complication	Approximate Incidence (%)

Data from Lindsay, 2005.

obvious reasons. If necessary, pituitary adenomas can be treated by transsphenoidal resection (Boscaro, 2001; Lindsay, 2005). Unilateral adrenalectomy has been safely performed in the early third trimester and can also be curative (Abdelmannan, 2011).

Adrenal Insufficiency—Addison Disease

Primary adrenocortical insufficiency is rare because more than 90 percent of total gland volume must be destroyed for symptoms to develop. *Autoimmune adrenalitis* is the most common cause in the developed world, but tuberculosis is a more frequent etiology in resource-poor countries (Kamoun, 2014). There is an increased incidence of concurrent Hashimoto thyroiditis, premature ovarian failure, type 1 diabetes, and Graves disease. These *polyglandular autoimmune syndromes* also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. The incidence of primary adrenal insufficiency has been cited as being as high as 1 in 3000 births in Norway (Lekarev, 2011). If untreated, symptoms often include weakness, fatigue, nausea and vomiting, and weight loss (Mestman, 2002). Because serum cortisol levels are increased during pregnancy, the finding of a low value should prompt an adrenocorticotrophic hormone (ACTH) stimulation test to document the lack of response to infused corticotropin (Salvatori, 2005).

In a large Swedish cohort study, 1188 women with Addison disease were compared with more than 11,000 age-matched controls who delivered between 1973 and 2006. Women diagnosed with adrenal insufficiency within 3 years of delivery were twice as likely to deliver preterm, were three times more likely to deliver a low-birthweight infant, and were more likely to undergo cesarean delivery (Björnsdóttir, 2010). Most pregnant women with Addison disease are already taking cortisone-like drugs. These should be continued and women observed for evidence of

either inadequate or excessive corticosteroid replacement. During labor, delivery, and postpartum, or after a surgical procedure, corticosteroid replacement must be increased appreciably to approximate the normal adrenal response—so-called *stress doses*. Hydrocortisone, 100 mg, is usually given intravenously every 8 hours. It is important that shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—be recognized and treated promptly.

■ Primary Aldosteronism

Hyperaldosteronism is caused by an adrenal aldosteronoma in approximately 75 percent of cases. Idiopathic bilateral adrenal hyperplasia comprise the remainder, except for rare cases of adrenal carcinoma (Abdelmannan, 2011; Ganguly, 1998). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

In normal pregnancy, as discussed in Chapter 4 (p. 61), progesterone blocks aldosterone action, and thus there are very high levels of aldosterone (Appendix, p. 1290). Accordingly, the diagnosis of hyperaldosteronism during pregnancy can be difficult. Since renin levels are suppressed in pregnant women with hyperaldosteronism, a plasma aldosterone-to-renin activity ratio may be helpful for diagnosis (Kamoun, 2014). Medical management includes potassium supplementation and antihypertensive therapy. In many cases, hypertension responds to *spironolactone*, but β -blockers or calcium-channel blockers may be preferred because of the potential fetal antiandrogenic effects of spironolactone. Mascetti and coworkers (2011) reported successful use of *amiloride* in a pregnant woman. Use of *eplerenone*, a mineralocorticoid receptor antagonist, has also been reported (Cabassi, 2012). Tumor resection is curative, and laparoscopic adrenalectomy has been shown to be safe (Kamoun, 2014; Kosaka, 2006; Miller, 2012).

PITUITARY DISORDERS

There is impressive pituitary enlargement during pregnancy, predominately from lactotrophic cellular hyperplasia induced by estrogen stimulation (Chap. 4, p. 67).

■ Prolactinomas

These adenomas are found often in nonpregnant women since the advent of widely available serum prolactin assays. Serum levels less than 25 pg/mL are considered normal in nonpregnant women (Motivala, 2011). Adenoma symptoms and findings include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size measured by CT or MR imaging. A microadenoma is ≤ 10 mm, and a macroadenoma is > 10 mm. Treatment for microadenomas is usually with bromocriptine, a dopamine agonist and powerful prolactin inhibitor, which frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical resection before pregnancy is attempted (Schlechte, 2007).

In a pooled analysis of more than 500 pregnant women with prolactinomas, only 1.4 percent with *microadenomas* developed symptomatic enlargement during pregnancy (Molitch, 2003).

Symptomatic enlargement of *macroadenomas*, however, is more frequent and was found in 26 percent of 84 pregnant women included in this analysis. Schlechte (2007) also reported that 15 to 35 percent of suprasellar macroadenomas have tumor enlargement that causes visual disturbances, headaches, and diabetes insipidus.

Gillam and colleagues (2006) recommend that pregnant women with microadenomas be queried regularly for headaches and visual symptoms. Those with macroadenomas should be followed more closely and have visual field testing during each trimester. CT or MR imaging is recommended only if symptoms develop. Serial serum prolactin levels are of little use because of normal increases during pregnancy (Appendix, p. 1291). Symptomatic tumor enlargement should be treated immediately with a dopamine antagonist such as bromocriptine or cabergoline. The safety of bromocriptine in pregnancy is well established. It is less well known for cabergoline, which is increasingly used in nonpregnant women because it is better tolerated and more effective. It is generally considered safe for use in pregnancy (Briggs, 2011). Lebbe and colleagues (2010) described 100 pregnancies exposed to cabergoline and found no adverse effects. Similar findings were reported in 85 exposed Japanese pregnant women (Ono, 2010). Surgery is recommended for women with no response, and Gondim and associates (2003) have described transnasal transseptal endoscopic resection.

■ Acromegaly

This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decrease as placental epitopes are secreted. Diagnosis is confirmed by the failure of an oral glucose tolerance test to suppress pituitary growth hormone (Melmed, 2006). There have been fewer than 100 cases of acromegaly reported during pregnancy (Motivala, 2011). Pregnancy is probably rare in women with acromegaly, because half are hyperprolactinemic and anovulatory. In a recent report describing 46 pregnant women with acromegaly, Caron and coworkers (2010) concluded that such women were at marginally increased risk for gestational diabetes and hypertension.

Management is similar to that for prolactinomas, with close monitoring for symptoms of tumor enlargement. Dopamine agonist therapy is not as effective as it is for prolactinomas. And transsphenoidal resection, generally considered first-line treatment outside of pregnancy, may be necessary for symptomatic tumor enlargement during pregnancy (Motivala, 2011). Guven and associates (2006) reported a case of pituitary apoplexy necessitating emergent transsphenoidal adenoma resection and cesarean delivery at 34 weeks. Successful treatment of pregnant women with the somatostatin-receptor ligand *octreotide* and with the GH analogue *pegvisomant* has also been reported (Brian, 2007; Herman-Bonert, 1998; Neal, 2000).

■ Diabetes Insipidus

The vasopressin deficiency evident in diabetes insipidus is usually due to a hypothalamic or pituitary stalk disorder rather than to a pituitary lesion (Lamberts, 1998). True diabetes insipidus is a rare complication of pregnancy.

Therapy for diabetes insipidus is intranasal administration of a synthetic analogue of vasopressin, *desmopressin*, which is 1-deamino-8-d-arginine vasopressin (DDAVP). Ray (1998) reviewed 53 cases in which DDAVP was used during pregnancy with no adverse sequelae. Most women require increased doses during pregnancy because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer, 1994). By this same mechanism, *subclinical diabetes insipidus* may become symptomatic or cases of *transient diabetes insipidus* may be encountered during pregnancy (Brewster, 2005; Wallia, 2013). The prevalence of vasopressinase-induced diabetes insipidus is estimated at 2 to 4 per 100,000 pregnancies (Wallia, 2013).

In our experiences, as described in Chapter 55 (p. 1086), transient secondary diabetes insipidus is more likely encountered with *acute fatty liver of pregnancy* (Nelson, 2013). This probably is due to altered vasopressinase clearance because of hepatic dysfunction.

Sheehan Syndrome

Sheehan (1937) reported that pituitary ischemia and necrosis associated with obstetrical blood loss could result in hypopituitarism. With modern methods of hemorrhagic shock treatment, Sheehan syndrome is now seldom encountered (Feinberg, 2005; Tessnow, 2010). An example is shown in [Figure 58-7](#).

FIGURE 58-7 Sheehan syndrome in a 23-year-old primipara who had major postpartum hemorrhage and hypotension intraoperatively during cesarean delivery. Magnetic resonance imaging was obtained because she failed to lactate, and her serum prolactin level was 18 ng/mL. This sagittal magnetic resonance image shows a large pituitary gland mass (arrows) consistent with hemorrhage. Subsequent imaging showed complete hematoma involution, and replacement therapy was not required.

Affected women may have persistent hypotension, tachycardia, hypoglycemia, and lactation failure. Because deficiencies of some or all pituitary responsive hormones may develop after the initial insult, Sheehan syndrome can be heterogenous and may not be identified for years (Tessnow, 2010). In one cohort study of 60 women from Costa Rica with Sheehan syndrome, the average time to diagnosis was 13 years (Gei-Guardia, 2011). Because adrenal insufficiency is the most life-threatening complication, adrenal function should be immediately assessed in any woman suspected of having Sheehan syndrome. After glucocorticoid replacement, subsequent analyses and replacement of thyroid, gonadal, and growth hormones should be considered (Gei-Guardia, 2011; Tessnow, 2010).

Lymphocytic Hypophysitis

This autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. Most cases are temporally linked to pregnancy (Caturegli, 2005; Foyouzi, 2011; Madsen, 2000). There are varying degrees of hypopituitarism or symptoms of mass effect, including headaches and visual field defects. A sellar mass is seen with CT or MR imaging. A mass accompanied by a modestly elevated serum prolactin level—usually < 100 pg/mL—suggests lymphocytic hypophysitis. In contrast, levels > 200 pg/mL are encountered with a prolactinoma. The etiology is unknown, but nearly 30 percent have a history of coexisting autoimmune diseases including Hashimoto thyroiditis, Addison disease, type 1 diabetes, and pernicious anemia. Treatment is with hormone replacement and because the disease may be self-limited, a careful withdrawal of hormone replacement should be attempted after inflammation resolution (Foyouzi, 2011; Gagneja, 1999). Surgery during pregnancy is warranted only in cases of severe chiasmal compression unresponsive to corticosteroid therapy (Lee, 2003).

CHAPTER 59

Connective-Tissue Disorders

IMMUNE-MEDIATED CONNECTIVE-TISSUE DISEASES . . .	1168
SYSTEMIC LUPUS ERYTHEMATOSUS	1169
ANTIPHOSPHOLIPID ANTIBODY SYNDROME	1173
RHEUMATOID ARTHRITIS	1176
SYSTEMIC SCLEROSIS—SCLERODERMA	1178
VASCULITIS SYNDROMES	1179
INFLAMMATORY MYOPATHIES	1180
HEREDITARY CONNECTIVE-TISSUE DISORDERS	1181

Connective-tissue disorders, which are also termed collagen-vascular disorders, have two basic underlying causes. First are the *autoantibody-mediated immune-complex diseases* in which connective-tissue damage is caused by deposition of immune complexes in specific organ(s) or tissue sites. Because these are manifest by sterile inflammation—predominately of the skin, joints, blood vessels, and kidneys—they are referred to as rheumatic diseases. Many of these immune-complex diseases are more prevalent in women, for example, systemic lupus erythematosus (SLE), rheumatoid arthritis, and a host of vasculitis syndromes. Second are the *inherited disorders* of bone, skin, cartilage, blood vessels, and basement membranes. Some examples include Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

IMMUNE-MEDIATED CONNECTIVE-TISSUE DISEASES

These disorders can be separated into those associated with and those without autoantibody formation. So-called *rheumatoid factor (RF)* is an autoantibody found in many autoimmune

inflammatory conditions such as SLE, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective-tissue disease, dermatomyositis, polymyositis, and various vasculitis syndromes. The *RF-seronegative spondyloarthropathies* are strongly associated with expression of the HLA-B27 antigen and include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and other arthritis syndromes.

Pregnancy may mitigate activity in some of these syndromes as a result of the immunosuppression that also allows successful engraftment of fetal and placental tissues. These changes are discussed in detail in Chapters 4 and 5 (p. 56). One example is pregnancy-induced predominance of T2 helper cells compared with cytokine-producing T1 helper cells (Keeling, 2009). Pregnancy hormones alter immune cells, for example, estrogens upregulate and androgens downregulate T-cell response, and progesterone is immunosuppressive (Cutolo, 2006; Häupl, 2008a; Robinson, 2012).

Some immune-mediated diseases may either be caused or activated as a result of previous pregnancies. To explain, fetal cells and free fetal DNA are detectable in maternal blood beginning early in pregnancy (Simpson, 2013; Sitar, 2005; Waldorf, 2008). *Fetal cell microchimerism* is the persistence of fetal cells in the maternal circulation and organs following pregnancy. These persistent fetal cells may stimulate autoantibodies, or they may become engrafted in maternal tissues. This raises the possibility that fetal cell microchimerism is related to the predilection of autoimmune disorders for women (Adams, 2004; Lissauer, 2009). Evidence for this includes findings of fetal stem cells engrafted in maternal tissues in women with autoimmune thyroiditis and systemic sclerosis (Jimenez, 2005; Srivatsa, 2001). Such microchimerism has also been described in women with SLE and those with rheumatoid arthritis-associated HLA alleles (Johnson, 2001; Lee, 2010; Rak, 2009a). Similarly, engrafted maternal cells may provoke autoimmune conditions in a woman's offspring (Ye, 2012). Perhaps related, women with SLE have a 0.6 male:female offspring ratio suggesting excessive male fetal loss in these women (Aggarwal, 2013).

TABLE 59-1. Some Autoantibodies Produced in Patients with Systemic Lupus Erythematosus (SLE)

Antibody	Prevalence (%)	Clinical Associations
Antinuclear (ANA)	84–98	Best screening test, multiple antibodies; a second negative test makes SLE unlikely
Anti-double-stranded (ds)-DNA	62–70	High titers SLE-specific; may correlate with disease activity, nephritis, and vasculitis
Anti-Smith (Smith)	25–38	Specific for SLE
Anti-RNP	33–40	Not SLE-specific, high titers associated with rheumatic syndromes
Anti-Ro (SS-A)	30–49	Not SLE-specific; associated with Sjögren syndrome, predisposes to cutaneous lupus, neonatal lupus with heart block, reduced risk of nephritis
Anti-La (SS-B)	10–35	Associated with anti-Ro; possible decreased nephritis risk
Antihistone	70	Common in drug-induced lupus (95%)
Antiphospholipid	21–50	Lupus anticoagulant and anticardiolipin antibodies associated with thrombosis, fetal loss, thrombocytopenia, valvular heart disease; false-positive test for syphilis
Anti-erythrocyte	60	Small number develop hemolysis
Antiplatelet	30	Thrombocytopenia in 15%; poor clinical test

Data from Arbuckle, 2003; Hahn, 2012.

Systemic Lupus Erythematosus

Lupus is a heterogeneous autoimmune disease with a complex pathogenesis that results in interactions between susceptibility genes and environmental factors (Hahn, 2012; Tsokos, 2011). Immune system abnormalities include overactive B lymphocytes that are responsible for autoantibody production. These result in tissue and cellular damage when autoantibodies or immune complexes are directed at one or more cellular nuclear components (Tsokos, 2011). In addition, immunosuppression is impaired, including regulatory T-cell function (Tower, 2013). Some autoantibodies produced in patients with lupus are shown in Table 59-1.

Almost 90 percent of lupus cases are in women, and its prevalence in those of childbearing age is approximately 1 in 500 (Lockshin, 2000). Accordingly, the disease is encountered relatively frequently during pregnancy. The 10-year survival rate is 70 to 90 percent (Hahn, 2012; Tsokos, 2011). Infection, lupus

flares, end-organ failure, hypertension, stroke, and cardiovascular disease account for most deaths.

Genetic influences are implicated by a higher concordance with monozygotic compared with dizygotic twins—25 versus 2 percent, respectively. Moreover, there is a 10-percent frequency in patients with one affected family member. The relative risk of disease is increased if there is inheritance of the “autoimmunity gene” on chromosome 16 that predisposes to SLE, rheumatoid arthritis, Crohn disease, and psoriasis (Hahn, 2012). Susceptibility genes such as *HLA-A1*, *B8*, *DR3*, *DRB1*, and *TET3* explain only a portion of the genetic heritability (Hom, 2008; Tsokos, 2011; Yang, 2013).

Clinical Manifestations and Diagnosis

Lupus is notoriously variable in its presentation, course, and outcome (Table 59-2). Findings may be confined initially to one organ system, and others become involved later. Or,

TABLE 59-2. Clinical Manifestations of Systemic Lupus Erythematosus

Organ System	Clinical Manifestations	Percent
Systemic	Fatigue, malaise, fever, weight loss	95
Musculoskeletal	Arthralgias, myalgias, polyarthritis, myopathy	95
Hematological	Anemia, hemolysis, leukopenia, thrombocytopenia, lupus anticoagulant, splenomegaly	85
Cutaneous	Malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, alopecia, skin rashes	80
Neurological	Cognitive dysfunction, mood disorder, headache, seizures	60
Cardiopulmonary	Pleuritis, pericarditis, myocarditis, endocarditis, pneumonitis, pulmonary hypertension	60
Renal	Proteinuria, casts, nephrotic syndrome, renal failure	30–50
Gastrointestinal	Nausea, pain, diarrhea, abnormal liver enzyme levels	40
Vascular	Thrombosis: venous (10%), arterial (5%)	15
Ocular	Conjunctivitis	15

Modified from Hahn, 2012.

the disease may first manifest with multisystem involvement. Common findings are malaise, fever, arthritis, rash, pleuro-pericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. There is evidence that lupus is associated with decline in attention, memory, and reasoning (Kozora, 2008). Although *Libman-Sacks endocarditis* was described with lupus, it is likely due to presence of subsequently discussed anticardiolipin antibodies (Hojnik, 1996).

Identification of antinuclear antibodies (ANA) is the best screening test. However, a positive result is not specific for lupus. For example, low titers are found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs can also cause a positive reaction. Antibodies to double-stranded DNA (dsDNA) and to Smith (Sm) antigens are relatively specific for lupus, whereas other antibodies are not (see Table 59-1). Although hundreds of autoantibodies have been described in SLE, only a few have been shown to participate in tissue injury (Sherer, 2004; Tsokos, 2011). Microarray profiles are being developed for customized and more accurate SLE diagnoses (Lin, 2013; Yeste, 2013).

Anemia develops frequently, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions. Lupus nephritis can also cause renal insufficiency, which is more common if there are antiphospholipid antibodies (Moroni, 2004). Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and higher rheumatoid factor levels. Elevated serum D-dimer levels often follow a flare or infection, but unexplained persistent elevations are associated with a high risk for thrombosis (Wu, 2008).

The diagnostic criteria for SLE are listed in Table 59-3. If any four or more of these 11 criteria are present, serially or simultaneously, the diagnosis of lupus is made.

Importantly, numerous drugs can induce a lupus-like syndrome. These include procainamide, quinidine, hydralazine, α -methyl dopa, phenytoin, and phenobarbital. Drug-induced lupus is rarely associated with glomerulonephritis and usually regresses when the medication is discontinued (Rubin, 1997).

Lupus and Pregnancy

Of nearly 16.7 million pregnancies in the United States from 2000 to 2003, 13,555 were complicated by lupus—an incidence of approximately 1 in 1250 pregnancies (Clowse, 2008). During the past several decades, pregnancy outcomes in women with SLE have improved remarkably. Important factors for pregnancy outcome include whether disease is active at the beginning of pregnancy, age and parity, coexistence of other medical or obstetrical disorders, and whether antiphospholipid antibodies are detected (p. 1173). There is evidence that newly diagnosed lupus during pregnancy tends to be severe (Zhao, 2013).

During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any given pregnancy, the clinical condition can worsen or *flare* without warning (Khamashta, 1997). Petri (1998) reported a 7-percent risk of major morbidity during

TABLE 59-3. Criteria of the American Rheumatism Association for Systemic Lupus Erythematosus (SLE)

Criteria ^a	Comments
Malar rash	Malar erythema
Discoid rash	Erythematous patches, scaling, follicular plugging
Photosensitivity	Exposure to UV light causes rash
Oral ulcers	Usually painless oral and nasopharyngeal ulcers
Arthritis	Nonerosive involving two or more peripheral joints with tenderness, swelling, or effusion
Serositis	Pleuritis or pericarditis
Renal	Proteinuria greater than 0.5 g/day or > 3+ dipstick, or cellular casts
Neurological	Seizures or psychosis without other cause
Hematological	Hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
Autoantibodies	Anti-dsDNA or anti-Sm antibodies, or false-positive VDRL, abnormal level of IgM or IgG anticardiolipin antibodies, or lupus anticoagulant
ANA	Abnormally elevated ANA titers

^aIf four or more criteria are present at any time during disease course, SLE can be diagnosed with 75-percent specificity and 95-percent sensitivity.

ANA = antinuclear antibodies; dsDNA = double-stranded DNA; Sm = Smith; UV = ultraviolet; VDRL = Venereal Disease Research Laboratory.

Modified from Hahn, 2012; Hochberg, 1997; Tan, 1982.

pregnancy. Women who have confined cutaneous lupus do not usually have adverse outcomes (Hamed, 2013). Frequent complications in a cohort of 13,555 women with SLE during pregnancy are shown in Table 59-4. The maternal mortality and severe morbidity rate was 325 per 100,000. In a review of 13 studies with 17 maternal deaths attributable to SLE and lupus nephritis, all occurred in those with active disease (Ritchie, 2012).

From the foregoing, it is certain that lupus can be life threatening for both mother and fetus. Generally speaking, pregnancy outcome is best in those women in whom: (1) lupus activity has been quiescent for at least 6 months before conception; (2) there is no lupus nephritis manifest by proteinuria or renal dysfunction; (3) there is no evidence of the antiphospholipid antibody syndrome or lupus anticoagulant; and (4) superimposed preeclampsia does not develop (Peart, 2014; Stojan, 2012).

Lupus Nephritis. Active nephritis has been associated with particularly bad pregnancy outcomes, although these have improved remarkably during the past 30 years (Moroni, 2005; Stojan, 2012). Women with renal disease have a high incidence

TABLE 59-4. Complications in 13,555 Pregnancies in Women with Systemic Lupus Erythematosus

Complications	Percent
Comorbid illness	
Pregestational diabetes	5.6
Thrombophilia	4.0
Hypertension	3.9
Renal failure	0.2
Pulmonary hypertension	0.2
Pregnancy complications	
Preeclampsia	22.5
Preterm labor	20.8
Fetal-growth restriction	5.6
Eclampsia	0.5
Medical complications	
Anemia	12.6
Thrombocytopenia	4.3
Thrombotic—stroke, pulmonary embolism, deep-vein thrombosis	1.7
Infections—pneumonia, sepsis syndrome	2.2
Maternal morbidity-mortality rate	325/100,000

Data from Clowse, 2008.

of gestational hypertension and preeclampsia. However, if their disease remains in remission, they usually have good pregnancy outcomes (Huong, 2001; Moroni, 2002). Of the 125 pregnancies reported by Lockshin (1989), 63 percent of women with preexisting renal disease developed preeclampsia compared with only 14 percent of those without underlying renal disease. Moroni and Ponticelli (2005) reviewed results from a total of 309 pregnancies complicated by established lupus nephritis. Of these, 30 percent suffered a flare, and 40 percent of these had associated renal insufficiency. The maternal mortality rate was 1.3 percent.

In two studies describing pregnancy outcomes in women with lupus nephritis, Wagner and coworkers (2009) compared outcomes of 58 women cared for during 90 pregnancies at the Mayo Clinic. Active nephritis was associated with a significantly higher incidence of maternal complications compared with women without nephritis—57 versus 11 percent. Quiescent nephritis had a nonsignificant effect on preeclampsia rates compared with lupus patients without renal impairment. The fetal death rate with active maternal nephritis was 35 percent compared with 9 percent in those with quiescent nephritis. In another study, Imbasciati and associates (2009) described outcomes in 113 pregnancies in 81 women with known lupus nephritis. During a third of pregnancies, there was a renal flare. After excluding nine miscarriages, of the 104 remaining pregnancies, a third were delivered preterm, a third of infants weighed < 2500 g, and the perinatal mortality rate was 6 percent.

Most recommend continuation of immunosuppressive therapy for nephritis during pregnancy. It is not clear whether the dose should be increased peripartum. Although it is often stated

that this is the time that activation or exacerbations are most likely to develop, the evidence is not conclusive.

Lupus versus Preeclampsia-Eclampsia. Chronic hypertension complicates up to 30 percent of pregnancies in women with SLE (Egerman, 2005). And as discussed, preeclampsia is common, and superimposed preeclampsia is encountered even more often in those with nephritis or antiphospholipid antibodies (Bertsias, 2008). It may be difficult, if not impossible to differentiate lupus nephropathy from severe preeclampsia if the kidney is the only involved organ (Petri, 2007). Central nervous system involvement with lupus may culminate in convulsions similar to those of eclampsia. Thrombocytopenia, with or without hemolysis, may further confuse the diagnosis because of its similarity to the hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome. Management is identical to that for preeclampsia-eclampsia, described in Chapter 40 (p. 749).

Management During Pregnancy

Lupus management consists primarily of monitoring maternal clinical and laboratory conditions as well as fetal well-being (Lateef, 2012). Pregnancy-induced thrombocytopenia and proteinuria resemble lupus disease activity, and the identification of a lupus flare is confounded by the increase in facial and palmar erythema of normal pregnancy (Lockshin, 2003). Some authorities have advocated a number of numerical scales to emphasize ongoing disease activity. Components are weighted for severity, both with the SLE-Pregnancy Disease Activity Index (SLEPDAI) and with the Lupus Activity Index (Buyon, 1999; Ruiz-Irastorza, 2004). We have not found these to be useful.

Lupus activity monitoring and identification of lupus flares by various laboratory techniques has been recommended. The sedimentation rate may be misleading because of pregnancy-induced hyperfibrinogenemia. Serum complement levels are also normally increased in pregnancy (Chap. 4, p. 56 and Appendix, p. 1291). And, although falling or low levels of complement components C₃, C₄, and CH₅₀ are more likely to be associated with active disease, higher levels provide no assurance against disease activation. Our experiences, as well as those of Varner and colleagues (1983) and Lockshin and Druzin (1995), are that there is no correlation between clinical manifestations of disease and complement levels.

Serial hematological studies may detect changes in disease activity. Hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. According to Lockshin and Druzin (1995), chronic thrombocytopenia in early pregnancy may be due to antiphospholipid antibodies. Later, thrombocytopenia may indicate preeclampsia.

Serum aminotransferase activity reflects hepatic involvement, as does a rise in serum bilirubin levels. Azathioprine therapy also may induce enzyme elevations. Urine is tested frequently to detect new-onset or worsening proteinuria. Overt proteinuria that persists is an ominous sign, even more so if accompanied by other evidence of the nephrotic syndrome or abnormal serum creatinine levels.

The fetus should be closely observed for adverse effects such as growth restriction and oligohydramnios. Many recommend screening for anti-SS-A (anti-Ro) and anti-SS-B (anti-La) antibodies, because of associated fetal complications described subsequently. As discussed in Chapter 17 (p. 335), antepartum fetal surveillance is done as outlined by the American College of Obstetricians and Gynecologists (2012a). Unless hypertension develops or there is evidence of fetal compromise or growth restriction, pregnancy is allowed to progress to term. Peripartum corticosteroids in “stress doses” are given to women who are taking these drugs or who recently have done so.

Pharmacological Treatment. There is no cure, and complete remissions are rare. Approximately a fourth of women have mild disease, which is not life threatening, but may be disabling because of pain and fatigue. Arthralgia and serositis can be managed by occasional doses of nonsteroidal antiinflammatory drugs (NSAIDs). However, chronic or large intermittent dosing is avoided due to pregnancy side effects with these drugs described in Chapter 12 (p. 247) (Briggs, 2011). Low-dose aspirin can be used throughout gestation. Severe disease is managed with corticosteroids such as prednisone, 1 to 2 mg/kg orally per day. After the disease is controlled, this dose is tapered to a daily morning dose of 10 to 15 mg. Corticosteroid therapy can result in the development of gestational diabetes.

Immunosuppressive agents such as azathioprine are beneficial in controlling active disease (Contreras, 2004; Hahn, 2012). In nonpregnant patients, these are usually reserved for lupus nephritis or disease that is corticosteroid resistant. Azathioprine has a good safety record during pregnancy (Fischer-Betz, 2013; Petri, 2007). Its recommended daily oral dose is 2 to 3 mg/kg. According to Buhimschi and Weiner (2009), cyclophosphamide is teratogenic, and although not usually recommended during pregnancy, severe disease may be treated after 12 weeks’ gestation. As discussed in Chapter 12 (p. 250), medications to be avoided include mycophenolate mofetil and methotrexate (Anderka, 2009; Briggs, 2011; Food and Drug Administration, 2008). In some situations, mycophenolate is the only treatment that achieves disease stability. In these cases, counseling regarding fetal risks is essential (Bramham, 2012).

Antimalarials help control skin disease. Although these agents cross the placenta, hydroxychloroquine has not been associated with congenital malformations. Because of the long half-life of antimalarials and because discontinuing therapy can precipitate a lupus flare, most recommend their continuation during pregnancy (Borden, 2001; Harris, 2002). Levy and associates (2001) randomly assigned 20 pregnant women to receive hydroxychloroquine or placebo and reported improved SLEPDAI scores with hydroxychloroquine.

When severe disease supervenes—usually a lupus flare—high-dose glucocorticoid therapy is given. Petri (2007) recommends pulse therapy consisting of methylprednisolone, 1000 mg given intravenously over 90 minutes daily for 3 days, then a return to maintenance doses if possible.

Perinatal Mortality and Morbidity

Adverse perinatal outcomes are increased significantly in pregnancies complicated by lupus. These include preterm delivery,

fetal-growth restriction, stillbirths, and neonatal lupus syndrome (Madazli, 2014). Outcomes are worse with a lupus flare, significant proteinuria, or renal impairment, and with chronic hypertension, preeclampsia, or both (Aggarwal, 1999; Bramham, 2012; Scott, 2002; Wagner, 2009). The observations of Lee and coworkers (2009) are worrisome. In a mouse SLE model, they showed that autoantibodies directed against the *N*-methyl-D-aspartate neuroreceptor caused fetal neurotoxicity. This suggests an underlying etiology for the CNS manifestations and learning disorders in children of affected mothers. Ongoing work on anti-dsDNA antibodies has identified peptides that can protect target organs from antibody-mediated damage (Diamond, 2011).

The reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly, 1988; Lubbe, 1984). Placental pathology is discussed in more detail in Chapter 6 (p. 119).

Neonatal Lupus Syndrome. This unusual constellation is characterized by newborn skin lesions—lupus dermatitis; a variable number of hematological and systemic derangements; and occasionally congenital heart block (Boh, 2004; Lee, 2009). Although usually associated with anti-SS-A and -SS-B antibodies, McGeachy and Lam (2009) described an affected infant in whom only anti-ribonucleoprotein (RNP) antibodies were found. Thrombocytopenia and hepatic involvement are seen in 5 to 10 percent of affected infants. One report suggests that neonatal lupus may appear up to 4 weeks after birth (Stirnemann, 2002). Lockshin and colleagues (1988) prospectively followed 91 infants born to women with lupus. Eight were possibly affected—four had definite neonatal lupus and four had possible disease. Clinical manifestations, which include cutaneous lupus, thrombocytopenia, and autoimmune hemolysis, are transient and clear within a few months (Lee, 1984). This may not be so for congenital heart block. In subsequent offspring, the recurrence risk for neonatal lupus is up to 25 percent (Julkunen, 1993).

Congenital Heart Block. Fetal and neonatal heart block results from diffuse myocarditis and fibrosis in the region between the atrioventricular (AV) node and bundle of His. Buyon and associates (1993) reported that congenital heart block developed almost exclusively in fetuses of women with antibodies to the SS-A or SS-B antigens. These antibodies may also cause otherwise unexplained stillbirths (Ottaviani, 2004). Even in the presence of such antibodies, however, the incidence of myocarditis is only 2 to 3 percent but increases to 20 percent with a prior affected child (Bramham, 2012; Lockshin, 1988). Fetal cardiac monitoring should be performed between 18 and 26 weeks’ gestation in pregnancies with either of these antibodies. The cardiac lesion is permanent, and a pacemaker is generally necessary. Long-term prognosis is poor. Of 325 infants with cardiac neonatal lupus, nearly 20 percent died, and of these, a third were stillborn (Izmirly, 2011).

Maternal administration of corticosteroids, plasma exchange, or intravenous immunoglobulin have not been found to reduce

the risk of congenital heart block. Corticosteroid therapy to treat fetal heart block has not been subjected to randomized trials. There is some evidence that early treatment may mitigate fetal myocarditis. Shinohara and coworkers (1999) reported no heart block in 26 neonates whose mothers received corticosteroids before 16 weeks' gestation as part of SLE maintenance therapy. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks for SLE exacerbation. Rein and colleagues (2009) followed 70 fetuses prospectively of mothers positive for anti-SS-A or -SS-B antibodies with serial fetal kinetocardiography (FKCG) to measure AV conduction time. In six fetuses, first-degree heart block developed at 21 to 34 weeks, and maternal dexamethasone treatment was associated with normalization of AV conduction in all within 3 to 14 days. There were no recurrences, and the infants all were well at a median follow-up of 4 years. However, as noted in Chapter 16 (p. 322), corticosteroids may be less effective for higher degrees of heart block. Moreover, potential benefit should be weighed against the risks of chronic corticosteroid treatment, including impaired fetal growth (Friedman, 2009).

Long-Term Prognosis and Contraception

In general, women with lupus and chronic vascular or renal disease may limit family size because of morbidity associated with the disease as well as increased adverse perinatal outcomes. Two large multicenter clinical trials have shown that combination oral contraceptives (COCs) did not increase the incidence of lupus flares (Petri, 2005; Sánchez-Guerrero, 2005). Still, the American College of Obstetricians and Gynecologists (2013) recommends that COC use be avoided in women who have nephritis, antiphospholipid antibodies, or vascular disease. Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Chabbert-Buffet, 2010). Concerns that intrauterine device (IUD) use and immunosuppressive therapy lead to increased infection rates in these patients are not evidenced-based. Tubal sterilization may be advantageous and is performed with greatest safety postpartum or whenever the disease is quiescent. These options are discussed in further detail in Chapters 38 and 39.

■ Antiphospholipid Antibody Syndrome

Phospholipids are the main lipid constituents of cell and organelle membranes. There are proteins in plasma that associate

noncovalently with these phospholipids. Antiphospholipid antibodies are directed against these phospholipids or phospholipid-binding proteins (Erkan, 2011; Giannakopoulos, 2013; Tsokos, 2011). This antibody group may be of IgG, IgM, and IgA classes, alone or in combination. Antiphospholipid antibodies are most common with lupus and other connective-tissue disorders, although a small proportion of otherwise normal women and men are found to have these antibodies in various forms.

The stimulus for autoantibody production is unclear, but it possibly is due to a preceding infection. The pathophysiology encountered in the *antiphospholipid antibody syndrome*—variably referred to as APAS or APS—is mediated by one or more of the following: (1) activation of various procoagulants, (2) inactivation of natural anticoagulants, (3) complement activation, and (4) inhibition of syncytiotrophoblast differentiation (Moutsopoulos, 2012; Tsokos, 2011). Clinically, these result in arterial or venous thromboses or pregnancy morbidity, and virtually every organ system may be involved as shown in Table 59-5.

Central nervous system involvement is one of the most prominent clinical manifestations. In addition to cerebrovascular arterial and venous thrombotic events, there may be psychiatric features and even multiple sclerosis (Binder, 2010; Sanna, 2003). Renovascular involvement may lead to renal failure that may be difficult to differentiate from lupus nephritis (D'Cruz, 2009). Peripheral and visceral thromboses are also a feature. For example, Ahmed and associates (2009) reported a postpartum woman who developed spontaneous cecal perforation associated with a mesenteric vessel infarction. As discussed in Chapter 18 (p. 359), antiphospholipid antibodies have been associated with excessive pregnancy loss (Branch, 2010). These and other detrimental effects on pregnancy outcomes are discussed subsequently.

A small proportion of these patients develop the *catastrophic antiphospholipid antibody syndrome*—CAPS. This is defined as a rapidly progressive thromboembolic disorder simultaneously involving three or more organ systems or tissues (Moutsopoulos, 2012).

Specific Antiphospholipid Antibodies

Several autoantibodies have been described that are directed against a specific phospholipid or phospholipid-binding protein. First, β_2 -glycoprotein I—also known as apolipoprotein H—is a phospholipid-binding plasma protein that inhibits prothrombinase activity within platelets and inhibits

TABLE 59-5. Some Clinical Features of Antiphospholipid Antibody Syndrome

Venous thrombosis—thromboembolism, thrombophlebitis, livedo reticularis
Arterial thrombosis—stroke, transient ischemic attack, Libman-Sacks cardiac vegetations, myocardial ischemia, distal extremity and visceral thrombosis and gangrene
Hematological—thrombocytopenia, autoimmune hemolytic anemia
Other—neurological manifestations, migraine headaches, epilepsy; renal artery, vein, or glomerular thrombosis; arthritis and arthralgia
Pregnancy—preeclampsia syndrome, recurrent miscarriage, fetal death

Data from Giannakopoulos, 2013; Moutsopoulos, 2012.

ADP-induced platelet aggregation (Giannakopoulos, 2013; Shi, 1993). Thus, its normal action is to inhibit procoagulant binding and thereby prevent coagulation cascade activation. Logically, antibodies directed against β_2 -glycoprotein I would inhibit its anticoagulant activity and promote thrombosis. This is important from an obstetrical viewpoint because β_2 -glycoprotein I is expressed in high concentrations on the syncytiotrophoblastic surface. Complement activation may contribute to its pathogenesis (Avalos, 2009; Tsokos, 2011). Teleologically, this seems appropriate because the decidua intuitively should be a critical area to prevent coagulation that might result in intervillous space thrombosis. Another possibility is that β_2 -glycoprotein I may be involved in implantation, and it may result in pregnancy loss via an inflammatory mechanism (Iwasawa, 2012; Meroni, 2011).

Second, *lupus anticoagulant* (LAC) is a heterogeneous group of antibodies directed also against phospholipid-binding proteins. LAC induces prolongation in vitro of the prothrombin, partial thromboplastin, and Russell viper venom times (Feinstein, 1972). Thus, paradoxically, this so-called anticoagulant is actually powerfully thrombotic in vivo.

Last, there are *anticardiolipin antibodies* (ACAs). These are directed against one of the many phospholipid cardiolipins found in mitochondrial membranes and platelets.

Antibodies against Natural Anticoagulants

Antiphospholipid antibodies have also been described that are directed against the natural anticoagulant proteins C and S (Robertson, 2006). Another is directed against the anticoagulant protein annexin V, which is expressed in high concentrations by the syncytiotrophoblast (Chamley, 1999; Giannakopoulos, 2013). That said, criteria to diagnosis antiphospholipid-antibody syndrome require testing for elevated levels of the following antiphospholipid antibodies: LAC, ACA, and anti- β_2 glycoprotein I. Testing for other antibodies is not recommended (American College of Obstetricians and Gynecologists, 2012b).

Antiphospholipid Antibody Syndrome Diagnosis

Clinical classification criteria shown in Table 59-5 provide indications for testing. By international consensus, the syndrome is diagnosed based on laboratory and clinical criteria (Miyakis, 2006). First, one of two clinical criteria—which are vascular thrombosis or certain pregnancy morbidity—must be present. In addition, at least one laboratory criterion that includes LAC activity or medium- to high-positive levels of specific IgG- or IgM-ACAs must be confirmed on two occasions 12 weeks apart.

Tests for LAC are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. Tests considered more specific are the *dilute Russell viper venom test* and the *platelet neutralization procedure*. There is currently disagreement as to which of these two is best for screening. If either is positive, then identification of LAC is confirmed.

Branch and Khamashta (2003) recommend conservative interpretation of results based on repeated tests from a reliable laboratory that are consistent with each clinical case. Only approximately 20 percent of patients with APS have a

positive LAC reaction alone. Thus, anticardiolipin enzyme-linked immunosorbent assay (ELISA) testing should also be performed. Many laboratories have a premade panel to use for APS testing.

Efforts have been made to standardize ACA assays by using ELISA. Values are reported in units and expressed as *negative*, *low-positive*, *medium-positive*, or *high-positive* (Harris, 1987a,b). Despite this, these assays remain without international standardization (Adams, 2013; Branch, 2003; Capuano, 2007). Interlaboratory variation can be large, and agreement between commercial kits is poor.

Pregnancy and Antiphospholipid Antibodies

Nonspecific low levels of antiphospholipid antibodies are identified in approximately 5 percent of normal adults (Branch, 2010). When Lockwood and coworkers (1989) first studied 737 normal pregnant women, they reported that 0.3 percent had lupus anticoagulant and 2.2 percent had elevated concentrations of either IgM or IgG anticardiolipin antibodies. Later studies confirmed this, and taken together, they totaled almost 4000 normal pregnancies with an average prevalence for APAs of 4.7 percent. This is the same as for normal nonpregnant individuals (Harris, 1991; Pattison, 1993; Yasuda, 1995).

In women with high levels of ACAs, and especially when lupus anticoagulant is identified, there are increased risks for decidual vasculopathy, placental infarction, fetal-growth restriction, early-onset preeclampsia, and recurrent fetal death. Some of these women, like those with lupus, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (American College of Obstetricians and Gynecologists, 2012b; Clowse, 2008). In 191 LAC-negative women with antiphospholipid-antibody syndrome, women with antibodies to cardiolipin and β_2 -glycoprotein I had significantly higher miscarriage rates than if either one alone was positive (Liu, 2013).

Pregnancy Pathophysiology. It is not precisely known how these antibodies cause damage, but it is likely that their actions are multifactorial (Tsokos, 2011). Platelets may be damaged directly by antiphospholipid antibody or indirectly by binding β_2 -glycoprotein I, which causes platelets to be susceptible to aggregation (Chamley, 1999; Giannakopoulos, 2013). Rand and colleagues (1997a,b, 1998) propose that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the antiphospholipid antibody or indirectly by antibody binding to either β_2 -glycoprotein I or annexin V. This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium. It results in exposure of basement membrane to which damaged platelets can adhere and form a thrombus (Lubbe, 1984).

Pierro and associates (1999) reported that antiphospholipid antibodies decreased decidual production of the vasodilating prostaglandin E_2 . Decreased protein C or S activity and increased prothrombin activation may also be contributory (Ogunyemi, 2002; Zangari, 1997). Amengual and coworkers (2003) presented evidence that thrombosis with APS is due to activation of

the tissue factor pathway. Finally, uncontrolled placental complement activation by antiphospholipid antibodies may play a role in fetal loss and growth restriction (Holers, 2002).

Complications from APS cannot be completely explained by thrombosis alone. Animal models suggest that these are due to inflammation rather than thrombosis (Cohen, 2011). Some investigators theorize that APS-associated clotting is triggered by a “second hit” from innate inflammatory immune responses and recommend antiinflammatory agents (Meroni, 2011).

Adverse Pregnancy Outcomes. Antiphospholipid antibodies are associated with increased rates of fetal wastage (Chap. 18, p. 359). In most early reports, however, women were included *because* they had had repeated adverse outcomes. Both are common—recall that the incidence of antiphospholipid antibodies in the general obstetrical population is about 5 percent and early pregnancy loss approximates 20 percent. Accordingly, data currently are too limited to allow precise conclusions to be drawn concerning the impact of these antibodies on adverse pregnancy outcomes. Fetal deaths, however, are more characteristic with APS than are first-trimester miscarriages (Oshiro, 1996; Roque, 2001). It has also been shown that women with higher antibody titers have worse outcomes compared with those with low titers (Nodler, 2009; Simchen, 2009).

Looking at the issue another way, the frequency of antiphospholipid antibodies may be increased with associated adverse obstetrical outcomes. Polzin and colleagues (1991) identified antiphospholipid antibodies in a fourth of 37 women with growth-restricted fetuses, however, none had evidence for lupus anticoagulant. Approximately a third of women with APS will develop preeclampsia during pregnancy (Clark, 2007b). Moodley and associates (1995) found antiphospholipid antibodies in 11 percent of 34 women with severe preeclampsia before 30 weeks.

When otherwise unexplained fetal deaths are examined, the data are mixed. Haddow and coworkers (1991) measured ACAs in 309 pregnancies with fetal death and found no differences compared with those in 618 normal pregnancies. In women with a history of recurrent pregnancy loss, those with antiphospholipid antibodies had a higher rate of preterm delivery (Clark, 2007a). In a case-control study of 582 stillbirths and 1547 live births, Silver and colleagues (2013) found a three- to fivefold increased risk for stillbirth in women with elevated anticardiolipin and anti- β_2 -glycoprotein I levels. Due to the risk of fetal-growth abnormalities and stillbirth, serial sonographic assessment of fetal growth and antepartum testing in the third trimester are recommended by the American College of Obstetricians and Gynecologists (2012b).

Treatment in Pregnancy. Because of the heterogeneity of studies, current treatment recommendations for women with antiphospholipid antibodies can be confusing (Branch, 2003; Robertson, 2006). As discussed, antiphospholipid antibodies that bind to immunoglobulins G, M, and A are semiquantified, and GPL, MPL, and APL binding units are expressed as negative, low-positive, medium-positive, or high-positive

(American College of Obstetricians and Gynecologists, 2012b). Of the three, higher titers for GPL and MPL anticardiolipin antibodies are clinically important, whereas low-positive titers are of questionable clinical significance. And *any titer* of APL antibodies has no known relevance at this time.

As discussed in Chapter 52 (p. 1033), women with prior thromboembolic events who have antiphospholipid antibodies are at risk for recurrence in subsequent pregnancies. For these women, prophylactic anticoagulation with heparin throughout pregnancy and for 6 weeks postpartum with either heparin or warfarin is recommended (American College of Obstetricians and Gynecologists, 2012b). For those without history of thromboembolic events, recommendations for management from the American College of Obstetricians and Gynecologists (2012b) and the American College of Chest Physicians (Bates, 2012) are varied and listed in Table 52-8 (p. 1046). Some acceptable schemes include close antepartum observation with or without prophylactic or intermediate-dose heparin, and some form of postpartum anticoagulation for 4 to 6 weeks.

Recent trials have caused the need for heparin to be questioned in women with antibodies but no history of thrombosis (Branch, 2010). Although this is less clear, some recommend that women be treated if they have medium- or high-positive ACA titers or LAC activity and a previous second- or third-trimester fetal death not attributable to other causes (Dizon-Townson, 1998; Lockshin, 1995). Some report that women with recurrent early pregnancy loss and medium- or high-positive titers of antibodies may benefit from therapy (Robertson, 2006). Some individual agents are now considered for pregnant women with antiphospholipid antibody syndrome who have no prior thromboembolic event. These agents are described in the following paragraphs.

Aspirin, given in doses of 60 to 80 mg orally daily, blocks the conversion of arachidonic acid to thromboxane A_2 while sparing prostacyclin production. This reduces synthesis of thromboxane A_2 , which usually causes platelet aggregation and vasoconstriction, and simultaneously spares prostacyclin, which normally has the opposite effect. There appear to be no major side effects from low-dose aspirin other than a slight risk of small-vessel bleeding during surgical procedures. Low-dose aspirin does not appear to reduce adverse pregnancy outcomes in antiphospholipid antibody-positive women without the complete syndrome (Del Ross, 2013).

Unfractionated heparin is given subcutaneously in dosages of 5000 to 10,000 units every 12 hours. Some prefer low-molecular-weight heparin, such as 40 mg enoxaparin once daily, because of its ease of administration and smaller risk of osteoporosis and heparin-induced thrombocytopenia (Kwak-Kim, 2013). With therapeutic dosing, some recommend measurement of heparin levels because clotting tests may be altered by lupus anticoagulant (Cowchock, 1998). The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia, 1996). As discussed, heparin binds to β_2 -glycoprotein I, which coats the syncytiotrophoblast. This prevents binding of anticardiolipin and anti- β_2 -glycoprotein I antibodies to

their surfaces, which likely prevents cellular damage (Chamley, 1999; Tsokos, 2011). Heparin also binds to antiphospholipid antibodies in vitro and likely in vivo. It is problematic that heparin therapy is associated with a number of complications that include bleeding, thrombocytopenia, osteopenia, and osteoporosis. A detailed description of the use of various heparins and their doses and adverse effects is found in Chapter 52 (p. 1037).

Glucocorticosteroids generally should not be used with *primary APS*—that is, without an associated connective-tissue disorder. For women with lupus or those being treated for APS who develop lupus, corticosteroid therapy is indicated (Carbone, 1999). In such cases of *secondary APS* seen with lupus, the dose of prednisone should be maintained at the lowest effective level to prevent flares.

Immunoglobulin therapy is controversial and has usually been reserved for women with either overt disease or heparin-induced thrombocytopenia, or both (Alijotas-Reig, 2013). It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal-growth restriction (Cowchock, 1996, 1998; Heilmann, 2003; Silver, 1997). Intravenous immunoglobulin (IVIG) is administered in doses of 0.4 g/kg daily for 5 days—total dose of 2 g/kg. This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Treatment is expensive, and at \$75 per gram, one course for a 70-kg woman costs more than \$10,000. A Cochrane review of seven trials found no improvement in the livebirth rate for immunotherapy given to women with recurrent pregnancy loss (Porter, 2006). Xiao and associates (2013) studied prednisone and aspirin in 87 patients compared with prednisone, aspirin, low-molecular-weight heparin, and IVIG in 42 women with antiphospholipid antibody syndrome. They reported livebirth rates of 84 and 98 percent and obstetrical morbidity rates of 23 and 7 percent, respectively. We are of the view that randomized trials are needed before there is widespread application of this expensive and cumbersome therapy.

Immunosuppression has not been well evaluated, but azathioprine and cyclosporine do not appear to improve standard therapies (Silver, 1997). As mentioned with lupus on page 1172, methotrexate, cyclophosphamide, and mycophenolate mofetil are contraindicated because of teratogenic potential (Briggs, 2011; Buhimschi, 2009). Hydroxychloroquine therapy may be beneficial with APS (Albert, 2014).

Aspirin plus heparin is the most efficacious regimen (de Jesus, 2014). Low-dose unfractionated heparin—7500 to 10,000 units is used subcutaneously twice daily. Concurrently, low-dose aspirin—60 to 80 mg orally once daily—is given. Although typically given in addition to heparin in women with a prior thromboembolic event, the benefit of aspirin is unclear (American College of Obstetricians and Gynecologists, 2012b; Bouvier, 2014).

Treatment Efficacy. Fetal loss is common in women with antiphospholipid antibodies if untreated (Branch, 1992; Rai, 1995). Even with treatment, recurrent fetal loss rates remain at 20 to 30 percent (Branch, 2003; Empson, 2005; Ernest, 2011). Importantly, some women with lupus and antiphospholipid antibodies have normal pregnancy outcomes without treatment. Again, it is emphasized that women with lupus

anticoagulant and prior bad pregnancy outcomes have had live-borns without treatment (Trudinger, 1988).

In a manner similar to neonatal lupus syndrome (p. 1172), up to 30 percent of neonates demonstrate passively acquired antiphospholipid antibodies, and thus there is concern for their adverse effects. For example, Tincani and coworkers (2009) found increased learning disabilities in these children. Simchen and colleagues (2009) reported a fourfold increased risk for perinatal strokes. Of 141 infants followed in a European registry, the rate of preterm birth was 16 percent; low birthweight, 17 percent; and behavioral abnormalities in 4 percent of the children. There were no cases of neonatal thrombosis (Motta, 2010).

Rheumatoid Arthritis

This is a chronic multisystem disease of unknown cause with an immunologically mediated pathogenesis. Infiltrating T cells secrete cytokines that mediate inflammation and systemic symptoms. Its worldwide prevalence is 0.5 to 1 percent, women are affected three times more often than men, and peak onset is from 25 to 55 years (Shah, 2012). The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Criteria for classification are shown in Table 59-6, and a score of 6 or greater fulfills the requirements for definitive diagnosis.

There is a genetic predisposition, and heritability is estimated at 15 to 30 percent (McInnes, 2011). Genome-wide associated studies have identified more than 30 loci involved in rheumatoid arthritis pathogenesis (Kurkó, 2013). There is an association with the class II major histocompatibility complex molecule HLA-DR4 and HLA-DRB1 alleles (McInnes, 2011; Shah, 2012). In addition, there is a genetic component to joint destruction in rheumatoid arthritis, as alterations in the *IL2RA* gene are associated with less destructive disease (Knevel, 2013). Cigarette smoking appears to increase the risk of rheumatoid arthritis (Papadopoulos, 2005). As discussed subsequently, a protective effect of pregnancy has been reported for development of rheumatoid arthritis, and this may be related to HLA-disparate fetal microchimerism (Guthrie, 2010; Hazes, 1990).

Clinical Manifestations

Rheumatoid arthritis is a chronic polyarthritis with symptoms of synovitis, fatigue, anorexia, weakness, weight loss, depression, and vague musculoskeletal symptoms. The hands, wrists, knees, and feet are commonly involved. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extraarticular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. The American College of Rheumatology criteria for rheumatoid arthritis diagnosis have been revised and are shown in Table 59-6 (Aletaha, 2010). The revision focuses on features at earlier stages to permit earlier therapy initiation with a goal of preventing or decreasing long-term sequelae.

Management

Treatment is directed at pain relief, inflammation reduction, protection of articular structures, and preservation of function.

TABLE 59-6. Criteria for Classification of Rheumatoid Arthritis

Factor	Criteria	Score
Joint involvement	1 large—shoulder, elbow, hip, knee, ankle	0
	2–10 large	1
	1–3 small—MCP, PIP, thumb IP, MTP, wrists	2
	4–10 small	3
	> 10—at least 1 small	5
Serological testing	Negative RF and negative ACPA	0
	Low-positive RF or anti-CCP	2
	High-positive RF or anti-CCP	3
Acute-phase reactants	Normal CRP and ESR	0
	Abnormal CRP or ESR	1
Duration of symptoms	Less than 6 weeks	0
	6 weeks or longer	1

ACPA = anti-citrullinated protein antibody; CCP = cyclic citrullinated peptides; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; IP = interphalangeal joint; MCP = metacarpophalangeal joint; MTP = metatarsophalangeal joint; PIP = proximal interphalangeal joint; RF = rheumatoid factor.

Criteria established in collaboration with the American College of Rheumatology and the European League Against Rheumatism. A score ≥ 6 fulfills criteria for diagnosis. Modified from Aletaha, 2010.

Physical and occupational therapy and self-management instructions are essential. Although aspirin and other NSAIDs are the cornerstone of symptomatic therapy, they do not retard disease progression. Conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1)—an enzyme critical to normal platelet function, and COX-2—an enzyme that mediates inflammatory response mechanisms. Gastritis with acute bleeding is an unwanted side effect common to conventional NSAIDs. Specific COX-2 inhibitors have been used to avert this complication. However, there are now concerns that their long-term use is associated with increased risk for myocardial infarction, stroke, and heart failure (Solomon, 2005). A systematic review by Adams and colleagues (2012) identified two studies of women treated for inflammatory arthritis. They reported a higher rate of cardiac malformations in infants exposed to NSAIDs in the first trimester. In addition, NSAIDs are associated with early spontaneous abortions, ductus constriction, and neonatal pulmonary hypertension (Briggs, 2011). Thus, risks versus benefits of these medications must be considered.

Glucocorticoid therapy may be added to NSAIDs. Of these, prednisone, 7.5 mg orally daily for the first 2 years of active disease, substantively reduces progressive joint erosions (Kirwan, 1995). Although corticosteroids are usually avoided if possible, low-dose therapy is used by some along with salicylates.

Because NSAIDs and glucocorticoids are primarily for symptomatic relief, the American College of Rheumatology (2012) recommends disease-modifying antirheumatic drugs (DMARDs). These have the potential to reduce or prevent joint damage and are given within 3 months of diagnosis. There are several DMARDs, and many have considerable toxicity. For example, methotrexate and leflunomide are teratogenic (Briggs, 2011). Sulfasalazine and hydroxychloroquine are safe for use in pregnancy (Partlett, 2011; Raza, 2010). These, combined

with COX-2 inhibitors and with relatively low-dose prednisone—7.5 to 20 mg daily—for flares are often all the pharmacotherapy needed. Azathioprine treatment may be used if immunosuppressive drugs are warranted. From their review, Kuriya and associates (2011) found that a fourth of women with rheumatoid arthritis took a DMARD within 6 months of conception. During pregnancy, 4 percent of 393 pregnant women were given a category D or X medication. Methotrexate was the most common—2.9 percent. These authors advocate continued efforts to counsel women and their physicians regarding potential risks of many rheumatoid arthritis therapies during pregnancy.

Cytokine inhibitors, which include etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade), are also being used (McInnes, 2011). The newer immune-targeted drugs for rheumatoid arthritis have shown great promise. But, their use in pregnancy is limited, and fetal safety issues are a concern (Makol, 2011; Ojeda-Urbe, 2013). In the review by Kuriya and coworkers (2011) discussed earlier, 13 percent of 393 women were given a biological cytokine-inhibiting DMARD—primarily etanercept. Experience with these agents in pregnancy has been accruing (Verstappen, 2011). Berthelot and colleagues (2009) found more than 300 reported cases in their review and noted no fetal effects from exposure. Patients considered for etanercept treatment can be entered into a registry at 877-311-8972. There is also little known regarding pregnancy effects of the interleukin-1 receptor antagonist, anakinra (Kineret), and the antagonist to the B-cell CD20 antigen, rituximab (Rituxan).

Other drugs used less frequently include penicillamine, gold salts, minocycline, and cyclosporine. Orthopedic surgery for joint deformities, including replacement, is frequently performed outside of pregnancy.

Pregnancy and Rheumatoid Arthritis

Up to 90 percent of women with rheumatoid arthritis will experience improvement during pregnancy (de Man, 2008). Animal studies suggest this may be due to regulatory T-cell alterations. Transfer of regulatory T cells from pregnant mice conferred protection to those not pregnant (Munoz-Suano, 2012). That said, some women develop disease during pregnancy, and others become worse (Nelson, 1997).

A downside to this respite during pregnancy is that postpartum exacerbation is common (Østensen, 2007). This may be due to alterations in innate immunity postpartum (Häupl, 2008b). Barrett and coworkers (2000a) reported that a postpartum flare was more common if women were breast feeding. These same investigators performed a prospective United Kingdom study involving 140 women with rheumatoid arthritis (Barrett, 2000b). During 1 to 6 months postpartum, there was only a modest fall in objective disease activity, and only 16 percent had complete remission. At least 25 percent had substantive levels of disability. They observed that although overall disease actually did not exacerbate postpartum, the mean number of inflamed joints increased significantly.

There are some studies that report a protective effect of pregnancy for women developing subsequent new-onset rheumatoid arthritis. Silman and associates (1992) performed a case-control study of 88 affected women. They found that although there was a protective effect of pregnancy in the long term, the likelihood of new-onset rheumatoid arthritis was increased sixfold during the first 3 postpartum months. Pikwer and colleagues (2009) reported a significant reduction in the risk of subsequent arthritis in women who breast fed longer than 12 months.

As an explanation for these findings, and as discussed previously, sex hormones supposedly interfere with a number of putative processes involved in arthritis pathogenesis, including immunoregulation and interactions with the cytokine system (Häupl, 2008a,b). First, Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of *pregnancy-associated α_2 -glycoprotein*. This compound has immunosuppressive properties. Second, Nelson and coworkers (1993) reported that amelioration of disease was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of arthritis. In addition to monocyte activations, there also may be T-lymphocyte activation (Förger, 2008).

Juvenile Rheumatoid Arthritis

This is a group of diseases that are the most frequent cause of chronic arthritis in children. They persist into adulthood. Østensen (1991) reviewed outcomes of 76 pregnancies in 51 affected Norwegian women. Pregnancy had no effects on presentation of disease, but disease activity usually became quiescent or remained so during pregnancy. Postpartum flares were common as was discussed for rheumatoid arthritis. Joint deformities often developed in these women, and 15 of 20 cesarean deliveries were done for contracted pelvis or joint prostheses. These observations are supported by the summary of similar results in 39 Polish women with juvenile rheumatoid arthritis (Musiej-Nowakowska, 1999).

Perinatal Outcome. There are no obvious adverse effects of rheumatoid arthritis on pregnancy outcome, but an increased risk for preterm birth is debated (Klipple, 1989; Langen, 2014; Wallenius, 2011). In a population-based cohort study, Skomsvoll and associates (2002) reported that women with rheumatic disease with two previous poor pregnancy outcomes were at high risk for recurrent adverse outcomes. Kaplan (1986) reported that women who later develop the disease had a prior higher-than-expected incidence of spontaneous abortion. However, Nelson and colleagues (1992) did not corroborate this.

Management During Pregnancy. Treatment of symptomatic women during pregnancy is with aspirin and NSAIDs. These are used with appropriate concerns for first-trimester effects, impaired hemostasis, prolonged gestation, premature ductus arteriosus closure, and persistent pulmonary circulation (Chap. 12, p. 247) (Briggs, 2011). Low-dose corticosteroids are also prescribed as indicated. Gold compounds have been administered in pregnancy. Of 14 women experiencing 20 pregnancies on gold therapy, 75 percent delivered healthy live-born neonates (Almarzouqi, 2007).

Immunosuppressive therapy with azathioprine, cyclophosphamide, or methotrexate is not routinely used during pregnancy. Of these, only azathioprine should be considered during early pregnancy because the other agents are teratogenic (Briggs, 2011; Buhimschi, 2009). As noted earlier, DMARDs including sulfasalazine and hydroxychloroquine are acceptable for use in pregnancy.

If the cervical spine is involved, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity (Chap. 4, p. 71). Importantly, there are anesthesia concerns regarding endotracheal intubation.

Following pregnancy, contraceptive counseling may include combination oral contraceptives. These are a logical choice because of their effectiveness and their potential to improve disease (Bijlsma, 1992; Farr, 2010). That said, all methods of contraception are appropriate.

Systemic Sclerosis—Scleroderma

This is a chronic multisystem disorder of unknown etiology. It is characterized by microvascular damage, immune system activation leading to inflammation, and excessive deposition of collagen in the skin and often in the lungs, heart, gastrointestinal tract, and kidneys. It is uncommon, displays a 3-to-1 female dominance, and typically affects those aged 30 to 50 years.

This strong prevalence of scleroderma in women and its increased incidence in the years following childbirth contribute to the hypothesis that *microchimerism* is involved as discussed on page 1168 (Lambert, 2010). Artlett and coworkers (1998) demonstrated Y-chromosomal DNA in almost half of women with systemic sclerosis compared with only 4 percent of controls. Rak and colleagues (2009b) identified male microchimerism in peripheral blood mononuclear cells more frequently in women with limited versus diffuse scleroderma—20 versus 5 percent.

Clinical Course

The hallmark is overproduction of normal collagen. In the more benign form—*limited cutaneous systemic sclerosis*—progression is slow. With *diffuse cutaneous systemic sclerosis*, skin thickening progresses rapidly, and skin fibrosis is followed by gastrointestinal tract fibrosis, especially the distal esophagus (Varga, 2012). Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension. Antinuclear antibodies are found in 95 percent of patients, and immunoincompetence often develops.

Frequent symptoms are Raynaud phenomenon, which includes cold-induced episodic digital ischemia in 95 percent, as well as swelling of the distal extremities and face. Half of patients have symptoms from esophageal involvement, especially fullness and epigastric burning pain. Pulmonary involvement is common and causes dyspnea. The 10-year cumulative survival rate is 70 percent in those with pulmonary fibrosis, and pulmonary arterial hypertension is the main causes of death (Joven, 2010; Ranque, 2010). Women with limited cutaneous disease such as the *CREST syndrome*—*calcinosis*, *Raynaud phenomenon*, *esophageal involvement*, *sclerodactyly*, and *telangiectasia*—have milder disease.

Overlap syndrome refers to the presence of systemic sclerosis with features of other connective-tissue disorders. *Mixed-connective-tissue disease* is a term used for the syndrome involving features of lupus, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-RNP antibodies (see Table 59-1). The disorder is also termed *undifferentiated connective-tissue disease* (Spinillo, 2008).

Although systemic sclerosis cannot be cured, treatment directed at end-organ involvement can relieve symptoms and improve function (Varga, 2012). Hydroxychloroquine and low-dose corticosteroids are helpful, and intravenous immunoglobulin may be indicated for pericarditis and hemolytic anemia. Renal involvement and hypertension are common. At times, angiotensin-converting enzyme (ACE) inhibitors may be required for blood pressure control despite their known teratogenicity (Buhimschi, 2009). *Scleroderma renal crisis* develops in up to a fourth of these patients and is characterized by obliterative vasculopathy of the renal cortical arteries. This results in renal failure and malignant hypertension. Interstitial restrictive lung disease is common and frequently becomes life threatening. Associated pulmonary hypertension is usually fatal. Cyclophosphamide provides some improvement (Tashkin, 2006).

Pregnancy and Systemic Sclerosis

The prevalence of scleroderma in pregnancy is estimated from a study of nearly 11.2 million pregnant women registered in the Nationwide Inpatient Sample. In this study, Chakravarty and associates (2008) reported that 504 women suffered from systemic sclerosis—a prevalence of approximately 1 in 22,000 pregnancies. These women usually have stable disease during gestation if their baseline function is good. As perhaps expected, dysphagia and reflux esophagitis are aggravated by pregnancy (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A decrease in amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen using manometry. Symptomatic treatment

for reflux is described in Chapter 54 (p. 1072). Women with renal insufficiency and malignant hypertension have an increased incidence of superimposed preeclampsia. In the presence of rapidly worsening renal or cardiac disease, pregnancy termination should be considered. As discussed, renal crisis is life threatening and is treated with ACE inhibitors, but it does not improve with delivery (Gayed, 2007). Pulmonary hypertension usually contraindicates pregnancy (Chap. 49, p. 987).

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring cesarean delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Black, 1989). Because of esophageal dysfunction, aspiration is also more likely, and epidural analgesia is preferable.

Pregnancy Outcomes

Maternal and fetal outcomes are related to the severity of underlying disease. Steen and colleagues (1989, 1999) described pregnancies in 214 women with systemic sclerosis—45 percent had diffuse disease. Major complications included renal crisis in three women and increased rates of preterm birth. Chung and coworkers (2006) also reported increased rates of preterm delivery, fetal-growth restriction, and perinatal mortality. A multicenter study of 109 pregnancies from 25 centers reported higher rates of preterm delivery, fetal-growth restriction, and very-low-birthweight infants (Taraboreli, 2012). These are likely related to placental abnormalities that include decidual vasculopathy, acute atherosclerosis, and infarcts. These reduce placental blood flow and are found in many cases (Doss, 1998; Papakonstantinou, 2007).

Contraception

Scleroderma may be associated with subfertility (Bernatsky, 2008; Lambe, 2004). For women who do not choose pregnancy, several reversible contraceptive methods are acceptable. However, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement. Due to the often unrelenting progression of systemic sclerosis, permanent sterilization should also be considered.

Vasculitis Syndromes

Inflammation and damage to blood vessels may be primary or due to another disease. Most cases are presumed to be caused by immune-complex deposition (Langford, 2012). Primary causes include polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, temporal or giant cell arteritis, Takayasu arteritis, Henoch-Schönlein purpura, Behçet syndrome, and cutaneous or hypersensitivity arteritis (Goodman, 2014). Some of these syndromes have antibodies directed against proteins in the cytoplasmic granules of leukocytes—*antineutrophil cytoplasmic antibodies*—*ANCA*. Their role in vasculitis is unclear, and disease activity is not related to increasing titers.

Polyarteritis Nodosa

This necrotizing vasculitis of small and medium-sized arteries is characterized clinically by myalgia, neuropathy, gastrointestinal

disorders, hypertension, and renal disease (Goodman, 2014). Approximately a third of cases are associated with hepatitis B antigenemia (Langford, 2012).

Symptoms are nonspecific and vague. Fever, weight loss, and malaise are present in more than half of cases. Renal failure, hypertension, and arthralgias are common. Diagnosis is made by biopsy, and treatment consists of high-dose prednisone plus cyclophosphamide. Vasculitis due to hepatitis B antigenemia responds to antivirals, glucocorticoids, and plasma exchange (Chap. 55, p. 1090).

There have been only a few reports of documented cases of polyarteritis nodosa associated with pregnancy. Even without definitive data, active arteritis in pregnancy is associated with high mortality rates. Owen and Hauth (1989) reviewed the courses of 12 such pregnant women. In seven, polyarteritis first manifested during pregnancy, and it was rapidly fatal by 6 weeks postpartum. The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, which resulted in one stillborn and three successful outcomes.

Wegener Granulomatosis

This is a necrotizing granulomatous vasculitis of the upper and lower respiratory tract and kidney. Disease frequently includes sinusitis and nasal disease—90 percent; pulmonary infiltrates, cavities, or nodules—85 percent; glomerulonephritis—75 percent; and musculoskeletal lesions—65 percent (Sneller, 1995). At least 90 percent have polyangiitis (Langford, 2012). It is uncommon and usually encountered after 50 years of age. Koukoura and associates (2008) reviewed 36 cases reported in association with pregnancy. In another report, a woman with Wegener disease developed thrombotic microangiopathy associated renal impairment at 32 weeks. A second woman had pneumonitis, but pregnancy did not appear to affect disease activity (Pagnoux, 2011). Because subglottic stenosis is found in up to a fourth, the anesthesia team should be consulted during pregnancy (Engel, 2011; Kayatas, 2012).

Corticosteroids are standard treatment, but azathioprine, cyclosporine, and intravenous immunoglobulin may also be used. For severe disease in the late second or third trimester, cyclophosphamide in combination with prednisolone seems acceptable.

Takayasu Arteritis

Also called *pulseless disease*, this syndrome is most prevalent in young women. It is a chronic inflammatory arteritis affecting large vessels (Goodman, 2014). Unlike *temporal arteritis*, which develops almost exclusively after age 55, the onset of Takayasu arteritis is almost always before age 40. It is associated with abnormal angiography of the upper aorta and its main branches and with upper extremity vascular impairment. Death usually results from congestive heart failure or cerebrovascular events. Computed tomography or magnetic resonance angiography can detect this disorder before the development of severe vascular compromise (Numano, 1999). Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Selection of surgical bypass or angioplasty has improved survival rates.

Severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis. Hypertension is relatively common and should be carefully controlled. Blood pressure is measured in the lower extremity. Overall, the prognosis for pregnancy is good (de Jesús, 2012; Hernández-Pacheco, 2011; Hidaka, 2012; Johnston, 2002; Kraemer, 2008; Mandal, 2012). When the abdominal aorta is involved, however, pregnancy outcome may be disastrous (Sharma, 2000). Vaginal delivery is preferred, and epidural analgesia has been advocated for labor and delivery (Langford, 2002).

Other Vasculitides

Vasculitis caused by *Henoch-Schönlein purpura* is uncommon after childhood. Tayabali and associates (2012) reviewed 20 pregnancies complicated by this vasculitis and described cutaneous lesions in three fourths. Approximately half had arthralgias. Jadaon and colleagues (2005) described 135 pregnancies in 31 women with *Behçet disease* compared with matched non-affected controls. Although there were no deleterious effects of pregnancy on the underlying disease, the miscarriage rate was significantly increased threefold. Hwang and coworkers (2009) described necrotizing villitis and decidual vasculitis in a placenta from a first-trimester pregnancy termination and another from a term delivery. *Churg-Strauss vasculitis* is rare in pregnancy. Hot and associates (2007) described a pregnant woman who responded to intravenous immune globulin therapy. Corradi and associates (2009) described an affected 35-year-old woman at term whose necrotizing vasculitis involved the heart, and she subsequently underwent cardiac transplantation.

INFLAMMATORY MYOPATHIES

This is the largest group of acquired and potentially treatable causes of skeletal muscle weakness. That said, these disorders have a prevalence of 1 in 100,000 persons (Dalakas, 2012). There are three major groups: polymyositis, dermatomyositis, and inclusion-body myositis, which all present with progressive asymmetrical muscle weakness. They have a variable association with connective-tissue diseases, malignancy, drugs, systemic autoimmune disease such as Crohn disease, and viral, bacterial, and parasitic infections.

Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective-tissue disorders. *Dermatomyositis* manifests as a characteristic rash accompanying or preceding weakness. Laboratory findings include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy, which shows perivascular and perimysial inflammatory infiltrates, vasculitis, and muscle fiber degeneration. It usually develops alone but can overlap with scleroderma or mixed connective-tissue disease.

Prevailing theories suggest that the syndromes are caused by viral infections, autoimmune disorders, or both. *Importantly, approximately 15 percent of adults who develop dermatomyositis have an associated malignant tumor.* The timing of myositis and tumor appearance may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. The disease usually responds to high-dose

corticosteroid therapy, immunosuppressive drugs such as azathioprine or methotrexate, or IVIG (Dalakas, 2012; Williams, 2007). Linardaki and colleagues (2011) report successful treatment with IVIG and corticosteroids in pregnancy.

Experiences in pregnancy are garnered mostly from case series and reviews. Gutierrez and coworkers (1984) reviewed outcomes in 10 pregnancies among seven women with active disease. They reported three abortions, three perinatal deaths, and five preterm deliveries. Rosenzweig and colleagues (1989) reviewed 24 pregnancy outcomes in 18 women with primary polymyositis-dermatomyositis. In 12, the diagnosis preceded pregnancy. Of these, a fourth had an exacerbation in the second or third trimester. Excluding abortions, there were two perinatal deaths and two growth-restricted neonates. In the other 12 in whom disease became manifest first during pregnancy, outcomes were even less favorable. Excluding abortions, half of the eight pregnancies resulted in perinatal death, and one woman died postpartum. Ohno (1992) and Papapetropoulos (1998) and their coworkers described similar cases. From their review, Doria and associates (2004) concluded that pregnancy outcome was related to disease activity and that new-onset disease was particularly aggressive.

HEREDITARY CONNECTIVE-TISSUE DISORDERS

Numerous inherited mutations involve genes that encode for structural proteins of bone, skin, cartilage, blood vessels, and basement membranes. Although connective tissues contain many complex macromolecules such as elastin and more than 30 proteoglycans, the most common constituents are fibrillar collagen types I, II, and III. Various mutations, some recessively and some dominantly inherited, result in clinical syndromes that include Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, chondrodysplasias, and epidermolysis bullosa. Of concern during pregnancy is the predilection for these disorders to result in aortic aneurysms (Schoenhoff, 2013).

■ Marfan Syndrome

This is a common autosomal dominant connective-tissue disorder that has a prevalence of 1 in 3000 to 5000 (Prockop, 2012). Marfan syndrome affects both sexes equally. It is caused by a mutation of the fibrillin-1 (*FBNI*) gene on the long arm of chromosome 15 (Loeys, 2002). The *FBNI* gene has a high mutation rate, and there are many mild, subclinical cases. In severe disease, there is degeneration of the elastic lamina in the media of the aorta. This weakness predisposes to aortic dilatation or dissecting aneurysm, which appears more commonly during pregnancy (Bloom, 2010; Curry, 2014; Savi, 2007). Marfan syndrome complicating pregnancy is discussed in detail in Chapter 49 (p. 993).

■ Ehlers-Danlos Syndrome

This disease is characterized by various connective tissue changes, including skin hyperelasticity. In the more severe types, there is a strong tendency for rupture of any of several arteries to cause either stroke or bleeding. Rupture of the colon

or uterus has been described. There are several types of disease based on skin, joint, or other tissue involvement. Some are autosomal dominant, some recessive, and some X-linked (Solomons, 2013). Their aggregate prevalence is approximately 1 in 5000 births (Prockop, 2012). Types I, II, and III are autosomally dominant, and each accounts for about 30 percent of cases. Type IV is uncommon but is known to predispose to preterm delivery, maternal great-vessel rupture, postpartum bleeding, and uterine rupture (Pepin, 2000). In most, the underlying molecular defect is one of collagen or procollagen.

In general, women with Ehlers-Danlos syndrome have an increased frequency of preterm rupture of membranes, preterm delivery, and antepartum and postpartum hemorrhage (Volkov, 2006). Several cases of spontaneous uterine rupture have been described (Bloom, 2010; Rudd, 1983; Walsh, 2007). Tissue fragility makes episiotomy repair and cesarean delivery difficult. Sorokin and colleagues (1994) surveyed female members of the Ehlers-Danlos National Foundation. They reported a stillbirth rate of 3 percent, a preterm delivery rate of 23 percent, and a cesarean delivery rate of 8 percent. Fifteen percent had problematic postpartum bleeding. A maternal and fetal death from spontaneous rupture of the right iliac artery was described by Esaka and coworkers (2009). Finally, Bar-Yosef and associates (2008) described a newborn with multiple congenital skull fractures and intracranial hemorrhage caused by Ehlers-Danlos type VIIC.

■ Osteogenesis Imperfecta

This disorder is characterized by very low bone mass resulting in brittle bones. Affected patients often have blue sclerae, hearing loss, a history of multiple fractures, and dental abnormalities. There are seven subtypes that range from severe to mild clinical disease. Subtypes show differing genetic inheritance and include autosomal dominant, autosomal recessive, and sporadic patterns. Type I is the mildest form, whereas type II is typically lethal in utero (Prockop, 2012). There are well-characterized gene mutations coding for type I procollagen. These are associated with the specific subtypes. For example, the typical mutation with type I is a premature stop codon in the *COL1A1* gene (Sykes, 1990). Osteogenesis imperfecta has a prevalence of 1 in 30,000 births for type I and 1 in 60,000 for type II.

Women with osteogenesis imperfecta, most commonly type I, may have successful pregnancies (Lyra, 2010). That said, there are several risks in pregnancy, including fractures, complications related to scoliosis with restrictive lung disease, micrognathia, brittle teeth, an unstable cervical spine, uterine rupture, and cephalopelvic disproportion. These women may also have hyperthyroidism and valvular heart disease. It is not unusual for affected women to enter pregnancy having had 20 to 30 prior fractures. Most women with this skeletal disorder require minimal treatment other than management of the fractures and consideration of bisphosphonates to decrease bone loss. The anesthesia team should be consulted during pregnancy regarding plans for delivery (Murray, 2010).

Depending on the type of osteogenesis imperfecta, the fetus may be affected and may also suffer fractures in utero or during delivery (Chap. 10, p. 217). Prenatal diagnosis is available in many situations, if desired.

CHAPTER 60

Neurological Disorders

CENTRAL NERVOUS SYSTEM IMAGING	1187
HEADACHE	1187
SEIZURE DISORDERS	1189
CEREBROVASCULAR DISEASES	1191
DEMYELINATING OR DEGENERATIVE DISEASES	1194
NEUROPATHIES	1197
SPINAL-CORD INJURY	1198
IDIOPATHIC INTRACRANIAL HYPERTENSION	1199
MATERNAL VENTRICULAR SHUNTS	1199
MATERNAL BRAIN DEATH	1199

A number of neurological diseases are relatively common in women of childbearing age. In the past, some of these may have precluded pregnancy, however, few do so now. Most of those encountered during pregnancy are the same as for nonpregnant women. That said, there are a few neurological disorders that may be seen more frequently in pregnant women. Some examples are Bell palsy, specific types of strokes, and benign intracranial hypertension or pseudotumor cerebri. Neurovascular disorders are an important cause of maternal mortality and accounted for 10 percent of maternal deaths in the United States from 1998 through 2005 (Berg, 2010b).

Because many neurological disorders are chronic, they frequently precede pregnancy. Although most women with chronic neurological disease who become pregnant will have successful outcomes, some of these disorders have specific risks with which clinicians should be familiar. Conversely, some women will have new-onset neurological symptoms during

pregnancy, and these frequently must be distinguished from other pregnancy complications. Psychiatric disorders may also manifest with cognitive and neuromuscular abnormalities, and they should be considered in the evaluation.

CENTRAL NERVOUS SYSTEM IMAGING

Computed tomography (CT) and magnetic resonance (MR) imaging have opened new vistas for the diagnosis, classification, and management of many neurological and psychiatric disorders. As discussed in Chapter 46 (p. 933), these cranial imaging methods can be used safely during pregnancy. CT scanning is commonly used whenever rapid diagnosis is necessary and is excellent for detecting recent hemorrhage (Smith, 2012). Because it does not use radiation, MR imaging is often preferred. It is particularly helpful to diagnose demyelinating diseases, screen for arteriovenous malformations, evaluate congenital and developmental nervous system abnormalities, identify posterior fossa lesions, and diagnose spinal cord diseases (Gjelsteen, 2008). Whenever either test is done, the woman should be positioned in a left lateral tilt with a wedge under one hip to prevent hypotension as well as to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. Fluoroscopy delivers more radiation but can be performed with abdominal shielding. Positron emission tomography (PET) and functional MRI (fMRI) have not been evaluated for use in pregnant patients (Chiapparini, 2010).

HEADACHE

The National Health Interview Survey is provided by the Centers for Disease Control and Prevention (Pleis, 2010). In the 2009 survey, a fifth of all women aged 18 to 44 years reported a severe headache or migraine within the past 3 months, and headache

TABLE 60-1. Classification of Headache^a

Primary
Tension-type (69%)
Migraine (16%)
Cluster and other trigeminal autonomic cephalgias (< 1%)
Other
Secondary
Systemic infection (63%)
Head or neck trauma (4%)
Cranial or cervical vascular disorders
Intracranial nonvascular
Substance use or withdrawal
Disorders of homeostasis
Head and neck disorders
Psychiatric disorders

^aPercentages in parentheses are estimated frequencies. Data from Goadsby, 2012. Adapted from the International Headache Society, 2004.

was the most common neurological complaint during pregnancy. Smitherman and coworkers (2013) found that 26 percent of nonpregnant women in this age group were similarly affected. Interestingly, Aegidius and colleagues (2009) reported an overall decrease in prevalence of all headache types during pregnancy in nulliparas, especially during the third trimester. The classification of headaches by the International Headache Society (2004) is shown in Table 60-1. Primary headaches are more common in pregnant women than those with secondary causes (Digre, 2013). Migraine headaches are those most likely to be affected by the hormonal changes of pregnancy (Torelli, 2010).

Tension-Type Headache

These are most common, and characteristic features include muscle tightness and mild to moderate pain that can persist for hours in the back of the neck and head. There are no associated neurological disturbances or nausea. The pain usually responds to rest, massage, application of heat or ice, antiinflammatory medications, or mild tranquilizers.

Migraine Headache

These headaches have a 1-year prevalence in all women of approximately 15 percent, and thus they are frequently encountered during pregnancy. The term *migraine* describes a periodic, sometimes incapacitating neurological disorder characterized by episodic attacks of severe headache and autonomic nervous system dysfunction (Goadsby, 2012). The International Headache Society (2004) classifies three migraine types based on the presence or absence of an aura as well as chronicity:

- 1. *Migraine without aura*—was formerly termed common migraine—and is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia.
- 2. *Migraine with aura*—formerly termed classic migraine—has similar symptoms preceded by premonitory neurological

- phenomena such as visual scotoma or hallucinations. A third of patients have this type of migraine, which sometimes can be averted if medication is taken at the first premonitory sign.
- 3. *Chronic migraine* is defined by a migraine headache occurring at least 15 days each month for more than 3 months.

Migraines may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. According to Lipton and associates (2007), their annual prevalence is 17 percent in women and 6 percent in men. Another 5 percent of women have *probable migraine*, that is, they have all criteria but one (Silberstein, 2007). Migraines are especially common in young women and have been linked to hormone levels (Torelli, 2010).

The exact pathophysiology of migraines is uncertain, but they occur when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of trigeminal sensory neurons (Brandes, 2007; D’Andrea, 2010). A predilection for the posterior circulation has been described by Kruit and coworkers (2004). Migraines—especially those with aura in young women—are associated with increased risk for ischemic strokes as discussed on page 1191. The risk is greater in those who smoke or use combination oral contraceptives.

Migraine in Pregnancy

The prevalence of migraine headaches in the first trimester is 2 percent (Chen, 1994). Prospective as well as observational studies have shown that most migraineurs have improvement during pregnancy (Adeney, 2006; Menon, 2008; Torelli, 2010). Still, migraines—usually those with an aura—occasionally appear for the first time during pregnancy. Pregnant women with preexisting migraine symptoms may have other symptoms suggestive of a more serious disorder, and new neurological symptoms should prompt a complete evaluation (Detsky, 2006; Heaney, 2010).

Although conventional thinking has been that migraine headaches do not pose increased maternal or fetal risks, several recent studies have refuted this (Allais, 2010). For example, women with severe migraines in the first 8 weeks may be at slightly increased risk for a fetus with limb-reduction defects (Banhidy, 2006). Preeclampsia and other cardiovascular morbidities are also increased (Facchinetti, 2009; Sanchez, 2008; Schürks, 2009). In a case-control study of nearly 18.5 million pregnancy-related discharges from 2000 through 2003, Bushnell and coworkers (2009) identified an incidence of migraine discharge codes of 185 per 100,000. Associated diagnoses and increased significant risks were found for migraines and stroke—15.8-fold; myocardial infarction—4.9; heart disease—2.1; venous thromboembolism—2.4; and preeclampsia/gestational hypertension—2.3-fold.

Management

Data are limited regarding nonpharmacological management in pregnancy such as biofeedback techniques, acupuncture, and transcranial magnetic stimulation (Airola, 2010; Dodick, 2010). Effective pharmacological interventions include nonsteroidal anti-inflammatory drugs, and most migraine headaches respond to

simple analgesics such as ibuprofen or acetaminophen, especially if given early. Because of patient idiosyncrasies, multitarget drug therapy is necessary in most cases for migraine relief (Gonzalez-Hernandez, 2014). Severe headaches should be treated aggressively with intravenous hydration and parenteral antiemetics and opioids. Although intravenous magnesium sulfate has gained favor in the past few years, a recent metaanalysis reported no beneficial effects (Choi, 2014). Ergotamine derivatives are potent vasoconstrictors that should be avoided in pregnancy (Briggs, 2011).

Triptans are serotonin 5-HT_{1B/2D}-receptor agonists that effectively relieve headaches by causing intracranial vasoconstriction (Contag, 2010). They also relieve nausea and vomiting and greatly reduce the need for analgesics. They can be given orally, by injection, as a rectal suppository, or as a nasal spray. The greatest experience is with sumatriptan (Imitrex), and although not studied extensively in pregnancy, it appears to be safe (Briggs, 2011; Nezvalová-Henriksen, 2010).

For women with frequent migraine headaches, oral prophylactic therapy is warranted. Amitriptyline (Elavil), 10 to 150 mg daily; propranolol (Inderal), 20 to 80 mg three times daily; or metoprolol (Lopressor, Toprol), 50 to 100 mg twice daily, is safe in pregnancy and has been used with success (Contag, 2010; Lucas, 2009; Marcus, 2007).

Cluster Headaches

This rare primary headache disorder is characterized by severe unilateral lancinating pain radiating to the face and orbit, lasting 15 to 180 minutes, and occurring with autonomic symptoms and agitation. Pregnancy does not affect symptom severity. Affected women should avoid tobacco and alcohol. Acute management includes 100-percent oxygen therapy and sumatriptan given as a 6-mg dose subcutaneously (Calhoun, 2010; Francis, 2010). If recurrent, prophylaxis is administered using a calcium-channel blocking agent.

SEIZURE DISORDERS

The Centers for Disease Control and Prevention reported that the prevalence of epilepsy in adults in 2005 was 1.65 percent (Kobau, 2008). There are 1.1 million American women of childbearing age who are affected. After headaches, seizures are the next most prevalent neurological condition encountered in pregnant women, and they complicate 1 in 200 pregnancies (Brodie, 1996; Yerby, 1994). Importantly, epilepsy accounted for 13 percent of maternal deaths in the United Kingdom for the 2005 to 2007 triennium (Lewis, 2007). Seizure disorders are also associated with altered fetal development, and they can adversely affect other pregnancy outcomes. The teratogenic effects of several anticonvulsant medications are unquestioned. The American Academy of Neurology and the American Epilepsy Society have developed guidelines regarding treatment in pregnant women, which are discussed subsequently (Harden, 2009a–c).

Pathophysiology

A seizure is defined as a paroxysmal disorder of the central nervous system characterized by an abnormal neuronal discharge

with or without loss of consciousness. Epilepsy encompasses different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures. The International League Against Epilepsy Commission on Classification and Terminology recently updated its terminologies for seizures (Berg, 2010a, 2011; Shorvon, 2011). This new classification schema is under development, and for now, most adults can be said to have either focal or generalized seizures.

Focal Seizures

These originate in one localized brain area and affect a correspondingly localized area of neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. *Focal seizures without dyscognitive features* start in one region of the body and progress toward other ipsilateral areas of the body, producing tonic and then clonic movements. Simple seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Cognitive function is not impaired, and recovery is rapid. *Focal seizures with dyscognitive features* are often preceded by an aura and followed by impaired awareness manifested by sudden behavioral arrest or motionless stare. Involuntary movements such as picking motions or lip smacking are common.

Generalized Seizures

These involve both brain hemispheres and may be preceded by an aura before an abrupt loss of consciousness. There is a strong hereditary component. In *generalized tonic-clonic seizures*, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. *Absence seizures*—also called *petit mal seizures*—are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

Causes of Seizure

Some identifiable causes of convulsive disorders in young adults include head trauma, alcohol- and other drug-induced withdrawals, cerebral infections, brain tumors, biochemical abnormalities, and arteriovenous malformations. A search for these is prudent with a new-onset seizure disorder in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion.

Preconceptional Counseling

Women with epilepsy should undergo education and counseling before pregnancy (Chap. 8, p. 158). Folic acid supplementation with 0.4 mg per day is begun at least 1 month before conception. The dose is increased to 4 mg when the woman taking antiepileptic medication becomes pregnant. These medications are assessed and adjusted with a goal of monotherapy using the least teratogenic medication. If this is not feasible,

then attempts are made to reduce the number of medications used and to use them at the lowest effective dose (Dunlop, 2008). Medication withdrawal should be considered if a woman is seizure free for 2 years or more.

Epilepsy During Pregnancy

The major pregnancy-related risks to women with epilepsy are increased seizure rates with attendant mortality risks and fetal malformations. Seizure control is the main priority. Earlier studies described worsening seizure activity during pregnancy, however, this is not as common nowadays because of more effective drugs. Contemporary studies cite increased seizure activity in only 20 to 30 percent of pregnant women (Mawer, 2010; Vajda, 2008; Viinikainen, 2006). Women who are seizure free for at least 9 months before conception will likely remain so during pregnancy (Harden, 2009b).

Increased seizure frequency is often associated with decreased and thus subtherapeutic anticonvulsant serum levels, a lower seizure threshold, or both. An impressive number of pregnancy-associated alterations can result in subtherapeutic serum levels. These include nausea and vomiting, decreased gastrointestinal motility, antacid use that diminishes drug absorption, pregnancy hypervolemia offset by protein binding, induction of hepatic enzymes such as cytochrome oxidases, placental enzymes that metabolize drugs, and increased glomerular filtration that hastens drug clearance. Importantly, some women discontinue medication because of teratogenicity concerns. Finally, the seizure threshold can be affected by pregnancy-related sleep deprivation as well as hyperventilation and pain during labor.

Pregnancy Complications

Women with epilepsy have a small increased risk of some pregnancy complications (Borthen, 2011; Harden, 2009b). A population-based study from Iceland found that epileptic women had a twofold increased cesarean delivery rate (Olafsson, 1998). In a cohort study from Montreal, Richmond and coworkers (2004) reported an increased incidence of non-proteinuric hypertension and labor induction. From a Swedish study of 1207 epileptic women, Pilo and colleagues (2006) reported a 1.5-fold increased incidence of cesarean delivery, preeclampsia, and postpartum hemorrhage. Postpartum depression rates have also been reported to be increased in epileptic women (Turner, 2009). Finally, children of epileptic mothers have a 10-percent risk of developing a seizure disorder.

Embryo-Fetal Malformations

For years, it was difficult to separate effects of epilepsy versus its therapy as the primary cause of fetal malformations. As discussed in Chapter 8 (p. 158), it is now believed that untreated epilepsy is not associated with an increased fetal malformation rate (Thomas, 2008; Viinikainen, 2006). That said, the fetus of an epileptic mother who takes certain anticonvulsant medications has an indisputably increased risk for congenital malformations. Moreover, monotherapy is associated with a lower birth defect rate compared with multiagent therapy. Thus, if necessary, increasing monotherapy dosage is at least initially preferable to adding another agent (Buhimschi, 2009).

Specific drugs, when given alone, increase the malformation rate (Chap. 12, p. 246). Some of these are listed in [Table 60-2](#). Phenytoin and phenobarbital increase the major malformation

TABLE 60-2. Teratogenic Effects of Common Anticonvulsant Medications

Drug (Brand Name)	Abnormalities Described	Affected	Embryo-Fetal Risk ^a
Valproate (Depakote)	Neural-tube defects, clefts, cardiac anomalies; associated developmental delay	10% with monotherapy; higher with polytherapy	Yes
Phenytoin (Dilantin)	Fetal hydantoin syndrome—craniofacial anomalies, fingernail hypoplasia, growth deficiency, developmental delay, cardiac anomalies, clefts	5–11%	Yes
Carbamazepine; oxcarbazepine (Tegretol; Trileptal)	Fetal hydantoin syndrome, as above; spina bifida	1–2%	Yes
Phenobarbital	Clefts, cardiac anomalies, urinary tract malformations	10–20%	Suggested
Lamotrigine (Lamictal)	Increased risk for clefts (Registry data)	Up to 1% (4- to 10-fold higher than expected)	Suggested
Topiramate (Topamax)	Clefts	2–3% (15- to 20-fold higher than expected)	Suggested
Levetiracetam (Keppra)	Theoretical—skeletal abnormalities; impaired growth in animals	Preliminary observations	Suggested

^aRisk categories from Briggs, 2011; Holmes, 2008; Hunt, 2008; Meador, 2009; Morrow, 2006; U.S. Food and Drug Administration (2011).

rate two- to threefold above baseline (Perucca, 2005; Thomas, 2008). A particularly potent teratogen is valproate, which has a dose-dependent effect and increases the malformation risk four- to eightfold (Eadie, 2008; Klein, 2014; Wyszynski, 2005). In general, with polytherapy, the risk increases with each drug added. At least at this time, the newer antiepileptic medications are reported to have no associations with a markedly increased risk of major birth defects (Molgaard-Nielson, 2011).

Management in Pregnancy

The major goal is seizure prevention. To accomplish this, treatment for nausea and vomiting is provided, seizure-provoking stimuli are avoided, and medication compliance is emphasized. The fewest necessary anticonvulsants are given at the lowest dosage effective for seizure control. Although some providers routinely monitor serum drug levels during pregnancy, these concentrations may be unreliable because of altered protein binding. Free or unbound drug levels, although perhaps more accurate, are not widely available. Importantly, there is no evidence that such monitoring improves seizure control (Adab, 2006). For these reasons, drug levels may be informative if measured following seizures or if noncompliance is suspected. Some of the newer agents such as lamotrigine and oxcarbazepine may be more amenable to serum drug level monitoring (Harden, 2009a; Pennell, 2008).

For women taking anticonvulsant drugs, a targeted sonographic examination at midpregnancy is recommended by some to search for anomalies (Chap. 10, p. 197). Testing to assess fetal well-being is generally not indicated for women with uncomplicated epilepsy.

Breast Feeding and Contraception

There are limited available data regarding the safety of breast feeding with the various anticonvulsant medications. That said, no obvious deleterious effects, such as long-term cognitive issues, have been reported (Briggs, 2011; Harden, 2009c). Some of the anticonvulsant agents are associated with increased oral contraceptive failures. Thus, other more reliable methods should be considered (Chap 38, p. 696).

CEREBROVASCULAR DISEASES

Abnormalities of the cerebrovascular circulation include strokes—both ischemic and hemorrhagic, as well as anatomical anomalies, such as arteriovenous malformations and aneurysms. The current endemic of obesity in this country, along with concomitant increases in heart disease, hypertension, and diabetes, has also resulted in increased stroke prevalence (Centers for Disease Control and Prevention, 2012). Women have a higher lifetime risk of stroke than men as well as higher associated mortality rates (Martínez-Sánchez, 2011; Roger, 2012). Moreover, pregnancy increases the immediate and lifetime risk of both ischemic and hemorrhagic stroke (Jamieson, 2010; Jung, 2010).

Stroke is relatively uncommon in pregnant women, but it contributes disparately to maternal mortality rates. Reported incidences of strokes in pregnancy range from 1.5 to 71 per 100,000 pregnancies (James, 2005; Kuklina, 2011; Scott, 2012). The incidence is increasing as measured by pregnancy-related hospitalizations for stroke (Callaghan, 2008; Kuklina, 2011).

Importantly, most are associated with hypertensive disorders or heart disease. Almost 9 percent of the pregnancy-related mortality rate in the United States is due to cerebrovascular accidents, with a third being associated with preeclampsia (Berg, 2010b).

Risk Factors

Most strokes in pregnancy manifest either during labor and delivery or in the puerperium. In a study of 2850 pregnancy-related strokes, approximately 10 percent developed antepartum, 40 percent intrapartum, and almost 50 percent postpartum (James, 2005). Several risk factors—unrelated and related to pregnancy—have been reported from studies that included more than 10 million pregnancies. These include older age; migraines, hypertension, obesity, and diabetes; cardiac disorders such as endocarditis, valvular prostheses, and patent foramen ovale; and smoking. Those related to pregnancy include hypertensive disorders, gestational diabetes, obstetrical hemorrhage, and cesarean delivery. By far, the most common risk factors are pregnancy-associated hypertensive disorders. As noted, one third of strokes are associated with gestational hypertension, and there is a three- to eightfold increased risk of stroke in hypertensive compared with normotensive women (Scott, 2012; Wang, 2011). Women with preeclampsia undergoing general anesthesia may be at higher risk of stroke compared with those given neuraxial anesthesia (Huang, 2010). Another risk factor for peripartum stroke is cesarean delivery, which increases the risk 1.5-fold compared with vaginal delivery (Lin, 2008).

Pregnancy-induced effects on cerebrovascular hemodynamics are unclear as related to risk for stroke. Although cerebral blood flow *decreased* by 20 percent from midpregnancy until term, importantly, it *increased* significantly with gestational hypertension (Zeeman, 2003, 2004b). Such hyperperfusion would at least intuitively be dangerous in women with certain vascular anomalies.

Ischemic Stroke

Acute occlusion or embolization of an intracranial blood vessel causes cerebral ischemia, which may result in death of brain tissue (Fig. 60-1). The more common associated conditions and etiologies of ischemic stroke are shown in Table 60-3. A transient ischemic attack (TIA) is caused by reversible ischemia, and symptoms usually last less than 24 hours. Patients with a stroke usually have a sudden onset of severe headache, hemiplegia or other neurological deficits, or occasionally, seizures. Focal neurological symptoms accompanied by an aura usually signify a first-episode migraine (Liberman, 2008).

Evaluation of an ischemic stroke includes echocardiography and cranial imaging with CT, MR, or angiography. Serum lipids are measured with the caveat that their values are distorted by normal pregnancy (Appendix, p. 1291). Antiphospholipid antibodies and lupus anticoagulant are sought—these cause up to a third of ischemic strokes in otherwise healthy young women (Chap. 59, p. 1173). Also, tests for sickle-cell syndromes are completed when indicated. With a thorough evaluation, most causes can be identified, although treatment is not always available. Some of these include cardiac-associated embolism, vasculitis, or vasculopathy such as Moyamoya disease (Ishimori, 2006; Miyakoshi, 2009; Simolke, 1991).

FIGURE 60-1 Illustrations of a brain showing various types of strokes seen in pregnancy: (1) subcortical infarction (preeclampsia), (2) hypertensive hemorrhage, (3) aneurysm, (4) embolism or thrombosis in middle cerebral artery, (5) arteriovenous malformation, and (6) cortical vein thrombosis.

TABLE 60-3. Some Associated Disorders or Causes of Ischemic and Hemorrhagic Strokes During Pregnancy or the Puerperium

Ischemic Stroke	Hemorrhagic Stroke
Preeclampsia syndrome	Chronic hypertension
Arterial thrombosis	Preeclampsia syndrome
Venous thrombosis	Arteriovenous malformation
Lupus anticoagulant	Saccular aneurysm
Antiphospholipid antibodies	Angioma
Thrombophilias	Cocaine, methamphetamines
Migraine induced	Vasculopathy
Paradoxical embolus	
Cardioembolic	
Sickle hemoglobinopathy	
Arterial dissection	
Vasculitis	
Moyamoya disease	
Cocaine, amphetamines	

From Smith, 2012; Yager, 2012.

Preeclampsia Syndrome

In reproductive-age women, a significant proportion of pregnancy-related ischemic strokes are caused by gestational hypertension and preeclampsia syndrome (Jeng, 2004). As shown in Figure 60-1, areas of subcortical perivascular edema and petechial hemorrhage may progress to cerebral infarction (Aukes, 2007, 2009; Zeeman, 2004a). Although these are usually clinically manifest by an eclamptic convulsion, a few women will suffer a symptomatic stroke from a larger cortical infarction (Chap. 40, p. 742).

Other conditions with findings similar to preeclampsia include *thrombotic microangiopathies* (Chap. 56, p. 1116) and the *reversible cerebral vasoconstriction syndrome* (Chap. 40, p. 743). The latter, which is also termed *postpartum angiopathy*, can cause extensive cerebral edema with necrosis as well as widespread infarction with areas of hemorrhage (Katz, 2014; Ramnarayan, 2009; Singhal, 2009).

Cerebral Embolism

These strokes usually involve the middle cerebral artery (see Fig. 60-1). They are more common during the latter half of pregnancy or early puerperium (Lynch, 2001). The diagnosis can be made with confidence only after thrombosis and hemorrhage have been excluded. The diagnosis is more certain if an embolic source is identified. Hemorrhage may be more difficult to exclude because embolization and thrombosis are both followed by hemorrhagic infarction. Paradoxical embolism is an uncommon cause, even considering that more than a fourth of adults have a

patent foramen ovale through which right-sided venous thromboemboli are deported (Kizer, 2005; Scott, 2012). Foraminal closure may not improve outcomes in these patients, however, this procedure has been performed during pregnancy (Dark, 2011; Furlan, 2012). Assorted cardioembolic causes of stroke include arrhythmias—especially atrial fibrillation, valvular lesions, mitral valve prolapse, mural thrombus, infective endocarditis, and peripartum cardiomyopathy.

Management of embolic stroke in pregnancy consists of supportive measures and antiplatelet therapy. Thrombolytic therapy and anticoagulation are controversial issues at this time (Kizer, 2005; Li, 2012).

Cerebral Artery Thrombosis

Most thrombotic strokes affect older individuals and are caused by atherosclerosis, especially of the internal carotid artery. Many are preceded by one or more transient ischemic attacks. Thrombolytic therapy with *recombinant tissue plasminogen activator—rt-PA* or *alteplase* is recommended within the first 3-hour window if there is measurable neurological deficit and if neuroimaging has excluded hemorrhage. This can be used in pregnancy. A principal risk is hemorrhagic transformation of an ischemic stroke in approximately 5 percent of treated patients (van der Worp, 2007).

Cerebral Venous Thrombosis

In a 10-center study in the United States, 7 percent of cerebral venous thromboses were associated with pregnancy (Wasay, 2008). Even so, pregnancy-associated cerebral venous thrombosis is rare in developed countries, and reported incidences range from 1 in 11,000 to 1 in 45,000 pregnancies (Lanska, 1997; Simolke, 1991). In the Nationwide Inpatient Sample of more than 8 million deliveries, James and associates (2005) observed that venous thrombosis caused only 2 percent of pregnancy-related strokes (Saposnik, 2011). There are numerous predisposing causes, and the greatest risk is in late pregnancy and the puerperium.

Thrombosis of the lateral or superior sagittal venous sinus usually occurs in the puerperium and often in association with preeclampsia, sepsis, or thrombophilia (see Fig. 60-1). It is more common in patients with inherited thrombophilias, lupus anticoagulant, or antiphospholipid antibodies (Chaps. 52, p. 1029 and 59, p. 1173). Headache is the most common presenting symptom, neurological deficits are common, and up to a third of patients have convulsions (Wasay, 2008). Diagnosis is with MR venography (Saposnik, 2011).

Management includes anticonvulsants for seizures, and although heparinization is recommended by most, its efficacy is controversial (de Freitas, 2008; Saposnik, 2011; Smith, 2012). Antimicrobials are given if there is septic thrombophlebitis, and fibrinolytic therapy is reserved for those women failing systemic anticoagulation. The prognosis for venous thrombosis in pregnancy is better than in nonpregnant subjects, and mortality rates are less than 10 percent (McCaulley, 2011). The recurrence rate is 1 to 2 percent during a subsequent pregnancy (Mehraein, 2003).

Recurrence Risk of Ischemic Stroke

Women with previous ischemic stroke have a low risk for recurrence during a subsequent pregnancy unless a specific, persistent cause is identified. Lamy and colleagues (2000) followed 37 women who had an ischemic stroke during pregnancy or the puerperium, and none of their 24 subsequent pregnancies was complicated by another stroke. In another study of 23 women who had prepregnancy strokes from a variety of causes, there were 35 subsequent pregnancies without a stroke recurrence (Coppage, 2004). Finally, in a follow-up study of 1770 nonpregnant women with antiphospholipid-related ischemic stroke, investigators reported no difference in the recurrence risk as long as preventative treatment was given with warfarin or aspirin (Levine, 2004). In another study of nonpregnant subjects, low-dose aspirin following venous thromboembolism decreased the risk of a subsequent stroke (Brighton, 2012).

Currently, there are no firm guidelines regarding prophylaxis in pregnant women with a stroke history (Helms, 2009). The American Heart Association stresses the importance of controlling risk factors such as hypertension and diabetes (Furie, 2011). Women with antiphospholipid antibody syndrome or certain cardiac conditions should be considered for prophylactic anticoagulation as discussed in Chapters 49 (p. 979) and 59 (p. 1175).

FIGURE 60-2 Large intracerebral hemorrhage caused by hypertensive stroke.

Hemorrhagic Stroke

The two distinct categories of spontaneous intracranial bleeding are intracerebral and subarachnoid hemorrhage. The symptoms of a hemorrhagic stroke are similar to those of an ischemic stroke. Their differentiation is only possible with CT or MR imaging (Morgenstern, 2010).

Intracerebral Hemorrhage

Bleeding into the brain parenchyma most commonly is caused by spontaneous rupture of small vessels previously damaged by chronic hypertension as depicted in Figure 60-1 (Qureshi, 2001; Takebayashi, 1983). Thus, pregnancy-associated hemorrhagic strokes such as the one shown in Figure 60-2 are often associated with chronic hypertension and superimposed preeclampsia (Cunningham, 2005; Martin, 2005). Because of its location, this type of hemorrhage has much higher morbidity and mortality rates than does subarachnoid hemorrhage (Morgenstern, 2010). Chronic hypertension is uniquely associated with *Charcot-Bouchard microaneurysms* of the penetrating branches of the middle cerebral artery. Pressure-induced rupture causes bleeding in the putamen, thalamus, adjacent white matter, pons, and cerebellum. In the 28 women described by Martin and associates (2005), half died and most survivors had permanent disabilities. This cautions for the importance of proper management for gestational hypertension—especially systolic hypertension—to prevent cerebrovascular pathology (Chap. 40, p. 761).

Subarachnoid Hemorrhage

In a study of 639 cases of pregnancy-related subarachnoid hemorrhage from the Nationwide Inpatient Sample, the incidence was 5.8 per 100,000 pregnancies, with half being postpartum (Bateman, 2012). These bleeds are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient (see Fig. 60-1). Ruptured saccular or “berry” aneurysms cause 80 percent of all subarachnoid hemorrhages. The remaining cases are caused by a ruptured arteriovenous malformation, coagulopathy, angiopathy, venous thrombosis, infection, drug abuse, tumors, or trauma. Such cases are

uncommon, and a ruptured aneurysm or angioma or bleeding from a vascular malformation has an incidence of 1 in 75,000 pregnancies. Although this frequency is not different from that in the general population, the mortality rate during pregnancy is reported to be as high as 35 percent.

Intracranial Aneurysm. Approximately 2 to 5 percent of adults have this lesion (see Fig. 60-1). Fortunately, only a small percentage rupture—approximately 0.1 percent for aneurysms < 10 mm and 1 percent for those > 10 mm (Smith, 2008). Most aneurysms identified during pregnancy arise from the circle of Willis, and 20 percent are multiple (Stoodley, 1998). Pregnancy does not increase the risk for aneurysmal rupture. However, because of their high prevalence, they are more likely to cause subarachnoid bleeding than other causes (Hirsch, 2009; Tiel Groenesteghe, 2009). Aneurysms are more likely to bleed during the second half of pregnancy—only approximately 20 percent bleed during the first half (Dias, 1990).

The cardinal symptom of a subarachnoid hemorrhage from an aneurysm rupture is sudden severe headache, accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, and altered consciousness. Patients typically have signs of meningeal irritation, nausea and vomiting, tachycardia, transient hypertension, low-grade fever, leukocytosis, and proteinuria. Prompt diagnosis and treatment may prevent potentially lethal complications. The American Heart Association recommends noncontrast cranial CT imaging as the first diagnostic test, although MR imaging may be superior (Chalela, 2007; Connolly, 2012).

Treatment includes bed rest, analgesia, and sedation, with neurological monitoring and strict blood pressure control. Repair of a potentially accessible aneurysm during pregnancy depends in part on the recurrent hemorrhage risk versus surgical risks. At least in nonpregnant patients, the risk of subsequent bleeding with conservative treatment is 20 to 30 percent for the first month and then 3 percent per year. The risk of rebleeding is highest within the first 24 hours, and recurrent hemorrhage leads to death in 70 percent.

Early repair is done by surgical clipping of the aneurysm or by endovascular coil placement completed using fluoroscopic angiography yet attempting to limit radiation exposure. For women remote from term, repair without hypotensive anesthesia seems optimal. For women near term, cesarean delivery followed by aneurysm repair is a consideration, and we have successfully done this in several cases. For aneurysms repaired either before or during pregnancy, most allow vaginal delivery if remote from aneurysmal repair. A problem is what defines “remote,” and although some recommend 2 months, the time for complete healing is unknown. For women who survive subarachnoid hemorrhage, but in whom surgical repair is not done, we agree with Cartlidge (2000) and recommend against bearing down—put another way, we favor cesarean delivery.

Arteriovenous Malformations. These are congenital focal abnormal conglomerations of dilated arteries and veins with subarteriolar disorganization (see Fig. 60-1). They lack capillaries and have resultant arteriovenous shunting. Although

unclear, the risk of bleeding may increase with gestational age. When arteriovenous malformations (AVMs) bleed, half do so into the subarachnoid space, whereas half are intraparenchymal with subarachnoid extension (Smith, 2008). They are uncommon and are estimated to occur in 0.01 percent of the general population. Bleeding does not appear to be more likely during pregnancy (Finnerty, 1999; Horton, 1990). AVMs are correspondingly rare during pregnancy, and in the study from Parkland Hospital, there was only one AVM in nearly 90,000 deliveries (Simolke, 1991).

Treatment of AVMs in nonpregnant patients is largely individualized. There is no consensus whether all those that are accessible should be resected. It also depends on whether the lesion is symptomatic or an incidental finding; its anatomy and size; presence of associated aneurysm, which is found in up to 60 percent; and especially, whether or not the lesion has bled. After hemorrhage, the risk of recurrent bleeding in unrepaired lesions is 6 to 20 percent within the first year, and 2 to 4 percent per year thereafter (Friedlander, 2007; Smith, 2008). The mortality rate with a bleeding AVM is 10 to 20 percent. In pregnancy, the decision to operate is usually based on neurosurgical considerations, and Friedlander (2007) recommends strong consideration for treatment if bleeding occurs. Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, we favor cesarean delivery. An unusual case of spontaneous regression of a cerebral AVM has been described (Couldwell, 2011).

DEMYELINATING OR DEGENERATIVE DISEASES

The *demyelinating diseases* are neurological disorders characterized by immune-mediated focal or patchy destruction of myelin sheaths accompanied by an inflammatory response. The *degenerative diseases* are multifactorial and are characterized by progressive neuronal death.

Multiple Sclerosis

In the United States, multiple sclerosis (MS) is second only to trauma as a cause of neurological disability in middle adulthood (Hauser, 2012b). Because the disease affects women twice as often as men and usually begins in the 20s and 30s, women of reproductive age are most susceptible. The familial recurrence rate of MS is 15 percent, and the incidence in offspring is increased 15-fold.

The demyelinating characteristic of this disorder results from predominately T cell-mediated autoimmune destruction of oligodendrocytes that synthesize myelin. There is a genetic susceptibility and likely an environmental trigger such as exposure to certain bacteria and viruses, for example, *Chlamydia pneumoniae*, human herpesvirus 6, or Epstein-Barr virus (Frohman, 2006; Goodin, 2009).

There are four clinical types of multiple sclerosis (Hauser, 2012b):

1. *Relapsing-remitting MS* accounts for initial presentation in 85 percent of affected individuals. It is characterized by unpredictable recurrent episodes of focal or multifocal

neurological dysfunction usually followed by full recovery. Over time, however, relapses lead to persistent deficits.

2. *Secondary progressive MS* disease is relapsing-remitting disease that begins to pursue a progressive downhill course after each relapse. It is likely that all patients eventually develop this type.
3. *Primary progressive MS* accounts for 15 percent of cases. It is characterized by gradual progression of disability from the time of initial diagnosis.
4. *Progressive-relapsing MS* refers to primary progressive MS with apparent relapses.

Classic findings of MS include sensory loss, visual symptoms from optic neuritis, weakness, paresthesias, and a host of other neurological symptoms. Almost 75 percent of women with isolated optic neuritis develop multiple sclerosis within 15 years. Clinical diagnosis is confirmed by MR imaging and cerebrospinal fluid analysis. In greater than 95 percent of cases, MR imaging shows characteristic multifocal white matter plaques that represent discrete areas of demyelination such as shown in [Figure 60-3](#). Their appearance and extent are less helpful for treatment response. Similarly, Kuhle and colleagues (2007) reported that identification of serum antibodies against myelin oligodendrocyte glycoprotein and myelin basic protein are not predictive of recurrent disease activity.

Effects of Pregnancy on MS

The *PR*egnanCy In Multiple Sclerosis—*PRIMS*—study is a European prospective multicenter study in which 254 pregnancies were described (Vukusic, 2006). A principal finding was a confirmed 70-percent reduction in relapse risk during pregnancy, but with a significantly increased relapse rate postpartum. This may be related to increased pregnancy-induced numbers of T-helper lymphocytes with an increased T2/T1 ratio (Airas, 2008). In a metaanalysis of women with more than 1200 pregnancies complicated by multiple sclerosis, their

relapse rate was 0.4 per year before pregnancy; 0.26 per year during pregnancy; and this increased to 0.7 per year after delivery (Finkelsztejn, 2011). Factors associated with postpartum relapse include a high relapse rate before pregnancy, relapses during pregnancy, and a high MS disability score (Portaccio, 2014; Vukusic, 2006). Breast feeding has no apparent effect on postpartum relapses (Airas, 2010; Portaccio, 2011).

Effects of MS on Pregnancy

There are usually no adverse effects on pregnancy outcome with uncomplicated disease. Some women may become fatigued more easily, those with bladder dysfunction are predisposed to urinary infection, and women with spinal lesions at or above T₆ are at risk for autonomic dysreflexia. Dahl and coworkers (2006) described 449 such pregnancies, and they reported a higher labor induction rate and longer second-stage labor. The increased induction rate as well as elective operations contributed to the overall increased cesarean delivery rate. They also reported outcomes in 649 affected women and described a lower mean birthweight but similar perinatal mortality rate compared with that of controls (Dahl, 2005). Other studies have corroborated that MS does not significantly affect obstetrical and neonatal outcomes (Finkelsztejn, 2011).

Management During Pregnancy and the Puerperium

Goals are to arrest acute or initial attacks, employ disease-modifying agents, and provide symptomatic relief. Some treatments may need to be modified during pregnancy. Acute or initial attacks are treated with high-dose intravenous methylprednisolone—500 to 1000 mg daily for 3 to 5 days, followed by oral prednisone for 2 weeks. Plasma exchange may be considered. Symptomatic relief can be provided by analgesics; carbamazepine, phenytoin, or amitriptyline for neurogenic pain; baclofen (Lioresal, Kemstro) for spasticity; α_2 -adrenergic

FIGURE 60-3 Magnetic resonance cranial images from a woman with multiple sclerosis. **A.** T2-weighted axial image shows bright signal abnormalities in white matter, typical for multiple sclerosis. **B.** Sagittal T2-FLAIR image shows hyperintense areas within the corpus callosum that are representative of demyelination in multiple sclerosis. (From Hauser, 2012b, with permission.)

blockade for bladder neck relaxation; and cholinergic and anticholinergic drugs to stimulate or inhibit bladder contractions.

Several disease-modifying therapies can be used for relapsing multiple sclerosis or exacerbations. Examples include interferons $\beta 1a$ (Rebif) and $\beta 1b$ (Betaseron) and glatiramer acetate (Copaxone), which have been shown to decrease relapse rates by a third (Rudick, 2011). Data concerning safety in pregnancy are limited but overall reassuring (Amato, 2010; Salminen, 2010). Clinical trials with natalizumab (Tysabri), an alpha 4 integrin antagonist—especially when combined with interferon $\beta 1a$ —significantly reduced MS clinical relapse rates (Polman, 2006; Rudick, 2006). In a review of 35 pregnancies, early pregnancy drug exposure did not worsen outcomes (Hellwig, 2011). Because of limited data, however, women are currently advised to stop the drug 3 months before conception. Fingolimad (Gilenya) is a new oral medication, and pregnancy safety data are unavailable (Briggs, 2011).

Prevention of relapses postpartum is afforded by treatment with intravenous immune globulin (IVIG) given in a dose of 0.4 g/kg daily for 5 days during weeks 1, 6, and 12 (Argyriou, 2008). The Prevention of Postpartum Relapses with Progesterin and Estradiol in Multiple Sclerosis (POPART'MUS) trial is a multicenter randomized controlled trial currently enrolling patients (Vukusic, 2009).

Huntington Disease

This adult-onset neurodegenerative disease results from an autosomal dominant expanded CAG trinucleotide repeat within the Huntington gene on chromosome 4. It is characterized by a combination of choreoathetotic movements, progressive dementia, and psychiatric manifestations. Because the mean age of onset is 40 years, Huntington disease rarely complicates pregnancy. Prenatal diagnosis is discussed in Chapter 14 (p. 297). However, prenatal screening is controversial because this usually is a late-onset adult disease. Thus, extensive pretest counseling is imperative (Novak, 2010).

Myasthenia Gravis

This autoimmune-mediated neuromuscular disorder affects approximately 1 in 7500 persons. It is more common in women, and its incidence peaks in their 20s and 30s. The etiology is unknown, but genetic factors likely play a role. Most patients demonstrate antibodies to the acetylcholine receptor, although 10 to 20 percent are seronegative. The latter often have antibodies to muscle-specific tyrosine kinase (MuSK) that regulates assembly of the acetylcholine receptor subunits at the neuromuscular junction (Cavalcante, 2011; Pal, 2011).

Cardinal features of MG are weakness and easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Deep tendon reflexes are preserved. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized. Other autoimmune diseases may coexist, and hypothyroidism should be excluded. The clinical course is marked by exacerbations and remissions, especially when it first

becomes clinically apparent. Remissions are not always complete and are seldom permanent. Systemic diseases, concurrent infections, and even emotional upset may precipitate exacerbations, of which there are three types:

1. *Myasthenic crises*—characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis.
2. *Refractory crises*—characterized by the same symptoms but unresponsive to the usual therapy.
3. *Cholinergic crises*—excessive cholinergic medication leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea.

All three of these can be life threatening, but a refractory crisis is a medical emergency. Those with bulbar myasthenia are at particular risk because they may be unable to swallow or even ask for help.

Management

Myasthenia is manageable but not curable. Thymectomy is generally recommended for long-term benefits in the 75 percent of patients who have thymic hyperplasia or a thymoma seen with CT or MR imaging (Drachman, 2012; Nam, 2011). Anticholinesterase medications such as pyridostigmine (Mestinon), an analogue of neostigmine, improve symptoms by impeding acetylcholine degradation. They seldom produce normal muscle function. Ironically, overdose is manifest by increased weakness—the cholinergic crisis—that may be difficult to differentiate from myasthenic symptoms. Most of those refractory to anticholinesterase therapy respond to immunosuppressive therapy with glucocorticoids, azathioprine, methotrexate, cyclosporine, and mycophenolate mofetil. Tacrolimus, an immunosuppressant used in organ transplantation, and rituximab, a chimeric monoclonal antibody, are currently being evaluated (Ibrahim, 2010; Maddison, 2011; Yoshikawa, 2011). Cyclophosphamide is reserved for severe, generalized refractory cases. When short-term, rapid clinical improvement is needed—such as for a surgical procedure or a myasthenic crisis—high-dose immunoglobulin G or plasma exchange is usually effective (Barth, 2011; Cortese, 2011; Mandawat, 2010).

Myasthenia and Pregnancy

Because the greatest period of risk is within the first year following diagnosis, it seems reasonable to postpone pregnancy until there is sustained improvement. Antepartum management of myasthenia includes close observation with liberal rest and prompt treatment of infections (Heaney, 2010; Kalidindi, 2007). Women in remission who become pregnant while taking corticosteroids or azathioprine should continue these. Thymectomy has been successfully performed during pregnancy in refractory cases (Ip, 1986). Acute onset of myasthenia or its exacerbation demands prompt hospitalization and supportive care. Plasmapheresis and high-dose immunoglobulin therapy should be used for emergency situations (Drachman, 2012).

Although pregnancy does not appear to affect the overall course of MG, fatigue common to most pregnancies may be exacerbated, and the expanding uterus may compromise respiration. During pregnancy, maternal hypotension or hypovolemia

are avoided. The clinical course of MG during pregnancy is unpredictable, and frequent hospitalizations are the norm. Up to a third of women have worsening MG during pregnancy, with exacerbations occurring equally in all three trimesters (Djelmis, 2002; Podciechowski, 2005).

Myasthenia gravis has no significant adverse effects on pregnancy outcomes (Wen, 2009). Preeclampsia is a concern because magnesium sulfate may precipitate a severe myasthenic crisis (Hamaoui, 2009; Heaney, 2010). Although phenytoin use is also problematic in this regard, its adverse effects are less troublesome, and thus many choose it for neuroprophylaxis in MG patients with severe preeclampsia. Because smooth muscle is unaffected, most women have normal labor. Oxytocin is given for the usual indications, and cesarean delivery reserved for obstetrical indications. Because narcotics may cause respiratory depression, close observation and respiratory support are essential during labor and delivery. Curariform drugs should be avoided—examples include magnesium sulfate discussed above, muscle relaxants used with general anesthesia, and aminoglycosides. Neuraxial analgesia is accomplished with amide-type local agents. Regional analgesia is preferred unless there is significant bulbar involvement or respiratory compromise (Almeida, 2010; Blichfeldt-Lauridsen, 2012). During second-stage labor, some women may have impaired voluntary expulsive efforts that may warrant operative vaginal delivery.

Neonatal Effects

As discussed above, 80 percent of mothers with myasthenia gravis have anti-acetylcholine-receptor IgG antibodies. These and anti-MuSK antibodies are transported transplacentally, and the fetus can be affected to cause hydramnios (Heaney, 2010). Similarly, 10 to 20 percent of neonates manifest MG symptoms (Murray, 2010; Niks, 2008). Transient symptoms usually include a feeble cry, poor suckling, and respiratory distress. Symptoms usually respond to cholinesterase inhibitors and resolve within a few weeks.

NEUROPATHIES

Peripheral neuropathy is a general term used to describe disorders of peripheral nerve(s) of any cause. Because neuropathy can result from a variety of sources, its discovery should prompt a search for an etiology. *Polyneuropathies* can be either axonal or demyelinating as well as acute, subacute, or chronic (Chaudhry, 2008). They are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic diseases.

Mononeuropathies are relatively common in pregnancy, and they signify focal involvement of a single nerve trunk and imply local causation such as trauma, compression, or entrapment. Traumatic pudendal, obturator, femoral, and common fibular mononeuropathies are usually caused by childbirth and are discussed in Chapter 36 (p. 676).

Guillain-Barré Syndrome

In 75 percent of cases, this acute demyelinating polyradiculoneuropathy has clinical or serological evidence for

an acute infection. Commonly associated are infection with *Campylobacter jejuni*, cytomegalovirus, and Epstein-Barr virus; surgical procedures; and immunizations (Haber, 2009; Hauser, 2012a). Guillain-Barré syndrome (GBS) is thought to be immune-mediated from antibodies formed against nonself antigens. Demyelination causes sensory and motor conduction blockade, and recovery occurs with remyelination in most cases.

Clinical features include areflexic paralysis—usually ascending—with or without sensory disturbances. Autonomic dysfunction is common. The full syndrome develops over 1 to 3 weeks. Management is supportive, but in the worsening phase, patients should be hospitalized because at least a third will need ventilatory assistance. Intravenous high-dose immunoglobulin (IVIG) or plasmapheresis is beneficial if begun within 1 to 2 weeks of motor symptoms, however, neither decreases mortality rates (Cortese, 2011; Gwathmey, 2011; Hughes, 2011). Although most patients recover fully within several months to a year, up to 20 percent are severely disabled, and 5 percent die, despite treatment (Yuki, 2012). Some manifest as *chronic inflammatory demyelinating polyneuropathy*, and our experiences indicate that it may be relatively common in these young women.

Pregnancy

Guillain-Barré syndrome is not more common in pregnancy, although inconclusive data suggest rates are increased in the puerperium (Cheng, 1998). Its clinical course in pregnancy is the same as for nonpregnant individuals, and after an insidious onset, paresis and paralysis most often continue to ascend to cause ventilatory weakness. Hurley and colleagues (1991) reported that a third of pregnant women required ventilatory support, with a mortality rate of 13 percent. The acute syndrome is treated with either high-dose IVIG or plasmapheresis (Chan, 2004; Yuki, 2012).

Bell Palsy

This disfiguring palsy is usually a mononeuropathic acute facial paralysis that is relatively common in reproductive-aged women (Fig. 60-4). It has a female predominance, and pregnant women

FIGURE 60-4 Bell facial nerve palsy developing on the day of delivery after a cesarean for dichorionic twins. This woman was treated with prednisone and antiviral medication, and the palsy had almost resolved 3 weeks postpartum.

are at a fourfold risk compared with nonpregnant women (Cohen, 2000; Heaney, 2010). The disease is characterized by facial nerve inflammation and often is associated with reactivation of herpes virus or herpes zoster virus.

Bell palsy usually has an abrupt and painful onset with maximum weakness by 48 hours. In some cases, hyperacusis and loss of taste accompany paralysis (Beal, 2012). Management includes supportive care with facial muscle massage and eye protection against corneal lacerations from drying. There is general consensus that prednisone, 1 mg per kg given orally daily for 5 days, will result in improved outcomes and a shortened recovery period (Salinas, 2010; Sullivan, 2007). It is controversial if addition of an antiviral medication will improve these outcomes (de Almeida, 2009; Lockhart, 2009; Quant, 2009).

Pregnancy

It is unclear if pregnancy alters the prognosis for spontaneous facial palsy recovery. Gillman and colleagues (2002) found that only half of pregnant women recovered to a satisfactory level after 1 year—this compared with approximately 80 percent of nonpregnant women and men. Some prognostic markers for incomplete recovery are bilateral palsy, recurrence in a subsequent pregnancy, greater percentage of nerve function loss, and a faster rate of loss (Cohen, 2000; Gilden, 2004). Corticosteroid therapy given early in the course of the disease significantly improves outcomes. Other than a fivefold increased rate for gestational hypertension or preeclampsia, women with Bell palsy do not have increased adverse pregnancy outcomes (Katz, 2011; Shmorgun, 2002).

■ Carpal Tunnel Syndrome

This syndrome results from compression of the median nerve and is the most frequent mononeuropathy in pregnancy (Padua, 2010). Symptoms include burning, numbness, or tingling along the inner half of one or both hands. Also, wrist pain and numbness extend into the forearm and sometimes into the shoulder (Katz, 2002). Symptoms are bilateral in 80 percent of pregnant women, and 10 percent have evidence for severe denervation (Seror, 1998). Differential diagnosis includes cervical radiculopathy of C₆–C₇ and de Quervain tendonitis, which is caused by swelling of the conjoined tendons and their sheaths near the distal radius. Nerve conduction studies may be helpful (Alfonso, 2010).

Pregnancy

The reported incidence is 7 to 43 percent and varies greatly because the range of symptoms is marked (Finsen, 2006; Padua, 2010). Symptomatic treatment with a splint applied to the slightly flexed wrist during sleep relieves pressure and usually provides relief. Although symptoms typically are self-limited, occasionally surgical decompression and corticosteroid injections are necessary (Keith, 2009; Shi, 2011). Symptoms may persist in more than half of patients at one year and in a third at 3 years (Padua, 2010).

SPINAL-CORD INJURY

According to the National Spinal Cord Injury Statistical Center (2012), there are approximately 12,000 spinal cord injuries

each year. At least half affect reproductive-age individuals, with a male-to-female predominance of 4 to 1. The severity of cord injury determines the short- and long-term prognosis as well as that for pregnancy. Incomplete neurological lesions are associated with at least some sensory and/or motor function below the level of injury, whereas there is none with complete cord transection. Many women develop sexual function alteration and transient hypothalamic pituitary hypogonadism, however, pregnancy is not uncommon if menstruation resumes (Bughi, 2008).

Women with spinal cord injury have an increased frequency of pregnancy complications that include preterm and low-birthweight infants. Most have asymptomatic bacteriuria with sporadic symptomatic urinary infections. Bowel dysfunction causes constipation in more than half, and anemia and pressure-necrosis skin lesions are also common. There are two serious and life-threatening complications with spinal cord injuries:

1. If the cord is transected above T₁₀, the cough reflex is impaired, respiratory function may be compromised, and pneumonitis from covert aspiration can be serious. Pulmonary function tests are considered, and some women may need ventilatory support in late pregnancy or in labor.
2. Women with lesions above T₅–T₆ are at risk for *autonomic dysreflexia*. With this, stimuli from structures innervated below the level of the spinal lesion results in massive disordered sympathetic stimulation. Abrupt catecholamine release can cause vasoconstriction with severe hypertension and symptoms that include throbbing headaches, facial flushing, sweating, bradycardia, tachycardia, arrhythmias, and respiratory distress. Dysreflexia can be precipitated by a variety of stimuli, such as urethral catheterization; bladder distention from retention; rectal or cervical distention with digital examinations; uterine contractions and cervical dilatation; or any other pelvic structure manipulation (American College of Obstetricians and Gynecologists, 2005; Krassioukov, 2009). In one report, 12 of 15 women at risk for autonomic dysreflexia suffered at least one episode during pregnancy (Westgren, 1993).

Because uterine contractions are not affected by spinal cord lesions, labor is usually easy—even precipitous, and comparatively painless. If the lesion is below T₁₂, uterine contractions are felt normally. For lesions above T₁₂, the risk of out-of-hospital delivery is substantial and can be minimized by teaching women to palpate for uterine contractions. This is especially important because up to 20 percent of women deliver preterm (Westgren, 1993). Some recommend tocodynamometry and weekly cervical examinations beginning at 28 to 30 weeks. Another reasonable option that we frequently employ at Parkland Hospital is elective hospitalization after 36 to 37 weeks (Hughes, 1991).

Spinal or epidural analgesia extending to T₁₀ prevents autonomic dysreflexia and should be instituted at the start of labor. If there are severe symptoms before epidural placement, steps are taken to abolish the provoking stimulus. A parenteral antihypertensive agent such as hydralazine or labetalol is given. Labor and vaginal delivery with epidural or spinal

analgesia are preferable and will minimize autonomic dysreflexia (Kuczkowski, 2006). Operative vaginal delivery is frequently necessary.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Also known as *pseudotumor cerebri* or *benign intracranial hypertension*, this disorder is characterized by increased intracranial pressure without hydrocephalus. The cause is unknown, but it may be the result of either overproduction or underabsorption of cerebrospinal fluid. Symptoms include headache in at least 90 percent of cases, visual disturbances such as loss of a visual field or central visual acuity in 70 percent, and commonly occurring papilledema that may be sight-threatening (Evans, 2000; Heaney, 2010). Other complaints are stiff neck, back pain, pulsatile tinnitus, cranial nerve palsies such as facial palsy, ataxia, or paresthesias. The syndrome is commonly found in young women and is prevalent in those who are obese, who recently gained weight, or both (Fraser, 2011). Along with symptoms, other criteria for diagnosis include elevated intracranial pressure > 250 mm H₂O, normal cerebrospinal fluid (CSF) composition, normal cranial CT or MR imaging findings, and no evidence for systemic disease (International Headache Society, 2005).

Idiopathic intracranial hypertension is usually self-limited. Visual defects can be prevented by lowering the cerebrospinal fluid pressure. Drugs given to lower pressure include acetazolamide (Diamox) to reduce fluid production, furosemide (Lasix), or topiramate (Topamax). Corticosteroids are now rarely used. Surgical intervention is occasionally necessary and is accomplished by either lumboperitoneal shunting of spinal fluid or optic nerve sheath fenestration.

Effects of Pregnancy

It is controversial if pregnancy is a risk factor for idiopathic intracranial hypertension. Certainly, symptoms may first appear in pregnancy, and women previously diagnosed may become symptomatic. These usually develop by midpregnancy, tend to be self-limited, and usually resolve postpartum.

There is general agreement that pregnancy does not alter management. Some recommend serial visual field testing to prevent permanent vision loss. In a report of 16 pregnant women, visual field loss developed in four, and it became permanent in one (Huna-Baron, 2002). Visual field loss is often coincident with the development of papilledema, for which acetazolamide is given. Lee and associates (2005) reported successful treatment of 12 pregnant women. Although outmoded for treatment of nonpregnant individuals, repeated lumbar punctures are generally successful in providing temporary relief throughout pregnancy. In some pregnant women, surgical therapy becomes necessary, and we and others have had promising results with optic nerve sheath fenestration (Thambisetty, 2007).

Pregnancy complications are likely due to associated obesity and not to intracranial hypertension. In a review of 54 pregnancies, there were no excessive adverse perinatal outcomes (Katz, 1989). The route of delivery depends on obstetrical indications, and conduction analgesia is safe (Aly, 2007; Karmaniolou, 2011).

MATERNAL VENTRICULAR SHUNTS

Pregnancies in women with previously placed ventricular shunts for obstructive hydrocephalus usually have satisfactory outcomes (Landwehr, 1994). Shunts may be ventriculoperitoneal, ventriculoatrial, or ventriculopleural. Partial obstruction of a shunt is common, especially late in pregnancy (Schiza, 2012). In one report of 17 such pregnancies, neurological complications were reported in 13 (Wisoff, 1991). Findings included headaches in 60 percent, nausea and vomiting in 35 percent, lethargy in 30 percent, and ataxia or gaze paresis, each in 20 percent. Most symptoms respond to conservative management. However, if CT scanning during symptom evaluation discloses acute hydrocephaly, then the shunt is tapped or pumped several times daily. In some cases, surgical revision is necessary and may be emergently required (Murakami, 2010).

Another shunting procedure involves placement of an endoscopic third ventriculostomy for hydrocephalus in children or adults (de Ribaupierre, 2007). One report described successful results in five pregnant women who underwent successful ventriculostomy placement (Riffaud, 2006). In a review, reproductive function and miscarriage rates were found to significantly worsen in these women (Bedaiwy, 2008).

Vaginal delivery is preferred in women with shunts, and unless there is a meningocele, conduction analgesia is permitted. Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or tubal sterilization.

MATERNAL BRAIN DEATH

Brain death is rare in obstetrics. Life-support systems and parenteral alimentation for up to 15 weeks have been described while awaiting delivery (Hussein, 2006; Powner, 2003; Souza, 2006). Some women were treated with aggressive tocolysis and antimicrobial therapy. Chiossi and coworkers (2006) reviewed outcomes in 17 women with persistent vegetative state who were given various levels of support. At least five died after delivery, and most of the remainder continued to be in the vegetative state. There are no published reports of neurological recovery with a diagnosis of brain death using the uniform Determination of Death Act definition (Wijdicks, 2010). The ethical, financial, and legal implications, both civil and criminal, that arise from attempting or not attempting such care are profound (Farragher, 2005; Feldman, 2000). In some women, perimortem cesarean delivery is performed as discussed in Chapter 47 (p. 956).

FEEDING AND EATING DISORDERS 1211

PERSONALITY DISORDERS 1211

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or may signal the onset of a new disorder. Psychiatric disorders during pregnancy have been associated with less prenatal care, substance abuse, poor obstetrical and infant outcomes, and a higher risk of postpartum psychiatric illness (Frieder, 2008). Of pregnant women identified with psychiatric disorders, Andersson and colleagues (2003) in one Swedish study reported that more than 80 percent had a mood disorder. According to the Agency for Healthcare Research and Quality, the period prevalence of any depressive disorder during pregnancy in the United States is 18 percent (Yonkers, 2011). Unfortunately, most pregnant women with depressive disorders are not treated. In the Swedish study mentioned above, only 5 percent of women identified with psychiatric disorders received some form of treatment.

Suicide is the fifth leading cause of death in the United States among women during the perinatal period, and major depression is among the strongest predictors of suicidal ideation (Melville, 2010). In both the United Kingdom and Australia, psychiatric illness is a leading cause of mortality for late maternal deaths—those between 43 and 365 days postpartum (Austin, 2007). Suicide by violent means was responsible for 65 percent of these. In a 10-year case-control analysis of Washington state hospitalizations, Comtois and associates (2008) studied 355 women with a postpartum suicide attempt. Significant risk factors and their associated rates included prior hospitalization for a psychiatric diagnosis—27-fold, and for substance abuse—sixfold. These rates were further increased if there were multiple hospitalizations.

PSYCHOLOGICAL ADJUSTMENTS TO PREGNANCY

Biochemical factors—including hormonal effects—and life stressors can markedly influence mental illness. Thus, intuitively, pregnancy exacerbates some coexisting mental disorders. Indeed, pregnancy-related shifts in sex steroids and monoamine neurotransmitter levels; dysfunction of the hypothalamic-pituitary-adrenal axis; thyroid dysfunction; and alterations in immune response are all associated with an increased risk for mood disorders (Yonkers, 2011). These changes, coupled with evidence of familiarity of depression, suggest that there may be a subgroup of women at risk for developing a unipolar major depressive disorder during pregnancy.

Women respond in a variety of ways to stressors of pregnancy, and some express persistent concerns regarding fetal health, child care, lifestyle changes, or fear of childbirth pain. Anxiety, sleep disorders, and functional impairment are common (Morewitz, 2003; Romero, 2014; Vythilingum, 2008). According to Littleton and coworkers (2007), however, anxiety symptoms in pregnancy are associated with psychosocial variables similar to those for nonpregnant women. The level

of perceived stress is significantly higher for women whose fetus is at high risk for a malformation, for those with preterm labor or delivery, and for those with other medical complications (Alder, 2007; Ross, 2006). Hippman (2009) screened 81 women for depression who had an increased risk for a fetus with aneuploidy. Half of these women had a positive depression screening score, whereas only 2.4 percent of those with a normal pregnancy did so.

A number of steps can be taken to diminish psychological stress in the event of a poor obstetrical outcome. For example, following a stillbirth, Gold (2007) encouraged parental contact with the newborn and provision of photographs and other infant memorabilia. Addressing associated sleep disorders also seems reasonable (Romero, 2014).

■ The Puerperium

The puerperium is a particularly stressful time and carries as increased risk for mental illness. Up to 15 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Tam, 2007; Yonkers, 2011). A few have a more severe, psychotic illness following delivery, and half of these have a bipolar disorder (Yonkers, 2011). Depressive disorders are more likely in women with obstetrical complications such as severe preeclampsia or fetal-growth restriction, especially if associated with early delivery. However, among women with a history of bipolar disorder, these factors do not seem to play as great a role in the development of mania or depression (Yonkers, 2011).

Maternity Blues

Also called *postpartum blues*, this is a time-limited period of heightened emotional reactivity experienced by half of women within approximately the first week after parturition. Prevalence estimates for the blues range from 26 to 84 percent depending on criteria used for diagnosis (O'Hara, 2014). This emotional state generally peaks on the fourth or fifth postpartum day and normalizes by day 10 (O'Keane, 2011). The predominant mood is happiness. However, affected mothers are more emotionally labile, and insomnia, weepiness, depression, anxiety, poor concentration, irritability, and affective lability may be noted. Mothers may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Supportive treatment is indicated, and sufferers can be reassured that the dysphoria is transient and most likely due to biochemical changes. They should be monitored for development of depression and other severe psychiatric disturbances.

■ Prenatal Evaluation

Screening for mental illness is generally done at the first prenatal visit. Factors include a search for psychiatric disorders, including hospitalizations, outpatient care, prior or current use of psychoactive medications, and current symptoms. Risk factors should be evaluated—for example, a prior personal or family history of depression conveys a significant risk for depression. Women with a history of sexual, physical, or verbal abuse; substance abuse; and personality disorders are also at greater risk for depression (Akman, 2007; Tam, 2007). Smoking and nicotine

dependence have been associated with an increase in rates of *all* mental disorders in pregnancy (Goodwin, 2007). Finally, because eating disorders may be exacerbated by pregnancy, affected women should be followed closely.

According to the American College of Obstetricians and Gynecologists (2012a), there is currently insufficient evidence to make a firm recommendation for routine depression screening, either during or after pregnancy. At Parkland Hospital, all women are asked about depression and domestic violence at their first prenatal visit. They are also screened again during their first postpartum visit using the Edinburgh Postnatal Depression Scale (EPDS). In an analysis of more than 17,000 of these questionnaires, 6 percent had scores that indicated either minor or major depressive symptoms. Twelve of these 1106 women also had thoughts of self-harm (Nelson, 2013).

■ Treatment Considerations

A large number of psychotropic medications may be used for management of the myriad mental disorders encountered in pregnancy. For treatment options that include psychosocial and psychological interventions, treatment decisions are ideally shared between patients and their health-care providers. Women taking psychotropic medication should be informed of likely side effects. Many of these drugs are discussed in Chapter 12 as well as by the American College of Obstetricians and Gynecologists (2012b). Additionally, these drugs are discussed subsequently in this chapter. Babbitt (2014) and Pozzi (2014) and their colleagues have recently reviewed principles of antenatal and intrapartum care of women with major mental disorders.

■ Pregnancy Outcomes

There are only a few reports of psychiatric disorders and pregnancy outcomes. Some, but not all, link maternal psychiatric illness with untoward outcomes such as preterm birth, low birthweight, and perinatal mortality (Schneid-Kofman, 2008; Steinberg, 2014; Yonkers, 2009). In a population-based cohort of more than 500,000 California births, Kelly and colleagues (2002) assessed the perinatal effects of a psychiatric diagnosis that included all International Classification of Diseases 9th Edition Clinical Modification (ICD-9-CM) diagnostic codes. Women with these diagnoses had up to a threefold increased incidence of a very-low- or low-birthweight neonate or preterm delivery. In another study of more than 1100 women enrolled in a Healthy Start initiative, women with depression were found to be 1.5 times more likely to be delivered early compared with nondepressed women. Conversely, Littleton and associates (2007) reviewed 50 studies and concluded that anxiety symptoms—a common comorbidity in depression—had no adverse effect on outcomes.

CLASSIFICATION OF MENTAL DISORDERS

The *Diagnostic and Statistical Manual-V* is the most recent version by the American Psychiatric Association (2013). Its purpose is to assist in the classification of mental disorders, and it specifies criteria for each diagnosis. Shown in [Table 61-1](#) are 12-month prevalences of mental disorders for adults.

TABLE 61-1. The 12-Month Prevalence of Mental Disorders in Adults in the United States

Disorder ^a	1-Year Prevalence (%)	Adults Affected ^b	Lifetime Prevalence (%)	Comments
All disorders	26.2	58 million	—	1 in 4 adults affected annually
Mood disorders—all		21 million	20.8	Median onset age 30 years
Major depression	6.7	15 million	—	Leading cause of disability in the United States; high suicide rate
Dysthymia	1.5	3.3 million	—	Chronic, mild depression
Bipolar disorder	2.6	5.7 million	3.9	Manic-depressive illness
Suicide	—	32,400	—	90% have mental disorder; depression most common
Schizophrenia	1.1	18 million		Men = women; onset women 20s or early 30s
Anxiety disorder—all	18	40 million		Frequent co-occurrence with depression or substance abuse
Panic	2.7			
Obsessive-compulsive	1			
Posttraumatic stress	3.5			
Generalized anxiety	3.1			
Social phobias	6.8			
Eating disorders				Adolescent and adult females—85–95%
Anorexia nervosa		—	2–3	Mortality rate 0.56% per year
Bulimia nervosa		—	2–3	
Binge eating—6 months	2–5		—	

^aBased on Diagnostic and Statistical Manual-IV-R (DSM-IV-R) of the American Psychiatric Association, 2000b.

^bBased on 2004 census data.

From the National Institute of Mental Health, 2006, 2010.

Depressive Disorders

According to the National Institute of Mental Health (2010), the lifetime prevalence of depressive disorders in the United States is 21 percent. Women are 50 percent more likely than men to experience a major mood disorder during their lifetime. Historically, these include major depression—a unipolar disorder—and manic-depression—a bipolar disorder with both manic and depressive episodes. It also includes dysthymia, which is chronic, mild depression. When concurrent with medical complications such as diabetes, heart disease, and asthma, major mood disorders worsen medical outcomes, and as a group, contribute to two thirds of all suicides (Yonkers, 2011).

Major Depression

This is the most common depressive disorder, and an estimated 12 million women each year in the United States are affected (Mental Health America, 2013a). The lifetime prevalence is 17 percent, but only half ever seek care. The diagnosis is arrived at by identifying symptoms listed in [Table 61-2](#).

Major depression is multifactorial and prompted by genetic and environmental factors. First-degree relatives have a 25-percent risk, and female relatives are at even higher risk. One genome-wide linkage analysis of more than 1200 mothers suggests that variation in chromosomes 1 and 9 increases susceptibility to postpartum mood symptoms (Mahon, 2009). Families of affected individuals also often have members with alcohol

TABLE 61-2. Symptoms of Depressive Illness^a

Persistent sad, anxious, or “empty” feelings
Feelings of hopelessness and/or pessimism
Feelings of guilt, worthlessness, and/or helplessness
Irritability, restlessness
Loss of interest in activities or hobbies once pleasurable, including sex
Fatigue and decreased energy
Difficulty concentrating, remembering detail, and making decisions
Insomnia, early-morning wakefulness, or excessive sleeping
Overeating or appetite loss
Thoughts of suicide, suicide attempts
Persistent aches or pains, headaches, cramps, or digestive problems that do not ease even with treatment

^aNot all patients experience the same symptoms, and their severity, frequency, and duration will vary among individuals.

From the National Institute of Mental Health, 2010.

abuse and anxiety disorders. Provocative conditions leading to depression include life events that prompt grief reactions, substance abuse, use of certain medications, and other medical disorders. Although life events can trigger depression, genes influence the response to life events, making the distinction between genetic and environmental factors difficult.

Pregnancy

It is unquestionable that pregnancy is a major life stressor that can precipitate or exacerbate depressive tendencies. In addition, there are likely various pregnancy-induced effects. Hormones certainly affect mood as evidenced by premenstrual syndrome and menopausal depression. Estrogen has been implicated in increased serotonin synthesis, decreased serotonin breakdown, and serotonin receptor modulation (Deecher, 2008). Concordantly, women who experience postpartum depression often have higher predelivery serum estrogen and progesterone levels and experience a greater decline postpartum (Ahokas, 1999).

Dennis and associates (2007) queried the Cochrane Database and reported the prevalence of antenatal depression to average 11 percent. Melville and coworkers (2010) found it in nearly 10 percent of more than 1800 women enrolled for prenatal care at a single university obstetrical clinic. Others have reported the incidence to be much higher (Lee, 2007; Westdahl, 2007). In another report, Luke and colleagues (2009) found major depressive symptoms in 25 percent of pregnant African American women. Hayes and associates (2012) reported that 13 percent of pregnant women in the Tennessee Medicaid program filled an antidepressant prescription either before or during pregnancy. In another report of almost 119,000 pregnancies in seven health plans, Andrade and coworkers (2008) found that only 6.6 percent received antidepressants at any time during pregnancy. These findings support to the notion that only half of pregnant women with depression receive treatment.

Postpartum depression—major or minor—develops in 10 to 20 percent of parturients (Centers for Disease Control and Prevention, 2008; Mental Health America, 2013b). Available data indicate that unipolar major depression may be slightly more prevalent during the puerperium than among women in the general population (Yonkers, 2011). In addition to antenatal depression, postpartum depression has been associated with young maternal age, unmarried status, smoking or drinking, substance abuse, hyperemesis gravidarum, preterm birth, and high utilization of sick leave during pregnancy (Endres, 2013; Lee, 2007; Marcus, 2009).

Depression is frequently recurrent. At least 60 percent of women taking antidepressant medication before pregnancy have symptoms during pregnancy. According to Hayes and colleagues (2012), approximately three fourths of women taking antidepressants before pregnancy stopped taking them before or during the first trimester. For those who discontinue treatment, almost 70 percent have a relapse compared with 25 percent who continue therapy. Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both prior puerperal depression and a current

episode of “maternity blues” are at inordinately high risk for major depression. Indeed, the need for postpartum depression help was the fourth most common challenge identified at 2 to 9 months postpartum by the Pregnancy Risk Assessment Monitoring System—PRAMS (Kanotra, 2007).

Postpartum depression is generally underrecognized and undertreated. Major depression during pregnancy or after delivery can have devastating consequences for affected women, their children, and families. Among new mothers, one of the most significant contributions to their mortality rate is suicide, which is most common among women with mental illness (Koren, 2012; Palladino, 2011). If left untreated, up to 25 percent of women with postpartum depression will be depressed 1 year later. As the duration of depression increases, so too do the number of sequelae and their severity. In addition, maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child.

Treatment

Antidepressant medications, along with some form of psychotherapy, are indicated for severe depression during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2012b). Shown in [Figure 61-1](#) is one algorithm regarding initiation of treatment of mood disorders and management with a mental health professional. In women with severe depression a selective serotonin-reuptake inhibitor—SSRI—should be tried initially ([Table 61-3](#)). Tricyclic antidepressants and monoamine oxidase inhibitors are infrequently used in contemporary practice. If depressive symptoms improve during a 6-week trial, the medication should be continued for a minimum of 6 months to prevent relapse (Wisner, 2002). If the response is suboptimal or a relapse occurs, another SSRI is substituted, or psychiatric referral is considered. Mozurkewich and associates (2013) reported no salutary effects of docosahexaenoic acid (DHA) to prevent perinatal depression.

Importantly, in a recent metaanalysis by Huang and colleagues (2014), women using antidepressants during pregnancy were found to be at increased risk for preterm birth and low-birthweight neonates. Nevertheless, in their review of antidepressant medication use in pregnancy, Ray and Stowe (2014) concluded that the relative reproductive safety data is reassuring and that antidepressants remain a viable treatment option.

Recurrence some time after medication is discontinued develops in 50 to 85 percent of women with an initial postpartum depressive episode. Women with a history of more than one depressive episode are at greater risk (American Psychiatric Association, 2000a). Surveillance should include monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

Fetal Effects of Therapy

Some known and possible fetal and neonatal effects of treatment are listed in [Table 61-3](#). Studies implicating SSRIs with an increased teratogenic risk for fetal cardiac defects were

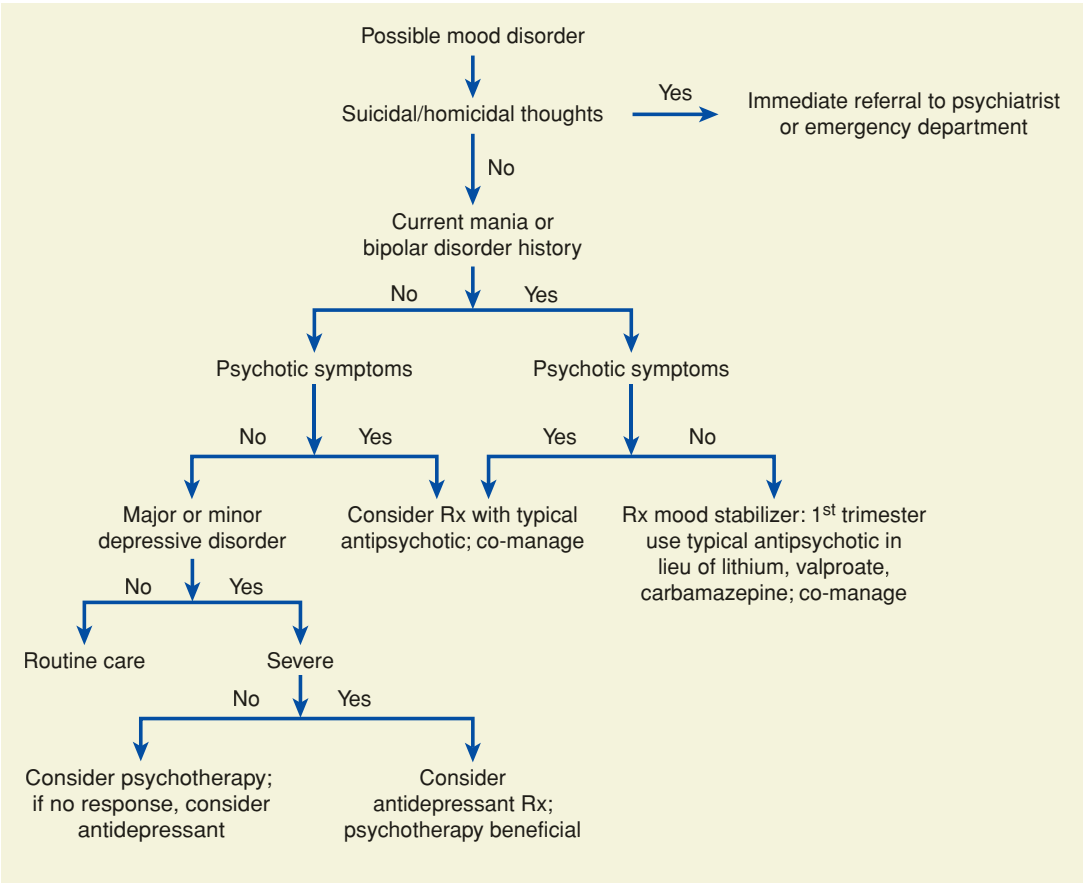

FIGURE 61-1 Treatment algorithm of pregnant women with mood disorders. (Modified from Yonkers, 2011.)

TABLE 61-3. Some Drugs Used for Treatment of Major Mental Disorders in Pregnancy

Indication of Class	Examples	Comments
Antidepressants		
SSRIs ^a	Citalopram, fluoxetine, paroxetine, sertraline	Possible link with heart defects; neonatal withdrawal syndrome; possible persistent pulmonary hypertension ^a ; paroxetine use avoided by some
Others	Bupropion, duloxetine, nefazodone, venlafaxine	
Tricyclics	Amitriptyline, desipramine, doxepin, imipramine, nortriptyline	Not commonly used currently; no evidence of teratogenicity
Antipsychotics		
Typical	Chlorpromazine, fluphenazine, haloperidol, thiothixene	
Atypical	Aripiprazole, clozapine, olanzapine, risperidone, ziprasidone	
Bipolar Disorders		
Lithium ^a	Lithium carbonate	Tx manic episodes; teratogen—heart defects, viz., Ebstein anomaly; few data after 12 wks
Valproic acid ^b		
Carbamazepine ^b		
Antipsychotics	See above	

^aChapter 12 (p. 250). ^bChapter 60 (p. 1190).

SSRI = selective serotonin-reuptake inhibitor; Tx = treat.

Data from American College of Obstetricians and Gynecologists, 2012b; Briggs, 2011; Buhimschi, 2009; Physicians' Desk Reference, 2012.

isolated to paroxetine and were most consistent for ventricular septal defects (VSDs). It is estimated that the risk is no greater than 1 in 200 exposed infants (Koren, 2012). Nevertheless, the American College of Obstetricians and Gynecologists (2012b) has recommended that paroxetine be avoided in women who are either pregnant or planning pregnancy. Fetal echocardiography should be considered in women exposed to paroxetine in the first trimester.

In a case-control study, there was a sixfold increased risk of persistent pulmonary hypertension of the newborn (PPHN) in infants exposed to SSRIs after 20 weeks (Chambers, 2006). This translates to an overall risk of pulmonary hypertension that would be less than 1 in 100 exposed infants (Koren, 2012). In contrast, a population-based cohort study of 1.6 million pregnancies from Nordic countries identified a twofold increased risk in exposed neonates. It was estimated that this yields an attributable risk of 2 per 1000 births (Kielar, 2012). This marginally increased risk must be weighed against the risk associated with discontinuing or tapering medication during pregnancy.

Women who abruptly discontinue either serotonin- or norepinephrine-reuptake inhibitor therapy typically experience some form of withdrawal. Not surprisingly, up to 30 percent of exposed neonates may also exhibit withdrawal symptoms. Symptoms are similar to opioid withdrawal, but typically are less severe. This condition—*neonatal behavioral syndrome*—is self-limited, and the newborn rarely remains in the nursery more than 5 days. (Koren, 2009). Currently, convincing evidence of long-term neurobehavioral effects of fetal exposure to these medications is lacking (Koren, 2012).

Some psychotropic medications pass into breast milk. However, in most cases, levels are very low or undetectable. Importantly, the average amount of drug detected in breast milk is higher with fluoxetine than most other reuptake inhibitors (National Library of Medicine, 2012). Adverse effects include transient irritability, sleep disturbances, and colic. Agents with lower excretion into breast milk may therefore be preferred.

Electroconvulsive Therapy

This form of depression treatment is occasionally necessary during pregnancy for women with major mood disorders unresponsive to pharmacotherapy. With proper preparation, the risks to both mother and fetus appear to be reasonable (Pinette, 2007). O'Reardon and coworkers (2011) reported a woman who underwent 18 electroconvulsive therapy (ECT) sessions during the second and third trimesters. She was delivered of a normal child without evidence of developmental delay up to 18 months of age. That said, adverse maternal and perinatal outcomes have been described from complications of convulsive therapy. Balki and associates (2006) reported a pregnancy in which fetal brain damage likely was caused by sustained maternal hypotension associated with treatment of status epilepticus stimulated by electroshock.

Women undergoing ECT should be fasting for at least 6 hours. They should be given a rapid-acting antacid before the procedure, and their airway should be protected to decrease the likelihood of aspiration. A wedge should be placed under the right hip to prevent sudden maternal hypotension from aortocaval

compression. Other important preparatory steps include cervical assessment, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation should be avoided. In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure.

There have been at least two reviews of ECT outcomes in pregnancy. In the earlier one, Miller (1994) found 300 cases and reported complications in 10 percent. These included fetal arrhythmias, vaginal bleeding, abdominal pain, and self-limited contractions. Women not adequately prepared had increased risks for aspiration, aortocaval compression, and respiratory alkalosis. In the more recent review, Andersen and Ryan (2009) described 339 cases, undoubtedly with some homology with the earlier study. In most cases, ECT therapy was done to treat depression, and it was 78-percent effective. They reported a 5-percent maternal ECT-related complication rate and a 3-percent associated perinatal complication rate that included two fetal deaths. For all of these reasons, we agree with Richards (2007) that ECT in pregnancy is not “low risk” and that it should be reserved for women whose depression is recalcitrant to intensive pharmacotherapy.

Bipolar and Related Disorders

According to the National Institute of Mental Health (2010), the lifetime prevalence for manic-depression illness is 3.9 percent. There is no difference in the prevalence of bipolar disorder between pregnant women and nonpregnant reproductive-aged women (Yonkers, 2011). It has a strong genetic component and has been linked to possible mutations on chromosomes 16 and 8 (Jones, 2007). The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk for first-degree relatives is 5 to 10 percent (Muller-Oerlinghausen, 2002). Periods of depression last at least 2 weeks. At other times, there are manic episodes, distinct periods during which there is an abnormally raised, expansive, or irritable mood. Potential organic causes of mania include substance abuse, hyperthyroidism, and central nervous system tumors. Importantly, however, pregnancy frequently prompts medication discontinuation, and this translates to a twofold increased risk for relapse during pregnancy (Viguera, 2007). Up to 20 percent of patients with manic-depression illness commit suicide.

Typical therapy for bipolar disorder includes mood stabilizers such as lithium, valproic acid, and carbamazepine, as well as antipsychotic medications (see Table 61-3). As depicted in Figure 61-1, treatment of bipolar disorder in pregnancy is complex and should be co-managed with a psychiatrist. Treatment decisions include risks versus benefits of using mood stabilizers, some of which are teratogenic. For example, lithium has been linked to Ebstein anomaly in exposed infants (Chap. 12, p. 250). More recent data, however, suggest a lower risk of cardiac malformations than previously indicated (Reprotox, 2012). Nevertheless, fetal echocardiography is recommended by many for exposed fetuses. There is some limited evidence suggesting that lithium in breast milk can adversely affect the infant when its elimination is impaired as

in dehydration or immaturity (Davanzo, 2011). Lithium use in mothers with a healthy term fetus, however, is considered moderately safe. A more detailed discussion of other mood stabilizers and antipsychotic medications side effects can be found in Chapter 12 (p. 250).

Postpartum Psychosis

This severe mental disorder is usually a bipolar disorder, but it may be due to major depression (American Psychiatric Association, 2013). Its incidence is estimated to be 1 in every 1000 deliveries, and it is more common in primiparas, especially those with obstetrical complications (Bergink, 2011; Blackmore, 2006). In most cases, illness manifests within 2 weeks of delivery. In a case-control study of postpartum women with their first lifetime episode of psychosis, the median onset of psychiatric symptoms was 8 days after delivery, and the median duration of the episode was 40 days (Bergink, 2011).

The most important risk factor for postpartum psychosis is a history of bipolar disease. These women typically exhibit symptoms sooner—1 to 2 days after delivery (Heron, 2007, 2008). Manic symptoms include feeling excited, elated, “high”; not needing sleep or unable to sleep; feeling active or energetic; and feeling “chatty.” Affected women have signs of confusion and disorientation but may also have episodes of lucidity. Because those with underlying disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is imperative. Postpartum psychosis has a 50-percent recurrence risk in the next pregnancy. As a result, Bergink and colleagues (2012) recommend initiating lithium therapy immediately postpartum in women with a history of postpartum psychosis.

The clinical course of bipolar illness with postpartum psychosis is comparable with that for nonpregnant women. Patients usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly (Kim, 2008). In most instances, women with postpartum psychosis ultimately develop relapsing, chronic psychotic manic-depression.

Anxiety Disorders

These relatively common disorders—18 percent prevalence overall—include panic attack, panic disorder, social anxiety disorder, specific phobia, separation anxiety disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, which are accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Schneier, 2006). They are treated with psychotherapy and medication, including selective serotonin-reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, and others.

Pregnancy

Despite their relative high prevalence in childbearing-aged women as shown in Table 61-1, little specific attention has been directed to anxiety disorders in pregnancy. Most reports conclude that there is no difference in rates in between preg-

nant and nonpregnant women. One recent analysis of 268 pregnant women with generalized anxiety disorder demonstrated that both symptoms and severity of anxiety decrease across pregnancy (Buist, 2011). Older studies indicate increased risks for adverse pregnancy outcomes with some of these disorders (American College of Obstetricians and Gynecologists, 2012b).

From their review, Ross and McLean (2006) concluded that some of the anxiety disorders may have important maternal-fetal implications. Some have been linked to preterm birth and fetal-growth restriction as well as poor neurobehavioral development (Van den Bergh, 2005). Children with a history of in utero exposure to maternal anxiety are felt to be at increased risk for a variety of neuropsychiatric conditions such as attention deficit/hyperactivity disorder (ADHD). Hunter and coworkers (2012) analyzed infants of 60 mothers with an anxiety disorder and found that auditory sensory gating—a reflection of inhibitory neurotransmission—was impaired, particularly in offspring of untreated women. Conversely, Littleton and associates (2007) found no excessive adverse pregnancy outcomes with “anxiety symptoms.” One important exception is their link with postpartum depression (Vythilingum, 2008).

Treatment

Mood and anxiety disorders coexist in more than half of women identified with either diagnosis (Frieder, 2008). Anxiety disorders can be effectively treated during pregnancy with psychotherapy, cognitive behavioral therapy, or medications. Antidepressants listed in Table 61-3 are often the first line of pharmacotherapy. Benzodiazepines are also commonly used to treat anxiety or panic disorders before and during pregnancy. Earlier case-control studies linked use of these central nervous system depressants to an increased risk for cleft lip and palate. However, a recent metaanalysis that included more than 1 million exposed pregnancies did not identify a teratogenic risk (Enato, 2011). Benzodiazepines, especially when taken during the third trimester, can cause neonatal withdrawal syndrome, which persists for days to weeks after delivery.

Schizophrenia Spectrum Disorders

This major form of mental illness affects 1.1 percent of adults (see Table 61-1). Schizophrenia spectrum disorders are defined by abnormalities in one or more of the following domains: delusions, hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms. Brain-scanning techniques such as positron-emission tomography (PET) and functional magnetic resonance imaging (fMRI) have shown that schizophrenia is a degenerative brain disorder. Subtle anatomical abnormalities are present early in life and worsen with time.

Schizophrenia has a major genetic component, and there is a 50-percent concordance in monozygotic twins. If one parent has schizophrenia, the risk to offspring is 5 to 10 percent. Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest that associated genes are located on chromosome 22q11 (Murphy, 2002).

But sophisticated gene mapping studies have shown clearly that schizophrenia is not related to a single gene or mutation. Instead, there are multiple DNA variants that likely interact to lead to schizophrenia (Kukshal, 2012). Other putative risk factors for subsequent schizophrenia in an exposed fetus include maternal iron deficiency anemia, diabetes, and acute maternal stress (Insel, 2008; Malaspina, 2008; Van Lieshout, 2008). These remain unproven, as does the association with maternal influenza A (Chap. 64, p. 1241).

Signs of illness begin approximately at age 20 years, and commonly, work and psychosocial functioning deteriorate over time. Women have a slightly later onset than men and are less susceptible to autism and other neurodevelopmental abnormalities. Thus, many investigators theorize that estrogen is protective. Affected women may marry and become pregnant before symptoms manifest. With appropriate treatment, patients may experience a decrease or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 2013).

Pregnancy

There has been an apparent increase in relative fertility in schizophrenic women (Solari, 2009). Most studies have not found adverse maternal outcomes, although researchers in a Swedish study noted increased risks of low birthweight, fetal-growth restriction, and preterm delivery (Bennedsen, 1999). In an Australian study of more than 3000 pregnancies in schizophrenic women, Jablensky and colleagues (2005) reported that placental abruption was increased threefold and “fetal distress”—vaguely defined—was increased 1.4-fold.

Treatment

Because schizophrenia has a high recurrence if medications are discontinued, it is advisable to continue therapy during pregnancy. After 40 years of use, there is no evidence that conventional or “typical” antipsychotic drugs listed in Table 61-3 cause adverse fetal or maternal sequelae (McKenna, 2005; Robinson, 2012; Yaeger, 2006). Because less is known about “atypical” antipsychotics, the American College of Obstetricians and Gynecologists (2012b) recommends against their routine use in pregnant and breast-feeding women. In response to adverse event reports, the Food and Drug Administration (2011) issued a safety communication alerting health-care providers concerning some antipsychotic medications. These have been associated with neonatal extrapyramidal and withdrawal symptoms similar to the neonatal behavioral syndrome seen in those exposed to selective serotonin-reuptake inhibitors.

Feeding and Eating Disorders

These severe disturbances in eating behavior largely affect adolescent females and young adults with a lifetime prevalence of 2 to 3 percent each (see Table 61-1). They include *anorexia nervosa*, in which the patient refuses to maintain minimally normal body weight. With *bulimia nervosa*, there usually is binge eating followed by purging or by excessive fasting to maintain normal body weight (Zerbe, 2008). Bulik

and coworkers (2009) studied pregnancy outcomes in almost 36,000 Norwegian women screened for eating disorders. Approximately 0.1 percent—1 in 1025—had anorexia nervosa; 0.85 percent—1 in 120—had bulimia nervosa; and 5.1 percent reported a binge-eating disorder—a 6-percent pregnancy prevalence similar to the 6-month prevalence for non-pregnant individuals (see Table 61-1). The last subtype had a higher risk for large-for-gestational age infants with a concomitantly increased cesarean delivery rate. All eating disorders begin with the desire to be slim, and women with chronic eating disorders may migrate between subtypes (Andersen, 2009).

Pregnancy

As discussed in Chapter 18 (p. 352), there is an increased risk for pregnancy complications with both eating disorders, but especially in women with bulimia nervosa (Andersen, 2009; Hoffman, 2011; Sollid, 2004). Generally, eating disorder symptoms improve during pregnancy, and remission rates may reach 75 percent. In contrast, what may appear as a typical case of hyperemesis gravidarum could actually be a new or relapsing case of bulimia nervosa or of anorexia nervosa, binge-purge type (Torgerson, 2008). As perhaps expected, anorexia is associated with low-birthweight infants (Micali, 2007). Additional risks associated with eating disorders include poor wound healing and difficulties with breast feeding (Andersen, 2009). At a minimum, closely monitoring gestational weight gain in women with a suspected history of an eating disorder seems prudent.

Personality Disorders

These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. They are rigid and unyielding personality traits. The American Psychiatric Association (2013) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.

Genetic and environmental factors are important in the genesis of these disorders, whose prevalence may be as high as 20 percent. Although management is through psychotherapy, most affected individuals do not recognize their problem, and thus only 20 percent seek help. In an observational study of 202 women with borderline personality disorder, De Genna and associates (2012) demonstrated that such women become pregnant during the most severe trajectory of their illness. They are at increased risk for teen and unintended pregnancies, however, it was not a risk factor for elective or spontaneous abortion.

Pregnancy

Personality disorders during pregnancy are probably no different than in nonpregnant women. Management of women with

some of these disorders may be vexing. Akman and colleagues (2007) reported that avoidant, dependent, and obsessive-compulsive disorders are associated with an excessive prevalence of postpartum major depression. Magnusson and associates (2007) found a link between some *personality traits*—not disorders—and excessive alcohol consumption, but not necessarily addiction or dependence. Conroy and coworkers (2010) found that a mother's ability to care for her newborn was obviously impaired only when a personality disorder was coupled with depression.

CHAPTER 62

Dermatological Disorders

PREGNANCY-SPECIFIC DERMATOSES 1214

DERMATOLOGICAL CONDITIONS NOT SPECIFIC TO PREGNANCY 1216

DERMATOLOGICAL TREATMENT 1217

Normal physiological changes of pregnancy include alterations to skin, hair, and nails as discussed in Chapter 4 (p. 51). In addition, several dermatoses are seen only in pregnancy. Finally, it is axiomatic that skin diseases that affect childbearing-age women are commonly encountered in pregnancy.

PREGNANCY-SPECIFIC DERMATOSES

Four dermatoses considered unique to pregnancy include intrahepatic cholestasis of pregnancy, pruritic urticarial papules and plaques of pregnancy (PUPPP), atopic eruption of pregnancy (AEP), and pemphigoid gestationis (Table 62-1). As a group, these are diagnosed in up to 5 percent of pregnancies with the following relative occurrences: intrahepatic cholestasis 1 in 100; PUPPP, 1 in 130 to 350; atopic eruptions, 1 in 300 to 450, and pemphigoid, 1 in 50,000 (Chander, 2011). Their gross appearance may be similar to each other or to other skin disorders, and pruritus is a common feature of all four. Only intrahepatic cholestasis and pemphigoid gestationis have been linked with adverse fetal outcomes.

Intrahepatic Cholestasis of Pregnancy

Previously termed pruritus gravidarum and in contrast to the other pregnancy-specific dermatoses, intrahepatic cholestasis of pregnancy generally has no primary skin lesions. Rarely, a rash preceded pruritus (Chao, 2011). Pruritus is associated with abnormally elevated serum bile acid levels, and hepatic

aminotransferase levels may also be mildly increased. Adverse fetal affects have been linked to this condition, and it is discussed in detail in Chapter 55 (p. 1084).

Pemphigoid Gestationis

This rare autoimmune bullous disease is notable for its maternal and fetal effects. Initially, pruritic papules and urticarial plaques form and are then followed in most cases after 1 to 2 weeks by vesicles or bullae. Lesions are frequently distributed periumbilically, and they often develop on other skin surfaces with sparing of mucous membranes, scalp, and face (Fig. 62-1).

Previously termed *herpes gestationis*, pemphigoid gestationis is not related to the herpesvirus. It is a result of a primary reaction between maternal immunoglobulin G (IgG) antibodies directed against collagen XVII found in the basement membrane of skin as well as amnionic epithelium (Kelly, 1988; Shimanovich, 2002). Collagen XVII is also termed bullous pemphigoid 180 (BP 180). Autoantibody binding to collagen XVII, either in the amnion or in the skin, activates complement to promote eosinophil chemotaxis to the antigen-antibody complexes on the basement membrane. Eosinophilic degranulation damages the dermal-epidermal junction with blister formation (Engineer, 2000).

Pregnancy

In most cases, pemphigoid gestationis develops during a first pregnancy, and it may rarely be associated with gestational trophoblastic disease (Takatsuka, 2012). Most subsequent pregnancies are also affected and usually earlier and more severely. Whites have a higher incidence, and other autoimmune diseases are common in affected women (Shornick, 1984, 1992).

Pemphigoid gestationis usually begins during the second or third trimester. The disease course is frequently marked by antepartum exacerbations and remissions and by intrapartum flares (Shornick, 1998). It is possible that there is an association

TABLE 62-1. Pregnancy-specific Dermatoses

Disorder	Frequency	Characteristic Lesion	Adverse Pregnancy Effects	Treatment
Cholestasis of pregnancy	Common	No primary lesions, secondary excoriations from scratching	Increased perinatal morbidity	Antipruritics, cholestyramine, ursodeoxycholic acid
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	Common	Erythematous pruritic papules or plaques; patchy or generalized on abdomen, thighs, buttocks, especially within striae, but with umbilical sparing	None	Antipruritics, emollients, topical corticosteroids, oral steroids if severe
Atopic eruptions of pregnancy (AEP)			None	
Eczema of pregnancy	Common	Dry, red scaly patches on extremity flexures, neck, face		
Prurigo of pregnancy	Common	1–5 mm pruritic red papules on extensor surfaces, trunk		
Pruritic folliculitis of pregnancy	Rare	Small red papules, sterile pustules on trunk		
Pemphigoid gestationis	Rare	Erythematous pruritic papules, plaques, vesicles, and bullae; abdomen often with umbilical involvement, extremities	Preterm birth, fetal-growth restriction, transient neonatal lesions	

of pemphigoid gestationis with preterm birth and fetal-growth restriction, especially with early-onset disease and with blistering (Chi, 2009). These theoretically may result from mild placental insufficiency stemming from IgG and complement deposition along the amnionic basement membrane (Huilaja, 2013). Because of this, antepartum surveillance of affected pregnancies may be prudent.

In approximately 10 percent of neonates, IgG antibodies passively transferred from the mother will cause similar skin lesions in the newborn (Erickson, 2002). These eruptions require only wound care and clear spontaneously within a few weeks as the passively acquired IgG levels decrease.

Slowly following delivery, maternal lesions resolve without scarring, and most women are disease-free after 6 months

(Jenkins, 1999). In some, however, resolution is protracted, and disease may be exacerbated during menses or by oral contraceptives (Semkova, 2009).

Diagnosis and Treatment

Before bullae form, these lesions may resemble PUPPP (p. 1216). Other diagnoses include pustular psoriasis of pregnancy, dermatitis herpetiformis, erythema multiforme, linear IgA bullous dermatosis, urticaria, allergic contact dermatitis, bullous pemphigoid, and atopic eruptions of pregnancy (Lipozenčić, 2012). Drug-induced blistering syndromes must also be excluded, as some are life-threatening. Examples include Stevens-Johnson syndrome and toxic epidermal necrolysis (Stern, 2012).

FIGURE 62-1 Pemphigoid gestationis. **A.** Bullae commonly develop within erythematous plaques. (Photograph contributed by Dr. Amit Pandya.) **B.** Abdominal lesions classically involve the umbilicus. **C.** Lesions on the wrist and forearm are shown here. (Photographs contributed by Dr. Kara Ehlers.)

Skin biopsy and serum antibody assays may be informative (Semkova, 2009). Immunofluorescent skin tissue staining is the gold standard, and C3 complement and sometimes IgG are seen deposited along the basement membrane between the epidermis and the dermis (Katz, 1976). Also, in many cases, circulating IgG antibodies against collagen XVII may be detected in patient serum (Powell, 2005; Sitaru, 2004).

Pruritus can be severe. Early in its course, topical high-potency corticosteroids and oral antihistamines may be effective. Oral prednisone, 0.5 to 1 mg/kg daily gradually tapered to a maintenance dose, may be needed for relief and also inhibition of new lesions. Plasmapheresis or high-dose intravenous immunoglobulin (IVIG) therapy has been used in intractable cases (Gan, 2012; Van de Wiel, 1980).

■ Pruritic Urticarial Papules and Plaques of Pregnancy (PUPPP)

This relatively common pregnancy-specific dermatosis is characterized by its intensely pruritic 1- to 2-mm erythematous papules that coalesce to form urticarial plaques and by its benign effects on pregnancy (Rudolph, 2005). Its cause is unknown, but it is not an autoimmune dermatosis. Also known as polymorphic eruption of pregnancy, PUPPP usually appears late in pregnancy, but 15 percent begin postpartum (Buccolo, 2005). The rash affects the abdomen and proximal thighs in 97 percent of women (Fig. 62-2). Lesions often initially form within striae but show periumbilical sparing. Rarely, the face, palms, and soles may be involved (High, 2005). It is more frequently seen in white and nulliparous women, those with multifetal gestation, and those carrying a male fetus (Regnier, 2008). It seldom recurs in subsequent pregnancies (Ahmadi, 2005).

Diagnosis and Treatment

PUPPP may be compared with a number of skin eruptions. Some include contact dermatitis, drug eruption, viral exanthem, insect bites, scabies infestation, pityriasis rosea, and the other pregnancy-specific dermatoses. It also may appear similar to early pemphigoid gestationis that has not yet blistered. In unclear cases, skin biopsy and negative serum collagen XVII antibody levels help to differentiate the two. Pruritus will usually respond

FIGURE 62-2 Pruritic urticarial papules and plaques of pregnancy (PUPPP) shows small papules within abdominal striae.

to treatment with oral antihistamines, skin emollients, and topical corticosteroids. A small number of women will need systemic corticosteroids to relieve severe itching (Scheinfeld, 2008).

PUPPP usually resolves within several days following delivery and leaves no scarring. In 15 to 20 percent of women, however, symptoms persist for 2 to 4 weeks postpartum (Vaughan Jones, 1999).

■ Atopic Eruption of Pregnancy (AEP)

This umbrella term is thought by some authorities, but not all, to encompass three conditions previously considered separate: eczema in pregnancy, prurigo of pregnancy, and pruritic folliculitis of pregnancy (Ambros-Rudolph, 2006; Cohen, 2007; Ingber, 2010). Two thirds of women with AEP have widespread eczematous changes, whereas the other third have papular lesions. As a group, these pose no adverse risk to the fetus. Diagnosis is greatly aided by a history of atopy and by rash characteristics.

Eczema in pregnancy has the appearance of traditional eczema but with a pregnancy onset. It is the most common pregnancy-specific dermatosis, and affected skin shows dry, thickened, scaly, red patches involving extremity flexures, nipples, neck, and face. In contrast, *prurigo of pregnancy*, also known as prurigo gestationis, is characterized by 5- to 10-mm, itchy, erythematous papules or nodules commonly found on the extensor surfaces and trunk. Last, *pruritic folliculitis of pregnancy* is rare and notable for small, erythematous follicular papules and sterile pustules predominantly on the trunk. Onset for all is during the second or third trimester, although eczema in pregnancy may develop earlier than the other two. All lesions commonly resolve with delivery, but may persist for up to 3 months postpartum. Recurrence with subsequent pregnancies is variable but common.

Diagnosis is one of exclusion. Serum bile acid levels are elevated to concentrations expected for normal pregnancy, and aminotransferase levels are normal. Serology specific for pemphigoid gestationis is negative. Many women with eczema of pregnancy have elevated serum IgE levels, which are not seen with the two other AEP dermatoses (Ambros-Rudolph, 2011).

For all three manifestations, skin lesions and pruritus are usually controlled with low- or moderate-potency topical corticosteroids and oral antihistamines. For severe eczema, second-line agents include short-course ultrapotent topical corticosteroids. However, oral corticosteroids, narrow-band ultraviolet B, or cyclosporine are occasionally required (Koutroulis, 2011).

DERMATOLOGICAL CONDITIONS NOT SPECIFIC TO PREGNANCY

Any chronic dermatological disorders can complicate pregnancy. *Acne* is unpredictably affected by pregnancy and if necessary, is treated with benzoyl peroxide, azelaic acid, or topical erythromycin, which are category B drugs (Krauthaim, 2003). Topical retinoids, which include tretinoin, adapalene, and tazarotene, also appear safe, but are probably best avoided during pregnancy, especially during the first trimester (Akhavan, 2003). If topical antibiotics are required, benzoyl peroxide plus

erythromycin is advocated to minimize *Propionibacterium acnes* drug resistance (Strauss, 2007; Thiboutot, 2009). With topical salicylic acid, systemic absorption is variable, and efforts to minimize absorption are encouraged (Lam, 2008).

Psoriasis also has a variable course during pregnancy, however, postpartum flares are common with nonsevere disease (Oumeish, 2006). Emollients and low- or moderate-potency topical corticosteroids are given initially. Anthralin and ultraviolet B phototherapy can also be used (Weatherhead, 2007). In resistant cases, restrained use of topical preparations such as high-potency or ultrapotent corticosteroids, calcipotriene, and coal tar appear to be safe in the second and third trimesters, and cyclosporine also may be used (Rosmarin, 2010; Ryan, 2010). With severe disease, a small increased risk for low-birthweight neonates has been shown by some (Lima, 2012; Yang, 2011). Also, in general, psoriatic patients have higher associated rates of depression (Rieder, 2012).

Psoriasis is most commonly of the chronic plaque variety. In contrast, with *generalized pustular psoriasis of pregnancy*—formerly called impetigo herpetiformis—severe systemic symptoms may develop. This rare pustular form has erythematous, sometimes pruritic, plaques ringed by sterile pustules that enlarge and then crust. Lesions initially involve intertriginous areas but may spread to the torso, extremities, and oral mucosa. Constitutional symptoms are common. For accurate diagnosis, skin biopsy is typically required (Roth, 2011). Extensive lesions can lead to sepsis from secondary infection and to massive fluid loss with hypovolemia and placental insufficiency. Treatment is with systemic corticosteroids along with antimicrobials for secondary infection, and cyclosporine is used in refractory cases (Geraghty, 2011; Huang, 2011). Pustular psoriasis typically resolves quickly in the puerperium, but recurrences have been reported in subsequent pregnancies and with menstruation or oral contraceptive use.

Erythema nodosum is a cutaneous reaction associated with numerous disorders that include pregnancy, but typically it is caused by infections, sarcoidosis, drugs, Behçet's syndrome, inflammatory bowel disease, or a malignancy (Mert, 2007; Papagrigoraki, 2010). Characteristically, 1- to 5-cm tender, red, warm nodules and plaques develop rapidly on the extensor surface of the legs and arms. Within a few days, lesions flatten and undergo the color evolution of a bruise—from dark red and purple to yellow green. Constitutional symptoms may also be present (Requena, 2007). Initial evaluation and treatment focuses on the underlying etiology.

Pyogenic granuloma are frequently seen in pregnancy. This is a lobular capillary hemangioma commonly forming on the mouth or hand in response to low-grade local irritation or traumatic injury (Fig. 62-3). They grow quickly and bleed with minimal provocation. Active bleeding can be controlled with pressure and application of a silver nitrate stick or Monsel paste (ferric subsulfate). These growths often resolve within months postpartum. But with symptomatic or postpartum lesions, or with unclear diagnosis, excision can be done using suture and scalpel, electrosurgical curettage, laser photocoagulation, or cryotherapy. Oral lesions are best referred to oral health-care specialists.

Rosacea fulminans—also known as pyoderma faciale—is characterized by facial pustules and coalescing draining sinuses.

FIGURE 62-3 Pyogenic granuloma is characterized grossly by a lobulated red growth on a pedunculated or sessile base. (Photograph contributed by Dr. Abel Moron.)

It may rarely complicate pregnancy. Topical or oral antimicrobials are primary treatment, although surgical drainage and corticosteroids have also been used (Fuentelsaz, 2011; Jarrett, 2010). *Hidradenitis suppurativa* has been said to improve with pregnancy, but in our experiences, it is not appreciably changed. Oral antimicrobials or clindamycin gel are initial choices. *Neurofibromatosis* lesions may increase in size and number as a result of pregnancy. Other skin conditions that are discussed include hirsutism and melanoma (Chap. 63, p 1233), cutaneous lupus (Chap. 59, p. 1169), and skin lesions seen with infections (Chaps. 64 and 65, p. 1239).

DERMATOLOGICAL TREATMENT

Local skin care, oral antihistamines, and topical corticosteroids are commonly used for many dermatoses. Oral antihistamines are given for pruritus. Suitable options include first-generation agents such as diphenhydramine (Benadryl), 25 to 50 mg every 6 hours, or chlorpheniramine (Chlor-Trimeton), 4 mg every 6 hours. Second-generation agents—loratadine (Claritin) 10 mg daily and cetirizine (Zyrtec) 5 or 10 mg daily—may produce less sedation and are also pregnancy category B.

Hundreds of topical corticosteroid preparations are available, and in the United States, these are categorized by potency into seven groups. For initial treatment of dermatological disorders, low- or moderate-potency agents are preferred. Low-potency agents include those in groups 6 and 7, such as 1-percent hydrocortisone or 0.05-percent desonide (DesOwen). Moderate-potency drugs are in groups 5, 4, and 3—such as 0.1-percent triamcinolone acetonide (Aristocort) or 0.1-percent mometasone furoate (Elocon). High-potency medications are in group 2, such as 0.05-percent betamethasone dipropionate (Diprolene). Ultrapotent agents in group 1, such as 0.05-percent clobetasol propionate (Temovate), are best reserved for refractory disorders and used for only 2 to 4 weeks on small surface areas.

Mild and moderate strengths are not associated with adverse pregnancy outcomes, whereas high- and ultrapotent agents pose a small risk for fetal-growth restriction if used long-term. Even

then, this risk is less than that with systemic corticosteroids (Chi, 2011). Importantly, with any topical agent, factors that increase systemic absorption include a large surface area treated, compromised epidermal barrier, occlusive dressings, prolonged treatment duration, and coadministration of topical agents that increase absorption.

With some severe skin diseases, systemic immune modulating agents, such as corticosteroids and cyclosporine, may be required. Although these are not contraindicated in pregnancy, their risks must be balanced against therapeutic benefits. Of these, cyclosporine is not recommended with breast feeding (Rosmarin, 2010). Bacterial infections are a potential secondary complication of skin disorders and are treated promptly with oral antimicrobial agents with gram-positive coverage. Therapeutic agents to be avoided during pregnancy include methotrexate, psoralen plus ultraviolet A, biological agents, mycophenolate mofetil, and systemic retinoids (Lam, 2008). These are discussed in more detail in Chapter 12 (p. 250).

CHAPTER 63

Neoplastic Disorders

PRINCIPLES OF CANCER THERAPY RELATED TO PREGNANCY	1219
REPRODUCTIVE TRACT NEOPLASMS	1221
BREAST CARCINOMA	1229
THYROID CANCER	1231
LYMPHOID CELL MALIGNANCIES	1231
MALIGNANT MELANOMA	1233
GASTROINTESTINAL TRACT CANCER	1233
MISCELLANEOUS TUMORS	1234

Neoplasms are commonly found in pregnant women. Although most are benign, if a malignancy complicates pregnancy, then usual management schemes become problematic. Uterine leiomyomas and ovarian cysts are the most frequently encountered benign neoplasms during pregnancy. Malignancies have an incidence of approximately 1 per 1000 pregnancies (Brewer, 2011). One third are diagnosed prenatally and the others within 12 months of delivery. Some of the more common cancers found in pregnant women are shown in [Figure 63-1](#). Of these, the three most common are breast—1 per 5000 pregnancies, thyroid—1 per 7000, and cervical—1 per 8500 (Smith, 2003). These, along with lymphoma and melanoma, account for 65 percent of cancer cases in pregnancy (Eibye, 2013).

PRINCIPLES OF CANCER THERAPY RELATED TO PREGNANCY

Management of the pregnant woman with cancer poses unique problems related to fetal concerns. Because of these, treatment must be individualized. Considerations include the type and

stage of cancer and the desire for pregnancy continuation with the inherent risks associated with modifying or delaying treatment.

Surgery

Operative procedures indicated for cancer include those for diagnosis, staging, or therapy. Fortunately, most procedures that do not interfere with the reproductive tract are well tolerated by both mother and fetus (Chap. 46, p. 927). Although many procedures have classically been deferred until after 12 to 14 weeks' gestation to minimize abortion risks, this probably is not necessary. We are of the opinion that surgery should be performed regardless of gestational age if maternal well-being is imperiled.

Both pregnancy and malignancy are risk factors for venous thromboembolism. There are no guidelines specific for thromboprophylaxis in pregnant women undergoing surgical procedures for cancer. Thus, depending on the complexity of the planned procedure, it seems reasonable to use mechanical prophylaxis compression or pneumatic stockings, low-molecular-weight heparin, or both (Chap. 52, p. 1044). There are general evidenced-based practice guidelines available from the American College of Chest Physicians (Guyatt, 2012).

Diagnostic Imaging

Sonography is a preferred imaging tool during pregnancy when appropriate. In addition, according to the American College of Obstetricians and Gynecologists (2009), most diagnostic radiographic procedures have very low x-ray exposure and should not be delayed if they would directly affect therapy (Chap. 46, p. 932). Computed tomography is useful for imaging extraabdominal tumors, and abdominal shielding usually helps to decrease fetal exposure. Routine magnetic resonance (MR) imaging use is not recommended, and if needed, is used preferentially after the first trimester.

FIGURE 63-1 Proportion of malignancies during pregnancy and within 12 months of delivery in 4.85 million women from the California Cancer Registry. GI = gastrointestinal. (Data from Smith, 2003.)

Gadolinium contrast administered with MR imaging crosses the placenta, resulting in high fetal concentrations. It should not be used in the first trimester and should be used later in pregnancy only when the benefits overwhelmingly outweigh the risks (Kanal, 2007). Some radioisotopes are relatively safe, but positron emission tomography (PET) scanning is usually not performed during pregnancy. Moreover, ^{18}F -FDG (fludeoxyglucose) is concentrated in both breast tissue and milk. Thus, in the puerperium, breast feeding should be discontinued for 72 hours following a procedure (Rizack, 2009).

Radiation Therapy

Therapeutic radiation often results in significant fetal exposure depending on the dose, tumor location, and field size. The most susceptible period is organogenesis, although there is no gestational age considered safe for therapeutic radiation exposure. Adverse effects include cell death, carcinogenesis, and mutagenic changes in future generations (Brent, 1999; Hall, 1991). Characteristic fetal effects are microcephaly and mental retardation, and even late exposure can cause growth restriction and brain damage. Thus, radiotherapy to the maternal abdomen is contraindicated. With some head and neck cancers, however, radiotherapy to supradiaphragmatic areas can be used relatively safely with abdominal shielding. In others, such as breast cancer, significant scatter doses can accrue to the fetus.

Chemotherapy

Various antineoplastic drugs may be given for primary treatment or for adjunctive therapy. Although chemotherapy often improves long-term maternal outcomes, many are reluctant to employ it during pregnancy. As discussed in Chapter 12

(p. 248), fetal concerns include malformations, growth restriction, mental retardation, and the risk of future malignancies. Risks are dependent primarily on fetal age at exposure, and most agents are potentially detrimental given in the first trimester during organogenesis. Indeed, embryonic exposure to cytotoxic drugs may cause major malformations in up to 20 percent of cases (Pavlidis, 2011).

After organogenesis, most antineoplastic drugs are without immediate obvious adverse sequelae (Abdel-Hady, 2012; Cardonick, 2004). Similarly, late mutagenic effects appear limited. Children born to 68 women receiving chemotherapy and who were assessed at 18 months had no excessive adverse effects to their central nervous system, heart, or hearing or to their general health or growth (Amant, 2012b).

Although not always practicable, some recommend that chemotherapy be withheld in the 3 weeks before expected delivery because neutropenia or pancytopenia might cause undue risk for maternal infection or hemorrhage. Another concern is that neonatal hepatic and renal clearance of chemotherapy metabolites is limited (Ko, 2011). For these reasons, chemotherapy is also contraindicated with breast feeding.

Molecular Therapy

Drugs designed to stimulate hemopoiesis are commonly used with cancer treatments. Some of these include the granulocyte colony-stimulating factors filgrastim (Neupogen) and pegfilgrastim (Neulasta). If required in pregnancy, limited data support the safety of these factors (Dale, 2003). Red blood cells can be stimulated by erythropoietin alfa (Procrit), which likely is also safe in pregnancy (Briggs, 2011).

Immunotherapy

Hybridized monoclonal antibodies directed against tumor-specific antigens are designed to treat an ever-increasing list of malignant neoplasms. Some of these drugs are described in the discussion of tumors for which they are used. Little is known regarding their fetal effects, but concerns for teratogenicity by tyrosine kinase inhibitors—for example, imatinib (Gleevec)—have been raised (Ali, 2009).

Fertility and Pregnancy after Cancer Therapy

The number of cancer survivors continues to increase. From the Childhood Cancer Survival Study (CCSS), a fourth of survivors have significant morbidity at 25 years (Diller, 2011). One is that subsequent fertility may be diminished after chemotherapy or radiotherapy, and couples should be counseled regarding potential risks (American Society for Reproductive Medicine, 2013). Guidelines for this counseling have been developed by the American Society of Clinical Oncology (Loren, 2013).

Embryo cryopreservation is standard and widely available, however, other methods are considered investigational and limited to referral centers. Some are oocyte or ovarian cryopreservation, preradiotherapy ovarian transposition, and/or ovarian suppression with gonadotropin-releasing hormone agonists before therapy. Educational materials concerning

these methods have been provided by a National Institutes of Health (NIH) interdisciplinary group—the Oncofertility Consortium (Woodruff, 2010). This is available online at: <http://oncofertility.northwestern.edu>.

Not surprisingly, abdominopelvic radiation impairs subsequent reproductive function (Wo, 2009). Data from the CCSS are informative for women who conceive following cancer therapy. Since the database was established in 1994, 4029 pregnancies have been reported in 1953 women. A number of reports have described increased adverse pregnancy outcomes by type of cancer treatment given. For example, fetuses born to women who had undergone prior pelvic radiation were more likely to have a birthweight < 2500 g (Green, 2002; Robison, 2005). There was a higher rate of preterm birth in cancer survivors—especially those given pelvic radiotherapy—compared with their siblings (Signorello, 2006). In another study of 917 pregnancies, cancer survivors had slightly higher rates of preterm birth and postpartum hemorrhage (Clark, 2007). In yet another study of 1657 women from the CCSS, Signorello and colleagues (2010) reported that uterine or ovarian irradiation significantly increased the risk of stillbirth and neonatal death. One possible explanation for adverse reproductive effects is that radiotherapy, but not chemotherapy, at a young age irreversibly reduces the uterine volume in survivors (Larsen, 2004). Perhaps the most reassuring findings from all of these studies are that fetuses of women who were treated in childhood with radiotherapy did not have significantly increased risks for congenital malformations (Lawrenz, 2012; Winther, 2009).

■ Placental Metastases

Tumors infrequently metastasize to the placenta. The most common types are malignant melanomas, leukemias, lymphomas, and breast cancer (Al-Adnani, 2007). Placentas from pregnancies in these and all other women with a malignancy should be sent for histological evaluation. Because tumor cells are usually confined within the intervillous spaces, fetal metastases are infrequent. Melanoma is the most common example, and typically fetal metastases are found in the liver or subcutaneous tissue with an 80-percent associated mortality rate (Alexander, 2003; Altman, 2003; Gottschalk, 2009).

REPRODUCTIVE TRACT NEOPLASMS

Benign neoplasms are common in the female reproductive tract and include leiomyomas, ovarian neoplasms, and endocervical polyps. Malignancies of these organs are the most frequent cancers encountered in pregnant women, and of these, cervical cancers make up the majority (Fig. 63-2).

■ Cervix

Endocervical Polyp

A number of benign, premalignant, and malignant cervical neoplasms are frequently recognized during pregnancy. Endocervical polyps are overgrowths of benign endocervical stroma covered by epithelium. If asymptomatic, these polyps

FIGURE 63-2 Frequency of reproductive-tract malignancies in 844 pregnant women. (Data from Haas, 1984; Lutz, 1977; Smith, 2003.)

are usually seen at the time of the initial pelvic examination, although they can cause bleeding at any time. They typically appear as single, red, smooth, elongated fleshy masses of variable size that extend outward from the endocervical canal. Typically benign, they can however be a source of Pap smear results describing atypical glandular cells of undetermined significance—AGUS. And although malignant transformation in these growths is uncommon, polypoid cervical cancers can mimic these (Chin, 2002; Younis, 2010). Thus, most recommend their removal and evaluation. Polyps with a slender stalk are removed by grasping the tumor with ring or polyp forceps. It is then twisted repeatedly about its base to strangulate feeding vessels. With repeated twisting, the base narrows and avulses. Monsel solution, which is ferric subsulfate, can be applied with pressure to the stalk stub for hemostasis. A thick-pedicle polyp may sometimes warrant surgical excision.

Epithelial Neoplasia

Pregnancy provides an opportune time to screen for premalignant and malignant cervical epithelial neoplasia, especially in women without regular access to health care. With prenatal Pap smear screening, the pregnancy status is noted on the requisition form because interpretation may be hindered by pregnancy-associated physiological changes (Connor, 1998). Some changes include glandular epithelial hyperplasia, Arias-Stella reaction, and presence of decidual cells.

Screening guidelines also applicable in pregnant women were updated in 2012 by the American Society for Colposcopy and Cervical Pathology (ASCCP). These include: (1) no screening until age 21, (2) cytology alone every 3 years in those aged 21 to 29 years, and (3) in those older than 30, human papillomavirus (HPV) and cytology co-testing every 5 years, or cytology alone every 3 years. Importantly, these broad guidelines do

not cover women in high-risk populations who may need more intensive screening. Examples include diethylstilbestrol (DES)-exposed women, cervical cancer survivors, and the immunocompromised (Saslow, 2012).

Oncogenic Human Papillomaviruses. Certain serovars of HPV are associated with high-grade intraepithelial lesions and invasive cancer. Some of these high-risk viruses—HPV types 16, 18, 31, 35, 45, 51, 52, and 56—may have an increased incidence in pregnant compared with nonpregnant women (Fife, 1996). Cotesting for such high-risk serotypes at the time of the Pap test is now incorporated into the recent screening guidelines for women 30 years and older. Cells can be collected directly into liquid-based cytology medium, namely, PreservCyt Solution of the ThinPrep Pap Test. Additionally, the cobas HPV Test and Digene HC2 HPV DNA test also allow collection into a specific collection medium if traditional cytology is performed.

HPV Vaccination. The clear link between HPV infection and cervical neoplasia has prompted development of two Food and Drug Administration-approved vaccines. These are available for girls and women aged 9 to 26 years. The quadrivalent HPV-6/11/16/18 vaccine (Gardasil) and the bivalent HPV-16/18 vaccine (Cervarix) decrease the incidence of high-grade dysplasia, and thus, cervical carcinoma (American College of Obstetricians and Gynecologists, 2012b; FUTURE II Study Group, 2007; Paavonen, 2009).

Vaccination is not recommended during pregnancy, and contraception during the series is recommended by the

American College of Obstetricians and Gynecologists (2010) and the Centers for Disease Control and Prevention (2010). That said, both vaccines are considered safe and are not associated with higher rates of adverse pregnancy outcomes if conception occurs during the series (Dana, 2009; Descamps, 2009; Garland, 2009). Completion of the series should be delayed until after delivery. Both of these inactivated vaccines can be given postpartum in a typical regimen of three doses, with injections given at 0, at 1 to 2, and at 6 months. The vaccines are safe for use in breast-feeding women.

Abnormal Cytological Results. The incidence of abnormal cervical cytology during pregnancy is at least as high as that reported for nonpregnant women. Abnormal cytological findings and their suggested management according to consensus guidelines are summarized in Table 63-1. Many of these cytological abnormalities should prompt colposcopy to exclude invasive cancer. Accordingly, lesions suspicious for high-grade disease or cancer should undergo biopsy (American College of Obstetricians and Gynecologists, 2013a). These may actively bleed because of hyperemia, but this can be stopped with Monsel paste and pressure, silver nitrate application, vaginal packing, or suture.

Unsatisfactory colposcopic evaluation is less common during pregnancy because the transformation zone is better exposed due to cervical eversion. With unsatisfactory visualization, colposcopy is repeated in 6 to 8 weeks, during which time the squamocolumnar junction will further evert (Randall, 2009). Once satisfactory examination is possible and advanced disease is excluded, additional colposcopic and cytological

examinations during pregnancy are not encouraged. After delivery, repeat cytology and colposcopy should generally be delayed for at least 6 weeks to allow reparative healing.

Cervical Intraepithelial Neoplasia. Women with histologically confirmed intraepithelial neoplasia during pregnancy may be allowed to deliver vaginally, with further evaluation planned after delivery. For those with cervical intraepithelial neoplasia (CIN) 1, the recommended management is reevaluation postpartum. For those with CIN 2 or 3 in which invasive disease has been excluded, or with advanced pregnancy, repeat colposcopic and cytological evaluations are performed at intervals no more frequent than 12 weeks. Repeat biopsy is recommended if appearance of the lesion worsens or if cytology suggests invasive cancer. Alternatively, deferring reevaluation until at least 6 weeks postpartum is acceptable (Wright, 2007b).

Regression of CIN lesions is common during pregnancy or postpartum. In a study of 1079 pregnant women with cervical dysplasia in which biopsy correlated with colposcopic findings, 61 percent reverted to normal postpartum (Fader, 2010). In another study, Yost and colleagues (1999) reported postpartum regression in 70 percent of women with CIN 2 and CIN 3 lesions. And although 7 percent of women with CIN 2 lesions progressed to CIN 3, none progressed to invasive carcinoma. In another study of 77 women with carcinoma in situ (CIS) diagnosed during pregnancy, a third had postpartum regression, two thirds had persistent CIS, and only two women had microinvasive cancer on cone biopsy after delivery (Ackermann, 2006).

Adenocarcinoma in situ (AIS) is managed similarly to CIN 3 (Dunton, 2008). Thus, unless invasive cancer is identified, treatment of AIS is not recommended until 6 weeks postpartum (Wright, 2007b).

Cervical Conization. If invasive epithelial lesions are suspected, conization is indicated and may be done with loop electrosurgical excisional procedure (LEEP) or by cold knife conization. If possible, conization is avoided in pregnancy because of increased risks for abortion, membrane rupture, hemorrhage, and preterm delivery. The epithelium and underlying stroma within the endocervical canal cannot be extensively excised without the risk of membrane rupture. Residual disease is common. Of 376 conization procedures during pregnancy, Hacker and colleagues (1982) found residual neoplasia in 43 percent of subsequent specimens. In addition, nearly 10 percent of 180 pregnant women required transfusion after conization (Averette, 1970).

Women with CIN treated *before* pregnancy may encounter pregnancy complications. Cicatricial cervical stenosis is uncommon, but it may follow cervical trauma from conization, the loop electrosurgical excision procedure (LEEP), and laser surgery. Cervical stenosis almost always yields during labor. A so-called conglutinated cervix may undergo almost complete effacement without dilation, with the presenting part separated from the vagina by only a thin layer of cervical tissue. Dilatation usually promptly follows pressure with a fingertip, although manual dilatation or cruciate incisions may be required.

For decades, cold-knife conization has been associated with cervical incompetence and preterm birth. However, the relationship between preterm birth and LEEP continues to be debated, with some studies showing increased risk, but others not (Castanon, 2012; Jakobsson, 2009; Samson, 2005; Werner, 2010). An important study confounder is the increased risk of preterm birth in women with CIN compared with the general population even if they have not undergone an excisional procedure (Bruinsma, 2007; Shanbhag, 2009).

Invasive Cervical Cancer

The incidence of invasive cervical carcinoma has dramatically declined and approximates 1 in 8500 pregnancies in the United States (Pettersson, 2010; Smith, 2003). The diagnosis is confirmed with biopsies taken during colposcopy, with conization, or from a grossly abnormal lesion. Of the histological types, squamous cell carcinomas comprises 75 percent of all cervical cancers, whereas adenocarcinomas account for 20 to 25 percent. Cancers may appear as exophytic or endophytic growth; as a polypoid mass, papillary tissue, or barrel-shaped cervix; as a cervical ulceration or granular mass; or as necrotic tissue. A watery, purulent, foul, or bloody discharge may also be present. Biopsy with Tischler forceps is warranted for suspicious lesions.

Cervical cancer is staged clinically, and 70 percent of cases that are diagnosed in pregnancy are stage I (Morice, 2012). Physiological pregnancy changes may impede accurate staging, and the extent of cancer is more likely to be underestimated in pregnant women (Oto, 2007). Specifically, induration of the broad ligament base, which characterizes tumor spread beyond the cervix, may be less prominent due to cervical, paracervical, and parametrial pregnancy-induced softening. Staging is modified and typically incorporates findings from pelvic examination and from renal sonography, chest radiography, cystoscopy, proctoscopy, and perhaps cone biopsy. Although MR imaging is not formally considered for clinical staging, it can be used without gadolinium contrast, ideally after the first trimester, to ascertain disease involvement of the urinary tract and lymph nodes (Fig. 63-3).

Management and Prognosis. Treatment of cervical cancer in pregnant women is individualized and depends on the clinical stage, fetal age, and individual desire to continue pregnancy (Hunter, 2008). Stage IA1 is termed microinvasive disease and describes lesions with deepest invasion ≤ 3 mm and widest lateral extension ≤ 7 mm (FIGO Committee on Gynecologic Oncology, 2009b). If diagnosed by cone biopsy, treatment follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is reserved until 6 weeks postpartum.

Truly invasive cancer demands relatively prompt therapy. During the first half of pregnancy, immediate treatment is advised by most, but this depends on the decision whether to continue pregnancy. With diagnosis during the latter half of pregnancy, most agree that pregnancy can safely be continued not only until fetal viability is reached, but also until fetal lung

FIGURE 63-3 Sagittal T-2 weighted magnetic resonance image of a gravid uterus at 32 weeks' gestation with a large cervical carcinoma (arrows).

maturity is attained (Greer, 1989). In two studies with a total of 40 women past 20 weeks with either stage I or stage IIA carcinoma, it was concluded that delayed treatment was reasonable in women without bulky lesions (Takushi, 2002; van Vliet, 1998). Another option is to complete staging using laparoscopic lymphadenectomy and to delay treatment if metastases are excluded (Alouini, 2008; Favero, 2010). In a recent metaanalysis, neoadjuvant chemotherapy with platinum derivatives was found to be promising for treatment in pregnancy (Zagouri, 2013).

Although surgical therapy and radiation are equally effective, radical hysterectomy plus pelvic lymphadenectomy is the preferred treatment for invasive carcinoma in most women with stage I and early stage IIA lesions (American College of Obstetricians and Gynecologists, 2010a). Before 20 weeks, hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy is often performed first. Radiotherapy for cervical cancer destroys ovarian and possibly sexual function, and frequently causes intestinal and urinary tract injury. In 49 women with pregnancy-associated stage IB cancer, there was a 30-percent severe complication rate from radiotherapy compared with only 7 percent with surgery (Nisker, 1983).

Although less commonly selected, fertility-preserving procedures for early-stage cervical cancers have been investigated. Ungár and colleagues (2006) performed abdominal radical trachelectomy before 20 weeks for stage IB1 carcinoma in five pregnant women. Yahata and associates (2008) treated four women at 16 to 23 weeks for stage IA1 adenocarcinoma with laser conization, and all delivered at term. Van Calsteren and coworkers (2008) reported similar success in a woman at 8 weeks with stage IB2 adenocarcinoma.

Radiotherapy is given for more advanced-stage cancer. External beam radiation is given for treatment early in pregnancy, and then if spontaneous abortion does not ensue, curettage is performed. During the second trimester, spontaneous abortion may not promptly occur and may necessitate hysterotomy in up to a fourth of cases.

Stage-for-stage, the survival rate for invasive cervical carcinoma is similar in pregnant and nonpregnant women (Sood, 1998). In a case-control study of 44 women with pregnancy-associated cervical cancer, the overall 5-year survival rate was approximately 80 percent in both pregnant women and nonpregnant controls (Van der Vange, 1995).

Delivery. Any adverse prognostic effects that vaginal delivery through a cancerous cervix might have are unknown. For this reason, the mode of delivery is controversial, especially for small, early-stage lesions. In some cases of bulky or friable lesions, there may be significant hemorrhage with vaginal delivery. Also, recurrences in the episiotomy scar, which result from tumor cells apparently “seeding” the episiotomy, have been reported (Goldman, 2003). Thus, most favor cesarean delivery and use a classical hysterotomy incision to avoid the risk of cutting through tumor.

Pregnancy after Radical Trachelectomy. There is growing experience with pregnancy in women who have previously undergone fertility-sparing radical trachelectomy for stage IB1 and IB2 cervical cancer before conception. During the typically vaginal procedure, the cervix is amputated at the level of the internal os, and a permanent-suture cerclage is placed around the isthmus for support in future pregnancies. The uterine isthmus is then reconstructed to the vagina. Because of the permanent cerclage, a classical cesarean incision is required for delivery.

Shepherd and colleagues (2006) presented outcomes for 123 such women cared for at their institution. Of 63 women who attempted pregnancy, 19 had 28 live births. All had classical cesarean deliveries, and a fourth were before 32 weeks. Similar findings were reported by Kim (2012) and Park (2014) and their colleagues.

Uterus

Leiomyomas

Also known as myomas and somewhat erroneously called *fibroids*, uterine leiomyomas are common benign smooth muscle tumors. Their incidence during pregnancy is approximately 2 percent, and the cited range depends on the frequency of routine sonography and population characteristics (Qidwai, 2006; Stout, 2010). For example, in a study of 4271 women, Laughlin and coworkers (2009) reported that first-trimester leiomyoma prevalence was highest in black women—18 percent—and lowest in whites—8 percent.

Leiomyomas vary in location and may develop as submucous, subserosal, or intramural growths. Less frequently, these develop in the cervix or broad ligament. Some become parasitic and their blood supply is derived from adjacent structures such as the highly vascularized omentum. In the rare manifestation of leiomyomatosis peritonealis disseminata, numerous

FIGURE 63-4 Sonogram of a pregnant uterus with a large uterine leiomyoma. The heterogeneous mass (arrows) lies beside the fetus (seen in cross section) and has the classic appearance of a leiomyoma in pregnancy. The placenta is located anteriorly, and the mass originates from the posterior lower uterine segment and occupies more than half of the total uterine volume.

subperitoneal benign smooth muscle tumors may appear similar to disseminated carcinomatosis. The tumors are likely caused by estrogen stimulation of multicentric subcoelomic mesenchymal cells to become smooth-muscle cells (Bulun, 2013). In their review of 45 cases, Lashgari and colleagues (1994) found that half were discovered during pregnancy. Often, these tumors regress after pregnancy.

The stimulatory effects of pregnancy on myoma growth are unpredictable and can be impressive. These tumors respond differently in individual women and may grow, regress, or remain unchanged in size during pregnancy (Laughlin, 2009; Neiger, 2006).

Especially during pregnancy, myomas can be confused with other adnexal masses, and sonographic imaging is indispensable (Fig. 63-4). In women in whom sonographic findings are unclear, MR imaging performed after the first trimester may be necessary (Torashima, 1997). Once diagnosed, leiomyomas do not require surveillance with serial sonography unless associated complications are anticipated.

Symptoms. Most leiomyomas are asymptomatic, but acute or chronic pain or pressure may develop. For chronic pain secondary to large tumor size, nonnarcotic analgesic drugs may be given. More acutely, in some cases, myomas outgrow their blood supply and hemorrhagic infarction follows, which is termed red or carneous degeneration. Clinically, there is acute focal abdominal pain and tenderness, and sometimes a low-grade fever and leukocytosis is noted. As such, tumor degeneration may be difficult to differentiate from appendicitis, placental abruption, ureteral stone, or pyelonephritis. Sonographic imaging may be helpful, but close observation is requisite because an infarcted myoma is essentially a diagnosis of exclusion. In some women, preterm labor is stimulated by associated inflammation.

Treatment is analgesic medications, and most often, symptoms abate within a few days. If further treatment is given to

forestall preterm labor, then close observation to exclude a septic cause is imperative. Although surgery is rarely necessary during pregnancy, myomectomy in highly selected cases has resulted in good outcomes (Celik, 2002; De Carolis, 2001). Most of 23 reported women were 14 to 20 weeks, and in almost half, surgery was performed because of pain. In some, an intramural leiomyoma was in contact with the implantation site. Except for one loss immediately following surgery at 19 weeks, most underwent cesarean delivery later at term.

Occasionally, pedunculated subserosal myomas will undergo torsion with subsequent painful necrosis. In such cases, laparoscopy or laparotomy can be used to ligate the stalk and resect the necrotic tumor. That said, we are of the opinion that surgery should be limited to tumors with a discrete pedicle that can be easily clamped and ligated.

Pregnancy Complications. Myomas are associated with a number of complications including preterm labor, placental abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage (Klatsky, 2008; Qidwai, 2006; Sheiner, 2004). In a review of pregnancy outcomes in 2065 women with leiomyomas, Coronado and coworkers (2000) reported that placental abruption and breech presentation were each increased fourfold; first-trimester bleeding and dysfunctional labor, twofold; and cesarean delivery, sixfold. Salvador and associates (2002) reported an eightfold increased second-trimester abortion risk in these women but found that genetic amniocentesis did not increase this risk.

The two factors most important in determining morbidity in pregnancy are leiomyoma size and location (Shavell, 2012). The proximity of myomas to the placental implantation site is also a factor. Specifically, abortion, preterm labor, placental abruption, and postpartum hemorrhage all are increased if the placenta is adjacent to or implanted over a leiomyoma. Tumors in the cervix or lower uterine segment may obstruct labor, as did the one shown in Figure 63-5. Despite these complications,

FIGURE 63-5 Cesarean delivery performed because of a large leiomyoma in the lower uterine segment. A classical vertical uterine incision, seen to the left of the myoma, was required for delivery of the fetus.

Qidwai and colleagues (2006) reported a 70-percent vaginal delivery rate in women in whom myomas were ≥ 10 cm. These data argue against empirical cesarean delivery for leiomyomas, and we allow a trial of labor unless myomas clearly obstruct the birth canal. If cesarean delivery is indicated, myomas are generally left alone unless they cause recalcitrant bleeding. An important caveat is that cesarean hysterectomy may be technically difficult because of lateral ureteral displacement by the tumors.

Bleeding due to myomas may develop during pregnancy from any of several factors. Especially common is bleeding with miscarriage, preterm labor, or placenta previa and abruption. Much less frequently, bleeding may result from a submucous myoma that has prolapsed from the uterus and into the cervix or vagina. In these unusual cases, although heavy or persistent bleeding may require earlier intervention, the stalk can be ligated vaginally near term if accessible to avoid tumor avulsion during delivery.

Fortunately, myomas rarely become infected (Genta, 2001). This is most frequent postpartum, especially if the tumor is located immediately adjacent to the implantation site (Lin, 2002). They also may become infected with an associated septic abortion and myoma perforation by a sound, dilator, or curette.

Fertility Considerations. Despite the relatively high prevalence of myomas in young women, it is not clear whether they diminish fertility, other than by possibly causing miscarriage as discussed in Chapter 18 (p. 359). In a review of 11 studies, Pritts (2001) concluded that submucous myomas did significantly affect fertility. He also found that hysteroscopic myomectomy improved infertility and early miscarriage rates in these women. Infertility-related myomas in other locations may require laparoscopy or laparotomy for excision.

Some of these methods of treatment for infertility may affect successful pregnancies. For example, after myomectomy, there is concern for uterine rupture before and during labor (American College of Obstetricians and Gynecologists, 2012a). Management is individualized, and review of the prior operative report is prudent. If resection resulted in a defect into or immediately adjacent to the endometrial cavity, then cesarean delivery is usually done before labor begins.

Although less effective than surgery, uterine artery embolization of myomas has also been used to treat infertility or myoma symptoms (Mara, 2008). Women so treated have increased rates of miscarriage, cesarean delivery, and postpartum hemorrhage (Homer, 2010). At this time, the Society of Interventional Radiology (Stokes, 2010) considers myoma embolization relatively contraindicated in women who plan future pregnancies.

Endometriosis and Adenomyosis

Rarely do endometriomas cause problems in pregnancy. If they are identified sonographically, they can be resected if cesarean delivery is performed. With vaginal delivery, endometriotic tumors or cysts may be removed after the puerperium or followed clinically depending on symptoms and cyst characteristics (Levine, 2010). Occasionally, endometriosis can develop

after delivery from endometrial implants within abdominal incisions made at cesarean delivery or within episiotomy scars (Bumpers, 2002).

Adenomyosis is traditionally found in older women. Its acquisition may be at least partially related to disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis, 2002). Although problems during pregnancy are rare, in an 80-year review, Azziz (1986) reported concurrent adenomyosis to be associated with uterine rupture, ectopic pregnancy, uterine atony, and placenta previa.

Endometrial Carcinoma

This estrogen-dependent neoplasia is usually found in women older than 40 years. Thus, it is seen only rarely with pregnancy. Hannuna and colleagues (2009) found 27 cases that were identified during pregnancy or within the first 4 months postpartum. Most were found in first-trimester curettage specimens.

These are usually early-stage well-differentiated adenocarcinomas for which treatment consists primarily of total abdominal hysterectomy and bilateral salpingo-oophorectomy. Much less commonly, to preserve future fertility, curettage with or without postprocedural progestational therapy has been used for the rare patient with cancer identified in a miscarriage curettage specimen (Schammel, 1998).

Many more studies describe a conservative approach for well-selected *nonpregnant* women diagnosed with endometrial cancer who wish to preserve fertility. In one study of 13 women treated with progestins for early-stage well-differentiated adenocarcinoma, nine had liveborn infants, and four of six women with a recurrence responded to another course of therapy (Gotlieb, 2003). Similar outcomes were described in 12 women by Niwa and associates (2005) and in 21 women by Signorelli and coworkers (2009). Despite these acceptable pregnancy rates, recurrences and death have been reported, and conservative management is not considered standard (Erkanli, 2010).

Ovary

Ovarian masses found during pregnancy are relatively common, and the reported incidences are population- and investigation-dependent. Factors include whether studies are referral or primary care sources, the frequency of prenatal sonography, and what size constitutes a “mass.” It is thus not surprising that the incidence has been reported as 1 in 100 to 1 in 2000 pregnancies (Whitecar, 1999; Zanetta, 2003). Of ovarian malignancies, the absolute incidence in the California Cancer Registry was 1 in 19,000 pregnancies (Smith, 2003).

The most frequent types of ovarian masses are corpus luteum cysts, endometriomas, benign cystadenomas, and mature cystic teratomas, colloquially termed dermoids. Because pregnant women are usually young, malignant tumors and those of low malignant potential are proportionately uncommon and vary from 4 to 13 percent (Hoffman, 2007; Sherard, 2003). Our experiences from Parkland Hospital are similar to those reported by Leiserowitz and colleagues (2006), who found that 1 percent of 9375 ovarian masses were frankly malignant and that another 1 percent was of low malignant potential.

FIGURE 63-6 Sonographic characteristics of common adnexal masses in pregnancy. **A.** A simple anechoic cyst with smooth walls is characteristic of a physiological corpus luteum cyst or benign cystadenoma. **B.** Cystic structure with diffuse internal low-level echoes suggestive of an endometrioma or hemorrhagic corpus luteum. **C.** Mature cystic teratoma appears as an adnexal cyst (*marked by calipers*) with accentuated lines and dots that represent hair in both longitudinal and transverse planes. At the central inferior aspect of this cyst, a mural nodule—Rokitansky protuberance—is seen. These typically rounded protuberances range in size from 1 to 4 cm, they are predominantly hyperechoic, and they create an acute angle with the cyst wall. Although not seen here, fat-fluid levels are often identified with cystic teratomas. (Image contributed by Dr. Elysia Moschos.)

Most ovarian masses are asymptomatic in pregnant women. Some cause pressure or chronic pain, and acute abdominal pain may be due to torsion, rupture, or hemorrhage. Seldom is blood loss significant enough to cause hypovolemia.

Sonography

Many ovarian masses are detected during routine prenatal sonography or during imaging done for other indications, including evaluation of symptoms. The typical sonographic appearance of these masses is shown in Figure 63-6. In some instances, MR imaging can be used to evaluate complicated anatomy (American College of Obstetricians and Gynecologists, 2013b).

Tumor Markers

Cancer antigen 125 (CA125) levels are frequently elevated with ovarian malignancy. Importantly, concentrations in early pregnancy and early puerperium are normally elevated, possibly from the decidua (Aslam, 2000; Haga, 1986; Spitzer, 1998). From the second trimester until term, levels are not normally higher than those in the nonpregnant woman (Appendix, p. 1289). Other tumor markers that have not been proven for diagnosis or posttreatment surveillance in pregnancy include OVA1, human chorionic gonadotropin (hCG), alpha-fetoprotein, and inhibins A and B (Liu, 2011). Of these, OVA1 is a biomarker blood test that measures five analytes, one of which is CA125.

Complications

The two most common complications of any ovarian mass are torsion and hemorrhage. Torsion usually causes acute constant or episodic lower abdominal pain that frequently is accompanied by nausea and vomiting. Sonography often aids the diagnosis. With color Doppler, presence of an ovarian mass with absent flow strongly correlates with torsion. However, minimal or early twisting may compromise only venous flow, thus leaving arterial supply intact. If torsion is suspected, laparoscopy or laparotomy is warranted. Contrary to prior teaching, adnexectomy is generally unnecessary to avoid clot release, thus, most

recommend attempts at untwisting (McGovern, 1999; Zweizig, 1993). With a salvageable ovary, within minutes, congestion is relieved, and ovarian volume and cyanosis diminish. If cyanosis persists, however, then removal of the infarcted adnexa is typically indicated.

If the adnexa is healthy, there are options. First, neoplasms are resected. However, ovarian cystectomy in an ischemic, edematous ovary may be technically difficult, and adnexectomy may be necessary. Second, unilateral or bilateral oophoropexy has been described to minimize the risk of repeated torsion (Djavanian, 2004; Germain, 1996). Techniques described include shortening of the uteroovarian ligament or fixing the uteroovarian ligament to the posterior uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010; Weitzman, 2008).

The most common case of ovarian hemorrhage follows rupture of a corpus luteum cyst. If the diagnosis is certain and symptoms abate, then observation and surveillance is usually sufficient. Concern for ongoing bleeding will typically prompt surgical evaluation. If the corpus luteum is removed before 10 weeks' gestation, progestational support is recommended to maintain the pregnancy. Suitable regimens include: (1) micronized progesterone (Prometrium) 200 or 300 mg orally once daily; (2) 8-percent progesterone vaginal gel (Crinone) one premeasured applicator vaginally daily plus micronized progesterone 100 or 200 mg orally once daily; or (3) intramuscular 17-hydroxyprogesterone caproate, 150 mg. For the last, if given between 8 and 10 weeks' gestation, only one injection is required immediately after surgery. If the corpus luteum is excised between 6 and 8 weeks' gestation, then two additional doses should be given 1 and 2 weeks after the first.

Management of an Asymptomatic Adnexal Mass

Because most of these are incidental findings, management considerations include whether resection is necessary and its timing. A cystic benign-appearing mass that is < 5 cm often requires no additional antepartum surveillance. Early in pregnancy, this is likely a corpus luteum cyst, which typically

resolves by the early second trimester. For cysts ≥ 10 cm, because of the substantial risk of malignancy, torsion, or labor obstruction, surgical removal is reasonable. Tumors between 5 and 10 cm should be carefully evaluated by sonography along with color Doppler and possibly MR imaging. If they have a simple cystic appearance, these cysts can be managed expectantly with sonographic surveillance (Schmeler, 2005; Zanetta, 2003). Resection is done if cysts grow, begin to display malignant qualities, or becomes symptomatic. However, if there are sonographic characteristics that suggest a cancer—thick septa, nodules, papillary excrescences, or solid components—then immediate resection is indicated (Caspi, 2000; Fleischer, 1990). Approximately 1 in 1000 pregnant women undergoes surgical exploration for an adnexal mass (Boulay, 1998). In general, we plan resection at 14 to 20 weeks because most masses that will regress will have done so by this time. Those with classic findings of endometrioma or mature cystic teratoma may be resected postpartum or during cesarean for obstetrical indications. Importantly, in any instance in which cancer is strongly suspected, the American College of Obstetricians and Gynecologists (2011) recommends consultation with a gynecologic oncologist.

Pregnancy-Related Ovarian Tumors

A group of adnexal masses result directly from the stimulating effects of various pregnancy hormones on ovarian stroma. These include pregnancy luteoma, hyperreactio luteinalis, and ovarian hyperstimulation syndrome.

Pregnancy Luteoma. These are rare, benign, ovarian neoplasms that are thought to arise from luteinized stromal cells and that classically cause elevated testosterone levels (Irving, 2011). Up to 25 percent of affected women will be virilized, and of these affected women, approximately half of their female fetuses will have some degree of virilization. Fortunately, most mothers and their fetuses are unaffected by the hyperandrogenemia because the placenta rapidly converts androgens to estrogens (Kaňová, 2011).

In some cases, an adnexal mass along with maternal virilization will prompt sonography and measurement of testosterone and CA125 levels. Luteomas range in size from microscopic to greater than 20 cm. They appear as solid tumors, may be multiple or bilateral, and may be complex because of hemorrhagic areas (Choi, 2000). Concerns for malignancy may be further investigated by MR imaging (Kao, 2005; Tannus, 2009).

Total testosterone levels are increased, but with the caveat that levels in normal pregnancy can be substantially elevated (Appendix, p. 1291). Levels of CA125 antigen tumor marker are normal with a pregnancy luteoma, and significantly elevated levels indicate another cause. Differential diagnoses are primary ovarian cancer or metastatic disease and include granulosa cell tumors, thecomas, Sertoli-Leydig cell tumors, Leydig cell tumors, stromal hyperthecosis, and hyperreactio luteinalis.

Generally, luteomas do not require surgical intervention unless there is torsion, rupture, or hemorrhage (Masarie, 2010). These tumors spontaneously regress during the first few months postpartum, and androgen levels drop precipitously during the first 2 weeks following delivery (Wang, 2005). Lactation may

be delayed a week or so by hyperandrogenemia (Clement, 1993; Dahl, 2008). Recurrence in subsequent pregnancies is rare.

Hyperreactio Luteinalis. In this condition, one or both ovaries develop multiple large theca-lutein cysts, typically after the first trimester. Cysts are caused by luteinization of the follicular theca interna layer, and most are in response to stimulation by exceptionally high hCG levels (Russell, 2009). For this reason, they are more common with gestational trophoblastic disease, twins, fetal hydrops, and other conditions with increased placental mass. Similar to luteoma, maternal virilization develops in approximately a third of women, but there have been no reports of fetal virilization (Kaňová, 2011).

These ovarian tumors appear sonographically to have a “spoke wheel” pattern (Fig. 20-3, p. 399). If the diagnosis is confident, and unless complicated by torsion or hemorrhage, surgical intervention is not required. These masses resolve after delivery.

Ovarian Hyperstimulation Syndrome. This rare event is typified by multiple ovarian follicular cysts accompanied by increased capillary permeability. It most often is a complication of ovulation-induction therapy for infertility, although it rarely may develop in an otherwise normal pregnancy. Its etiopathogenesis is thought to involve hCG stimulation of vascular endothelial growth factor (VEGF) expression in granulosa-lutein cells (Soares, 2008). This causes increased vascular permeability that can lead to hypovolemia with ascites, pleural or pericardial effusion, acute kidney injury, and hypercoagulability. There is a clinical spectrum with symptoms that may include abdominal distention, rapid weight gain, dyspnea, and progressive hypovolemia. Serious complications are renal dysfunction, adult respiratory distress syndrome, ovarian rupture with hemorrhage, and thromboembolism.

Although most cases of ovarian hyperstimulation are associated with in vitro fertilization, increasing hCG levels from pregnancy can worsen the syndrome (Chen, 2012). Detailed guidelines for management have been outlined by the American Society for Reproductive Medicine (2008). Treatment is primarily supportive with attention to maintaining vascular volume and thromboprophylaxis.

Ovarian Cancer

Malignancies of the ovary are most common in older women and are the leading cause of death in all women from genital-tract cancers (American Cancer Society, 2012). That said, the incidence of ovarian malignancy during pregnancy ranges from 1 in 20,000 to 50,000 births (Palmer, 2009; Eibye, 2013; Smith, 2003). Fortunately, 75 percent of these found in pregnancy are early-stage malignancies with a 5-year survival rate between 70 and 90 percent (Brewer, 2011). The types of malignancy are also markedly different in pregnant women compared with those in older women. In pregnant women, these are, in decreasing order of frequency, germ cell and sex cord-stromal tumors, low malignant potential tumors, and last, epithelial tumors (Morice, 2012).

Pregnancy apparently does not alter the prognosis of most ovarian malignancies. Management is similar to that for

nonpregnant women, with the usual proviso that it may be modified depending on gestational age. Thus, if frozen section histopathological analysis verifies malignancy, then surgical staging is done with careful inspection of all accessible peritoneal and visceral surfaces (Giuntoli, 2006; Yazigi, 1988). Peritoneal washings are taken for cytology; biopsies are taken from the diaphragmatic surface and peritoneum; omentectomy is done; and biopsies are taken from pelvic and infrarenal para-aortic lymph nodes. Depending on the uterine size, some of these components, especially lymphadenectomy, may not be technically feasible.

If there is advanced disease, bilateral adnexectomy and omentectomy will decrease most tumor burden. In early pregnancy, hysterectomy and aggressive surgical debulking procedures may be elected. In other cases, minimal debulking as described is done and the operation terminated. In some cases of aggressive or large-volume disease, chemotherapy can be given during pregnancy while awaiting pulmonary maturation. As discussed on page 1227, monitoring maternal CA125 serum levels during chemotherapy is not accurate in pregnancy (Aslam, 2000; Morice, 2012).

Adnexal Cysts

Paratubal and paroovarian cysts are either distended remnants of the paramesonephric ducts or are mesothelial inclusion cysts. Although most are ≤ 3 cm, they occasionally attain worrisome dimensions (Genadry, 1977). Their reported incidence is influenced by size, but one autopsy series in nonpregnant women cited this to be 5 percent (Dorum, 2005). The most common paramesonephric cyst is the hydatid of Morgagni, which is pedunculated and typically dangles from one of the fimbria. These cysts infrequently cause complications and are most commonly identified at the time of cesarean delivery or puerperal sterilization, at which time they can simply be drained or excised. Neoplastic paraovarian cysts are rare, histologically resemble tumors of ovarian origin, and rarely are of borderline potential or frankly malignant (Honore, 1980; Korbin, 1998).

Vulva and Vagina

Preinvasive Disease

In young women, vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN) are seen more often than invasive disease and are commonly associated with HPV infection. As with cervical neoplasia, these premalignant conditions are treated after the puerperium.

Squamous Cell Carcinoma

Cancer of the vulva or vagina is generally a malignancy of older women, and thus, these are rarely associated with pregnancy. Even so, any suspicious lesions should be biopsied. Treatment is individualized according to the clinical stage and depth of invasion. In a review of 23 cases, investigators concluded that radical surgery for stage I disease was feasible during pregnancy—including in the last trimester (Heller, 2000). We and others question the necessity of resection in late pregnancy in that definitive therapy can often be delayed because of vulvar

cancer's typical slow progression (Anderson, 2001). It appears that vaginal delivery is not contraindicated if vulvar and inguinal incisions are well healed.

Vulvar sarcoma, vulvar melanoma, and vaginal malignancies are rare in pregnancy and are the subjects of case reports (Alexander, 2004; Kuller, 1990; Matsuo, 2009).

BREAST CARCINOMA

The incidence of breast cancer is age dependent, however, because of its overall high frequency in women, it is relatively common in young women. Recall from Figure 63-1 that breast malignancies are the most frequent cancer found in pregnant women. And, as more women choose to delay childbearing, the frequency of associated breast cancer is certain to increase (Amant, 2012a). As an example, postponed childbearing was considered partially responsible for the increase in pregnancy-associated breast cancer in Sweden from 16 to 37 percent during the 40-year period from 1963 to 2002 (Andersson, 2009). Similar findings have been reported from Denmark (Eibye, 2013).

Risk Factors

Some, but not all, studies suggest that women with a family history of breast cancer—especially those with *BRCA1* and *BRCA2* breast cancer gene mutations—are more likely to develop breast malignancy during pregnancy (Johannsson, 1998; Shen, 1999; Wohlfahrt, 2002). However, although there is a definitely increased long-term risk with *BRCA1* and *BRCA2* mutations, it may be that parity modifies this risk. Specifically, parous women older than 40 years with these mutations have a significantly lower cancer risk than nulliparas with these mutations (Andrieu, 2006; Antoniou, 2006). Women with *BRCA1* and *BRCA2* gene mutations who undergo induced abortion or those who breast feed do not have an increased risk of breast cancer (Beral, 2004; Friedman, 2006). Moreover, Jernström and associates (2004) found that breast feeding actually conveyed a protective effect against this cancer in those with *BRCA1* gene mutation, but not in those with *BRCA2* mutations. Of other congenital risks, it is controversial whether diethylstilbestrol exposure in utero is associated with an increased breast cancer risk (Hoover, 2011; Larson, 2006; Titus-Ernstoff, 2006).

Diagnosis

More than 90 percent of pregnant women with breast cancer have a palpable mass, and greater than 80 percent are self-reported (Brewer, 2011). There are usually slight delays in clinical assessment, diagnostic procedures, and treatment of pregnant women with breast tumors (Berry, 1999). This can partially be attributed to increased pregnancy-induced breast tissue that obscures masses.

Evaluation of pregnant women with a breast mass should not differ from that for nonpregnant women. Thus, any suspicious breast mass should be pursued to diagnosis. Pragmatically, a palpable discrete mass can be biopsied or excised. If imaging is desirable to distinguish between a solid mass and a cystic

lesion, then sonography has high sensitivity and specificity (Navrozoglou, 2008). Mammography is appropriate if indicated, and the fetal radiation risk is negligible with appropriate shielding. Fetal exposure is only 0.04 mGy for the typical mammogram study. But, because breast tissue is denser in pregnancy, mammography has a false-negative rate of 35 to 40 percent (Woo, 2003). If the decision to biopsy is uncertain, then MR imaging may be used (Amant, 2010). With such techniques, masses can usually be described as either solid or cystic.

Cystic breast lesions are simple, complicated, or complex (Berg, 2003). Simple cysts do not require special management or monitoring, but they may be aspirated if symptomatic. Complicated cysts show internal echoes during sonography, and they sometimes are indistinguishable from solid masses. These are typically aspirated, and if the sonographic abnormality does not resolve completely, a core-needle biopsy is usually performed. Complex cysts have septa or intracystic masses seen on sonographic evaluation. Because some forms of breast cancer may be complex cysts, excision is usually recommended.

For solid breast masses, evaluation is with the triple test, that is, clinical examination, imaging, and needle biopsy. If all three suggest a benign lesion or if all three suggest a breast cancer, the test is said to be concordant. A concordant benign triple test is > 99-percent accurate, and breast lumps in this category can be followed by clinical examination alone. Fortunately, most masses in pregnancy have these three reassuring features. To the contrary, however, if any of the three assessments is suggestive of malignancy, then the mass should be excised regardless of the other two findings.

Management

Once breast cancer is diagnosed, a limited search of the most common metastatic sites is completed. For most women, this includes a chest radiograph, liver sonography, and skeletal MR imaging (Amant, 2012a).

Treatment of breast cancer is by a multidisciplinary team that includes an obstetrician, surgeon, and medical oncologist. Desires for pregnancy continuation are addressed up front. Data indicate that pregnancy interruption does not influence the course or prognosis of breast cancer (Cardonick, 2010). With pregnancy continuation, treatment in general is similar to that for nonpregnant women. However, chemotherapy and surgery are delayed to the second trimester, and adjuvant radiotherapy is withheld until after delivery (Brewer, 2011).

Surgical treatment may be definitive. In the absence of metastatic disease, either a wide excision or a modified or total mastectomy—each with axillary node staging—can be performed (Rosenkranz, 2006; Woo, 2003). Staging by sentinel lymph node biopsy and lymphoscintigraphy with technetium-99m is safe. Although often administered concurrently with lymphoscintigraphy, isosulfan blue and methylene blue dyes are pregnancy class C drugs, and some recommend that they be avoided (Mondi, 2007; Spanheimer, 2009). Breast reconstruction, if desired, is typically delayed until after delivery (Viswanathan, 2011).

Chemotherapy is usually given with either positive- or negative-node breast cancers. In premenopausal women, survival is improved even if lymph nodes are cancer free. For node-positive disease, multiagent chemotherapy is begun if delivery is not anticipated within several weeks. Drug classes are alkylating agents, anthracyclines, antimetabolites, and taxanes (Lippman, 2012). Cyclophosphamide, doxorubicin, methotrexate, and 5-fluorouracil are currently in use (García-Manero, 2009). After the first trimester, methotrexate can be substituted for doxorubicin. If an anthracycline-based agent such as doxorubicin is used, pretherapy maternal echocardiography is performed because of associated cardiotoxicity (Brewer, 2011). In 22 pregnant women treated with modified radical mastectomy that was followed by chemotherapy in most, Berry and colleagues (1999) reported minimal fetal risks. Moreover, Hahn and coworkers (2006) reported good short-term outcomes for the offspring of 57 women treated during pregnancy with multiagent chemotherapy for breast cancer.

Immunotherapy for breast cancers has become commonplace. Trastuzumab (Herceptin) is a monoclonal antibody to the HER2/neu receptor, which is found in approximately a third of invasive breast cancers (Hudis, 2007). The drug is used more commonly as adjunctive therapy for early disease in HER2/neu-positive tumors but is not recommended in pregnancy (Amant, 2010). This is because HER2/neu is strongly expressed in fetal renal epithelium, and trastuzumab has been linked with miscarriage, with fetal renal failure and related oligohydramnios, and with neonatal deaths from preterm birth (Azim, 2010). For these reasons, highly effective contraception is used during and for 6 months following trastuzumab treatment. For women who conceive after only brief exposure, fetal renal effects appear to be reversible, and short-term neonatal outcomes have been normal with no congenital anomalies reported (Azim, 2012).

Prognosis

The effects of pregnancy on the course of breast cancer and its prognosis are complex. There is no doubt that breast cancer is more aggressive in younger women, but whether it is more aggressive during pregnancy in these same women is debatable. Clinically, most studies indicate little difference in overall survival rates with pregnancy-associated breast cancer compared with similarly aged and staged nonpregnant women (Beadle, 2009). There have been other reports of worse overall survival rates with pregnancy-associated breast cancer (Rodriguez, 2008). These investigators did both conclude, however, that later disease stages are more prevalent in pregnant women.

Thus, it appears that because breast cancer is usually found at a more advanced stage in pregnant women, overall prognosis is diminished. In an earlier review, Jacob and Stringer (1990) reported that approximately 30 percent of pregnant women had stage I disease, 30 percent had stage II, and 40 percent had stages III or IV. In addition, the aggregate of studies published after 1990 indicate that up to 60 percent of pregnant women have concomitant axillary node involvement at diagnosis. And although, stage for stage, the 5-year survival rate is comparable in pregnant and nonpregnant women, the more advanced

stages that are typical of pregnant women worsen their prognosis (King, 1985; Nugent, 1985; Zemlickis, 1992).

Pregnancy Following Breast Cancer

After breast cancer treatment, chemotherapy will render some women infertile, and options for childbearing are limited (Kim, 2011). For those who became pregnant, there appear to be no adverse effects on long-term maternal survival rates (Averette, 1999; Velentgas, 1999). Moreover, a metaanalysis of 10 studies found that for women with early breast cancer, pregnancy that occurs 10 months after diagnosis may, in fact, have a survival benefit (Valachis, 2010). There are also no data indicating that lactation adversely affects the course of previously diagnosed breast cancer. Also, lactation and breast feeding are possible after conservative surgery and radiation of the treated breast (Higgins, 1994).

Recommendations for subsequent pregnancies in women successfully treated for breast malignancy are based on several factors that include consideration for the recurrence risk. Simply because recurrences are more common soon after treatment, it seems reasonable to advise a delay of 2 to 3 years for observation. Hormonal contraceptive methods are contraindicated, and a copper-containing intrauterine device is an excellent long-acting reversible method for many. Even with contraceptive failure, women who conceive do not appear to have diminished survival (Ives, 2006). It is reassuring that women who undertake pregnancy after breast cancer treatment overall have good outcomes (Langagergaard, 2006). Of particular concern is that women treated with tamoxifen are at risk for several months after its discontinuation for having an infant with congenital anomalies. This is because of its extremely long half-life, and thus delaying conception is recommended for at least 2 months after its completion (Braems, 2011).

THYROID CANCER

Various thyroid gland malignancies constitute the most common endocrine cancers. Because most of these originate within discrete nodules, their evaluation is important. This typically includes sonography and measurement of serum thyroid-stimulating hormone (TSH) and free thyroxine levels. Fine-needle aspiration is indicated for any suspicious nodule (Yazbeck, 2012).

With a diagnosis of thyroid malignancy, pregnancy termination is not necessary (Alves, 2011). Primary therapy is total thyroidectomy performed ideally during the second trimester. Postoperatively, replacement thyroxine is given to maintain serum TSH levels between 0.1 and 0.5 mIU/L (Abalovich, 2007). Most thyroid cancers are well differentiated and follow an indolent course. Thus, delayed surgical treatment does not usually alter outcome (Yazbeck, 2012). If surgical therapy is postponed until after pregnancy, thyroxine is given to suppress any growth stimulus of TSH on tumor cells (Pacini, 2012).

In some types of thyroid malignancies, primary or postoperative treatment is given with radioiodine. This is contraindicated in both pregnancy and lactation. Transplacental iodine-131 is avidly trapped by the fetal thyroid gland to cause hypothy-

roidism (Chap. 58, p. 1149). During lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to ^{131}I -containing milk ingestion and maternal risk from significant breast irradiation. To limit maternal exposure, a delay of 3 months between lactation and ablation will more reliably ensure complete breast involution (Sisson, 2011). Last, pregnancy should be avoided for 6 months to 1 year in women with thyroid cancer who receive ^{131}I doses. This time ensures thyroid function stability and confirms thyroid cancer remission (Abalovich, 2007).

LYMPHOID CELL MALIGNANCIES

Hematological malignancies comprise 10 to 20 percent of cancers in pregnancy (Cohen, 2011; Eibye, 2013; Smith, 2003). Some of these present as leukemia involving bone marrow and blood. Others are solid lymphomas, which may be of B- or T-cell origin.

Hodgkin Disease

This lymphoma is probably B-cell derived and is cytologically distinguished from other lymphomas by Reed–Sternberg cells. It is the most common malignant lymphoma in women of childbearing age. In a population-based review of approximately 4 million pregnancies, Smith and associates (2003) reported that Hodgkin lymphoma complicated only 1 in 34,000 live births. Our experiences are similar during the past 40 years at Parkland Hospital with nearly 500,000 births.

In more than 70 percent of Hodgkin disease cases, there is painless enlargement of lymph nodes above the diaphragm—the axillary, cervical, or submandibular chains. Approximately one third of patients have symptoms including fever, night sweats, malaise, weight loss, and pruritus. Diagnosis is by histological examination of involved nodes (Longo, 2012).

Staging and Treatment

The Ann Arbor staging system, shown in Table 63-2, is used for Hodgkin and other lymphomas. Recent studies have used

TABLE 63-2. Ann Arbor Staging System for Hodgkin and Other Lymphomas

Stage	Findings
I	Involvement in a single lymph node region or lymphoid site—e.g., spleen or thymus
II	Involvement of two or more lymph node groups on the same side of the diaphragm—the mediastinum is a single site
III	Involvement of lymph nodes on both sides of the diaphragm
IV	Extralymphatic involvement—e.g., liver or bone marrow

Substage A = no symptoms; substage B = fever, sweats, or weight loss; substage E = extralymphatic involvement excluding liver and bone marrow.

FIGURE 63-7 Hodgkin lymphoma. Magnetic resonance imaging for staging shows an axial T2-weighted image taken from the midabdomen that demonstrates bilateral paraaortic adenopathy (arrows). Amniotic fluid (AF), fetal abdomen (F), maternal right inferior liver (L), and maternal left kidney (K) are seen. (Image contributed by Dr. Desiree Morgan.)

risk categories—high, low, and very low—however, these are not succinctly defined (Armitage, 2010). Pregnancy limits the use of some radiographic studies for staging, but at minimum, chest radiography, abdominal imaging with sonography or MR imaging, and bone marrow biopsy are completed (Williams, 2001). MR imaging is excellent for evaluating thoracic and abdominal paraaortic lymph nodes (Fig. 63-7) (Brenner, 2012).

The current trend for nonpregnant individuals is to administer chemotherapy for all stages of Hodgkin disease. In pregnancy, for early-stage disease in the first trimester, options include observation until after 12 weeks, single-agent vinblastine until the second trimester, pregnancy termination followed by multiagent chemotherapy, or radiotherapy alone for isolated neck or axillary sites (El-Hemaidi, 2012; Rizack, 2009).

For advanced-stage disease, chemotherapy is recommended regardless of gestational age. Before 20 weeks, therapeutic abortion is a consideration, but if termination is unacceptable, then treatment with vinblastine followed by multiagent therapy in the second trimester can be used (Pereg, 2007). For most advanced-stage disease after the first trimester, cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) are given, and radiotherapy can be added postpartum (Cohen, 2011). In general, postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is made late in pregnancy (Shulman, 2008). Importantly, in our experiences, pregnant women with Hodgkin disease—even after they are “cured”—are inordinately susceptible to infection and sepsis. Active antineoplastic therapy increases this vulnerability.

Prognosis

The overall prognosis with Hodgkin lymphoma is good, and survival rates exceed 70 percent. Pregnancy does not adversely affect the course or survival rate of women with this lymphoma (Brenner, 2012; Pavlidis, 2002). Moreover, adverse perinatal

outcomes do not appear to be increased (Langagergaard, 2008). Finally, neither chemotherapy after the first trimester nor mediastinal and neck irradiation had reported adverse fetal effects (Jacobs, 1981).

The long-term prognosis for women with Hodgkin disease is encouraging. Horning and coworkers (1981) reported that half of women resumed normal menses after chemotherapy and that there were no birth defects in 24 neonates subsequently born to these women. Long-term complications of lymphoma treatment include secondary leukemia in those treated with chemotherapy, secondary breast cancer in those treated with radiotherapy, and myocardial damage and infarction, pulmonary fibrosis, hypothyroidism, and marrow suppression (Longo, 2012).

Non-Hodgkin Lymphomas

Although usually B-cell tumors, non-Hodgkin can also be T-cell or natural killer (NK)-cell neoplasms. Their biology, classification, and treatment are complex (Longo, 2012; O’Gara, 2009). For example, they are associated with viral infections, and indeed, their incidence has risen sharply at least partly because 5 to 10 percent of HIV-infected persons develop lymphoma. Other associated viruses include Epstein-Barr virus, hepatitis C virus, and human herpes virus 8. Some of these lymphomas are quite aggressive, and survival varies with the type of cell line involved.

Non-Hodgkin lymphomas are uncommon during pregnancy, and only approximately 100 cases have been reported (Brenner, 2012). They are staged according to the Ann Arbor system shown in Table 63-2. If diagnosed in the first trimester, pregnancy termination followed by multiagent chemotherapy is recommended for all but indolent or very early disease. These less aggressive forms may either be observed or be temporized with focal supradiaphragmatic radiotherapy, with full treatment after entering the second trimester. If one of these lymphomas is diagnosed after the first trimester, chemotherapy and immunotherapy with rituximab (Rituxan) are given (Cohen, 2011; Rizack, 2009). In a report describing follow-up at 6 to 29 years in 55 individuals whose mothers were given chemotherapy during pregnancy, there were no congenital, neurological, or psychological abnormalities (Avilés, 2001). Furthermore, these exposed persons had no cancers, including leukemia.

Burkitt lymphoma is an aggressive B-cell tumor associated with Epstein-Barr virus infection. Prognosis is poor, and treatment is given with multiagent chemotherapy. In a review of 19 women whose pregnancies were complicated by this lymphoma, 17 died within a year of diagnosis (Barnes, 1998).

Leukemias

In general, these malignancies arise either from lymphoid tissues—lymphoblastic or lymphocytic leukemias, or from bone marrow—myeloid leukemias. They can be acute or chronic. Although adult leukemias are more prevalent after age 40, they still are among the most common malignancies of young women. Leukemia was diagnosed in 1 in 40,000 pregnancies reported to the California Cancer Registry (Smith, 2003). In a

review of 350 reports of pregnancy complicated by leukemia, of 72 cases reported from 1975 until 1988, 44 had acute myelogenous leukemia; 20 had acute lymphocytic leukemia; and eight had one of the chronic leukemias (Caligiuri, 1989). The last are uncommon in young women, and chronic hairy-cell leukemia has been reported in only six pregnancies (Stiles, 1998).

Acute leukemias almost always cause marked peripheral blood count abnormalities, and frequently there is an elevated white blood cell count with readily recognizable circulating blast cells. The diagnosis is made from bone marrow biopsy.

Currently, with contemporary therapy, remission during pregnancy is common, compared with almost 100-percent mortality before 1970. The goal of remission is aggressively pursued with multiagent chemotherapy. There is no evidence that pregnancy termination further improves the prognosis, however, abortion is a consideration in early pregnancy to avoid potential chemotherapy teratogenesis. One example is treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid, also known as tretinoin (Carradice, 2002; Celo, 1994). This is a potent teratogen that causes retinoic acid syndrome (Chap. 12, p. 251). In other cases, pregnancy termination before viability may simplify management of the acutely ill woman.

Other than these caveats, treatment of pregnant women with leukemia is similar to that for nonpregnant women. After induction chemotherapy, postremission maintenance therapy is mandatory to prevent a relapse, which is usually then treated with stem-cell transplantation (Wetzler, 2012). If allogeneic stem-cell transplantation is indicated, early delivery is considered. With some chronic leukemias, it may be possible to delay therapy until after delivery (Fey, 2008). As with lymphoma, infection and hemorrhage are significant complications that should be anticipated in women with active disease. Puerperal infection is particularly problematic.

There are few contemporaneous studies of leukemia treated during pregnancy. In an earlier review of 58 cases, Reynoso and colleagues (1987) reported that 75 percent were diagnosed after the first trimester. Half were acute myelogenous leukemia, which had a remission rate of 75 percent with chemotherapy. Only 40 percent of these pregnancies resulted in liveborn infants. Preterm delivery and stillbirth rates were also reported to be increased (Caligiuri, 1989).

MALIGNANT MELANOMA

These malignant tumors most frequently originate in the skin from a preexisting nevus and its pigment-producing melanocytes. Melanomas should be suspected in pigmented lesions with changes in contour, surface elevation, discoloration, itching, bleeding, or ulceration, which should prompt biopsy. They are most common in light-skinned whites and develop relatively frequently in women of childbearing age. They sometimes are first diagnosed during pregnancy, and the reported incidence ranges widely from 0.03 to 2.8 per 1000 live births (Eibye, 2013; Smith, 2003; Wong, 1990). This is likely because many are treated on an outpatient basis, and thus they are not entered into a tumor registry. As noted on page 1221, malignant melanoma is one of the tumors that is known to metastasize to the placenta and fetus. Placental evaluation for metastasis should be performed after delivery.

Staging and Treatment

Staging is clinical as follows: stage I is a melanoma with no palpable lymph nodes; in stage II, lymph nodes are palpable; and in stage III, there are distant metastases. For patients with stage I, tumor thickness is the single most important predictor of survival. The Clark classification includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. The Breslow scale measures tumor thickness and size, in addition to depth of invasion.

Primary surgical treatment for melanoma is determined by the stage and includes wide local resection, sometimes with extensive regional lymph node dissection. Schwartz and associates (2003) recommend sentinel lymph node mapping and biopsy using ^{99m}Tc -sulfur colloid, which has a calculated fetal dose of 0.014 mSv or 0.014 mGy. Routine regional node dissection reportedly improves survival in nonpregnant patients with microscopic metastases (Cascinelli, 1998). For pregnant patients, an algorithm has been proposed that begins with resection of the primary tumor under local anesthesia and postpones sentinel lymph node biopsy until after delivery (Broer, 2012). Although prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy, it may be given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative. At this time, the role of estrogen receptor- β in melanoma progression is under investigation, and it may be a target for therapeutic intervention (de Giorgi, 2011).

Prognosis

Stage-for-stage, survival is equivalent between pregnant and nonpregnant women. Therapeutic abortion does not appear to improve survival. Clinical stage is the strongest determinant of survival, and women with deep cutaneous invasion or regional node involvement have the worst prognosis (Dipaola, 1997; Kjems, 1993; Lens, 2008). Approximately 60 percent of recurrences will manifest within 2 years, and 90 percent by 5 years. Thus, most recommend that pregnancy be avoided for 3 to 5 years after surgical resection. Interim contraception can include combination oral contraceptives, as they do not appear to have adverse effects (Gandini, 2011). Related, subsequent pregnancies in women with localized melanoma do not appear to adversely affect cancer survival rates (Driscoll, 2009).

GASTROINTESTINAL TRACT CANCER

Colorectal Cancer

Malignancies of the colon and rectum are the third most frequent in women of all age groups in the United States (American Cancer Society, 2012). Even so, colorectal tumors seldom complicate pregnancy because they are uncommon before age 40. Smith and colleagues (2003) reported an approximate incidence of 1 per 150,000 deliveries in the California Cancer Registry. It was about 1 per 35,000 births in the Danish Registry (Eibye, 2013). The majority—80 percent—of colorectal carcinomas in pregnant women arise from the rectum. In one review, there were only 41 reported cases in pregnancy with cancer above the peritoneal reflection (Chan, 1999).

The most frequent symptoms of colorectal cancer are abdominal pain, distention, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because many of these symptoms are common in pregnancy. Certainly, if symptoms suggestive of colon disease persist, digital rectal examination, stool tests for occult blood, and flexible sigmoidoscopy or colonoscopy should be done.

Treatment of colon cancer in pregnant women follows the same general guidelines as for nonpregnant women. Without evidence of metastatic disease, surgical resection is preferred, but most pregnant women have advanced lesions (Walsh, 1998). During the first half of pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus, therapeutic abortion is not mandated. During later pregnancy, therapy may be delayed until fetal maturation, however, hemorrhage, obstruction, or perforation may force surgical intervention (Minter, 2005). Vaginal delivery is usually avoided because lower rectal lesions may cause dystocia, or delivery may cause tumor hemorrhage.

There is no evidence that pregnancy influences the course of colorectal cancer, and the prognosis appears to be similar to that for identical stages in nonpregnant patients (Dahling, 2009). Carcinoembryonic antigen (CEA) is a tumor marker for colon cancer, and although it may be elevated during normal pregnancy, baseline values may be useful to monitor disease (Minter, 2005).

■ Other Gastrointestinal Neoplasms

Gastric cancer is rarely associated with pregnancy, and most reported cases are from Japan. Hirabayashi and associates (1987) reviewed outcomes in 60 pregnant women during a 70-year period from 1916 to 1985. Delayed diagnosis during pregnancy is common, and the prognosis is consistently poor (Lee, 2009). It is axiomatic that persistent unexplained upper gastrointestinal symptoms should be evaluated by endoscopy.

With Zollinger–Ellison syndrome, tumors typically found in the duodenum or pancreas secrete excess gastrin. This leads to increased stomach acid production and gastric ulceration. Most tumors are slow growing, and thus, the primary goal in pregnancy is control of acid secretion. Some advise surgical resection before pregnancy (Stewart, 1997). In pregnant women with metastatic disease or in those with previously undiagnosed tumors, antacids and antisecretory treatment with histamine H₂-receptor antagonists or proton-pump inhibitors usually controls acid secretion.

MISCELLANEOUS TUMORS

Various other neoplasms have been reported in pregnancy and are usually the subject of case reports. Examples include carcinoid tumors, which are usually of gastrointestinal origin (Durkin, 1983). Both pancreatic and hepatocellular cancer are rare during pregnancy (Kakoza, 2009; Marinoni, 2006; Papoutsis, 2012; Perera, 2011). Bladerston and coworkers (1998) described a massive intrahepatic cholangiocarcinoma masquerading as HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Gastrointestinal cancers

during pregnancy are often discovered because of ovarian metastases—Krukenberg tumors—which have a bleak prognosis (Glišić, 2006). Central nervous system benign and malignant neoplasms had a reported frequency of 1 in 10,000 to 28,000 (Eibye, 2013; Smith, 2003). Bladder and urachal duct carcinoma have been rarely reported coincident with pregnancy (McNally, 2013; Yeaton-Massey, 2013). Finally, bone and vaginal tumors have been described (ElNaggar, 2012; Kathiresan, 2011).

BACTERIAL INFECTIONS	1248
PROTOZOAL INFECTIONS	1254
EMERGING INFECTIONS	1257
TRAVEL PRECAUTIONS DURING PREGNANCY	1258
BIOTERRORISM	1258

Infections have historically been a major cause of maternal and fetal morbidity and mortality worldwide, and they remain so in the 21st century. The unique maternal-fetal vascular connection in some cases serves to protect the fetus from infectious agents, whereas in other instances it provides a conduit for their transmission to the fetus. Maternal serological status, gestational age at the time infection is acquired, the mode of acquisition, and the immunological status of both the mother and her fetus all influence disease outcome.

MATERNAL AND FETAL IMMUNOLOGY

Pregnancy-Induced Immunological Changes

Even after intensive study, many of the maternal immunological adaptations to pregnancy are not well elucidated. It is known that pregnancy is associated with an increase in CD4-positive T cells secreting Th2-type cytokines—for example interleukins 4, 5, 10, and 13. Th1-type cytokine production—for example, interferon gamma and interleukin 2—appears to be somewhat suppressed, leading to a *Th2 bias* in pregnancy. This bias affects the ability to rapidly eliminate certain intracellular pathogens

during pregnancy, although the clinical implications of this suppression are unknown (Jamieson, 2006a; Raghupathy, 2001; Svensson-Arvelund, 2014). Importantly, the Th2 humoral immune response remains intact.

Fetal and Newborn Immunology

The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. That said, fetal cell-mediated and humoral immunity begin to develop by 9 to 15 weeks' gestation (Warner, 2010). The primary fetal response to infection is immunoglobulin M (IgM). Passive immunity is provided by IgG transferred across the placenta. By 16 weeks, this transfer begins to increase rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. After birth, breast feeding is protective against some infections, although this protection begins to decline at 2 months of age. Current World Health Organization (2013) recommendations are to exclusively breast feed for the first 6 months of life with partial breast feeding until 2 years of age.

Vertical transmission refers to passage from the mother to her fetus of an infectious agent through the placenta, during labor or delivery, or by breast feeding. Thus, preterm rupture of membranes, prolonged labor, and obstetrical manipulations may increase the risk of neonatal infection. Those occurring less than 72 hours after delivery are usually caused by bacteria acquired in utero or during delivery, whereas infections after that time most likely were acquired afterward. [Table 64-1](#) details specific infections by mode and timing of acquisition.

Neonatal infection, especially in its early stages, may be difficult to diagnose because neonates often fail to express classic clinical signs. If the fetus was infected in utero, there may be depression and acidosis at birth for no apparent reason. The neonate may suck poorly, vomit, or show abdominal

TABLE 64-1. Specific Causes of Some Fetal and Neonatal Infections

Intrauterine

- Human transmission: staphylococcus, HSV
- Respirators and catheters: staphylococcus, coliforms

HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus.

distention. Respiratory insufficiency may develop, which may present similarly to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts may be depressed.

VIRAL INFECTIONS

■ Varicella-Zoster Virus

Several viruses that infect the mother can also cause devastating fetal infections. Varicella-zoster virus (VZV) is a double-stranded DNA herpes virus acquired predominately during childhood, and 95 percent of adults have serological evidence of immunity (Plourd, 2005). The incidence of adult varicella infections declined by 74 percent after the introduction of varicella vaccination, probably secondary to herd immunity (Marin, 2008). This has resulted in a decrease in maternal and fetal varicella infections (Khandaker, 2011). Primary infection—*varicella* or *chicken pox*—is transmitted by direct contact with an infected individual, although respiratory transmission has been reported. The incubation period is 10 to 21 days, and a nonimmune woman has a 60- to 95-percent risk of becoming infected after exposure (Whitley, 2012). She is then contagious from 1 day before the onset of the rash until the lesions are crusted over.

Maternal Infection

Primary varicella infection presents with a 1- to 2-day flu-like prodrome, which is followed by pruritic vesicular lesions that

crust over in 3 to 7 days. Infection tends to be more severe in adults, and a quarter of varicella deaths are within the 5 percent of nonimmune adults (Centers for Disease Control and Prevention, 2007).

Mortality is predominately due to varicella pneumonia, which is thought to be more severe during adulthood and particularly in pregnancy. Between 5 and 20 percent of infected pregnant women developed pneumonitis (Centers for Disease Control and Prevention, 2007; Harger, 2002). Risk factors for VZV pneumonia include smoking and having more than 100 cutaneous lesions. Maternal mortality rates with pneumonia have decreased to 1 to 2 percent (Chandra, 1998). Symptoms of pneumonia usually appear 3 to 5 days into the course of illness. It is characterized by fever, tachypnea, dry cough, dyspnea, and pleuritic pain. Nodular infiltrates are similar to other viral pneumonias (Chap. 51, p. 1018). Although resolution of pneumonitis parallels that of skin lesions, fever and compromised pulmonary function may persist for weeks.

If primary varicella infection is reactivated years later, it causes *herpes zoster* or *shingles* (Whitley, 2012). This presents as a unilateral dermatomal vesicular eruption associated with severe pain. Zoster does not appear to be more frequent or severe in pregnant women. Enders and associates (1994) reviewed 366 cases during pregnancy and found little evidence that zoster causes congenital malformations. Zoster is contagious if blisters are broken, although less so than primary varicella infection.

Fetal and Neonatal Infection

In women with chicken pox during the first half of pregnancy, the fetus may develop congenital varicella syndrome. Some features include chorioretinitis, microphthalmia, cerebral cortical atrophy, growth restriction, hydronephrosis, limb hypoplasia, and cicatricial skin lesions as shown in [Figure 64-1](#) (Auriti, 2009). Enders and coworkers (1994) evaluated 1373 pregnant women with varicella infection. When maternal infection developed before 13 weeks, only two of 472 pregnancies—0.4 percent—had neonates with congenital varicella.

FIGURE 64-1 Atrophy of the lower extremity with bony defects and scarring in a fetus infected during the first trimester by varicella. (From Paryani, 1986, with permission.)

The highest risk was between 13 and 20 weeks, during which time seven of 351 exposed fetuses—2 percent—had evidence of congenital varicella. After 20 weeks' gestation, the researchers found no clinical evidence of congenital infection. Thus, congenital infections, particularly after 20 weeks, are uncommon. Subsequent sporadic reports have described central nervous system abnormalities and skin lesions in fetuses who developed congenital varicella in weeks 21 to 28 of gestation (Lamont, 2011b; Marin, 2007).

If the fetus or neonate is exposed to active infection just before or during delivery, and therefore before maternal antibody has been formed, then there is a serious threat to newborns. Attack rates range from 25 to 50 percent, and mortality rates approach 30 percent. In some instances, neonates develop disseminated visceral and central nervous system disease, which is commonly fatal. For this reason, varicella-zoster immune globulin should be administered to neonates born to mothers who have clinical evidence of varicella 5 days before and up to 2 days after delivery.

Diagnosis

Maternal varicella infection is usually diagnosed clinically. The virus may also be isolated by scraping the vesicle base during primary infection and performing a Tzanck smear, tissue culture, or direct fluorescent antibody testing. Also, available nucleic acid amplification tests (NAATs) are very sensitive. Congenital varicella may be diagnosed using NAAT analysis of amniotic fluid, although a positive result does not correlate well with the development of congenital infection (Mendelson, 2006). A detailed anatomical sonographic evaluation performed at least 5 weeks after maternal infection may disclose abnormalities, but the sensitivity is low (Mandelbrot, 2012).

Management

Maternal Viral Exposure. There are several aspects of maternal varicella virus exposure and infection in pregnancy that affect management. Because most adults are VZV seropositive, exposed pregnant women with a negative history for chicken pox should undergo VZV serologic testing. At least 70 percent of these women will be seropositive, and thus immune. Exposed pregnant women who are susceptible should be given VariZIG, a recently approved varicella zoster immune globulin. Although best given within 96 hours of exposure, its use is approved for up to 10 days to prevent or attenuate varicella infection (Centers for Disease Control and Prevention, 2012a, 2013h).

Maternal Infection. *Any patient diagnosed with primary varicella infection should be isolated from pregnant women.* Because pneumonia often presents with few symptoms, a chest radiograph is recommended by many. Most women require only supportive care, but those who require intravenous (IV) fluids and especially those with pneumonia are hospitalized. Intravenous acyclovir therapy is given to women requiring hospitalization—500 mg/m² or 10 to 15 mg/kg every 8 hours.

Vaccination. An attenuated live-virus vaccine—*Varivax*—was approved in 1995. Two doses, given 4 to 8 weeks apart,

are recommended for adolescents and adults with no history of varicella. This results in 98-percent seroconversion (Centers for Disease Control and Prevention, 2007). Importantly, vaccine-induced immunity diminishes over time, and the breakthrough infection rate approximates 5 percent at 10 years (Chaves, 2007). *The vaccine is not recommended for pregnant women or for those who may become pregnant within a month following each vaccine dose.* That said, a registry of 981 vaccine-exposed pregnancies reports no cases of congenital varicella syndrome or other congenital associated malformations (Wilson, 2008). The attenuated vaccine virus is not secreted in breast milk. Thus, postpartum vaccination should not be delayed because of breast feeding (American College of Obstetricians and Gynecologists, 2013a; Bohlke, 2003).

Influenza

These respiratory infections are caused by members of the family Orthomyxoviridae. *Influenza A* and *B* form one genus of these RNA viruses, and both cause epidemic human disease. Influenza A viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) surface antigens. Influenza outbreaks occur annually, and the most recent epidemic was in 2013–2014 caused by an influenza A/H₁N₁ strain.

Maternal and Fetal Infection

Maternal influenza is characterized by fever, dry cough, and systemic symptoms. Infection usually is not life-threatening in otherwise healthy adults, but pregnant women appear to be more susceptible to serious complications, particularly pulmonary involvement (Cox, 2006; Neuzil, 1998; Rasmussen, 2012). In early 2003, widespread influenza A infection affected pregnant women. At Parkland Hospital, more than 100 women were hospitalized for this infection, and 12 percent had pulmonary infiltrates seen radiographically (Rogers, 2010).

There is no firm evidence that influenza A virus causes congenital malformations (Irving, 2000; Saxén, 1990). Conversely, Lynberg and colleagues (1994) reported increased neural-tube defects in neonates born to women with influenza early in pregnancy, but this was possibly associated with hyperthermia (Chap. 12, p. 284). Viremia is infrequent, and transplacental passage is rare (Rasmussen, 2012). Stillbirth, preterm delivery, and first-trimester abortion have all been reported, usually correlated to severity of maternal infection (Centers for Disease Control and Prevention, 2011; Pierce, 2011; Yates, 2010).

Influenza may be detected in nasopharyngeal swabs using viral antigen rapid detection assays (Table 64-2). Reverse transcriptase–polymerase chain reaction (RT-PCR) is the more sensitive and specific test, although not commercially available in many hospitals (Dolin, 2012). In contrast, rapid influenza diagnostic tests (RIDTs) are least indicative, with sensitivities of 40 to 70 percent. In the Parkland Hospital emergency room, immunofluorescent antibody assays are used. Nasopharyngeal specimens are collected as early as possible after symptom onset to maximize influenza testing sensitivity. Importantly, decisions to administer antiviral medications for

TABLE 64-2. Outpatient Influenza A and B Virus Testing Methods

Method ^a	Test Time
Viral cell culture	3–10 d
Rapid cell culture	1–3 d
Direct (DFA) or indirect (IFA) fluorescent antibody assay	1–4 hr
RT-PCR and other molecular assays	1–6 hr
Rapid influenza diagnostic tests	< 30 min

^aNasopharyngeal or throat swab.

RT-PCR = reverse transcription-polymerase chain reaction. Abbreviated from Centers for Disease Control and Prevention, 2013f.

influenza treatment or chemoprophylaxis should be based on clinical symptoms and epidemiological factors. Moreover, the start of therapy should not be delayed pending testing results (Centers for Disease Control and Prevention, 2013f).

Management

Two classes of antiviral medications are currently available. *Neuraminidase inhibitors* are highly effective for the treatment of early influenza A and B. These include *oseltamivir* (Tamiflu), which is taken orally for treatment and for chemoprophylaxis, and *zanamivir* (Relenza), which is inhaled for treatment. *Peramivir* is an investigational drug administered intravenously.

The *adamantanes* include amantadine and rimantadine, which were used for years for treatment and chemoprophylaxis of influenza A. In 2005, influenza A resistance to adamantane was reported to be > 90 percent in the United States, and thus, adamantane use is not currently recommended. It is possible that these drugs may again be effective for subsequently mutated strains.

There is limited experience with all five of these antiviral agents in pregnant women. They are Food and Drug Administration category C drugs, used when the potential benefits outweigh the risks. At Parkland Hospital, we recommend starting oseltamivir treatment within 48 hours of symptom onset—75 mg orally twice daily for 5 days. Prophylaxis with oseltamivir, 75 mg orally once daily for 10 days, is also recommended for significant exposures. Antibacterial medications should be added when a secondary bacterial pneumonia is suspected (Chap. 51, p. 1016).

Vaccination

Effective vaccines are formulated annually. Vaccination against influenza throughout the influenza season, but optimally in October or November, is recommended by the Centers for Disease Control and Prevention (CDC) (2013e) and the American College of Obstetricians and Gynecologists (2010) for all women who will be pregnant during the influenza season. This is especially important for those affected by chronic medical disorders such as diabetes, heart disease,

asthma, or human immunodeficiency virus (HIV) infection (Jamieson, 2012). Inactivated vaccine prevents clinical illness in 70 to 90 percent of healthy adults. Importantly, there is no evidence of teratogenicity or other adverse maternal or fetal events (Conlin, 2013; Kharbanda, 2013; Munoz, 2012; Nordin, 2013; Sheffield, 2012). Moreover, several studies have found decreased rates of influenza in infants up to 6 months of age whose mothers were vaccinated during pregnancy (Steinhoff, 2012; Zaman, 2008). Immunogenicity of the trivalent inactivated seasonal influenza vaccine in pregnant women is similar to that in the nonpregnant individual (Sperling, 2012). A live attenuated influenza virus vaccine is available for intranasal use but is not recommended for pregnant women.

Mumps

This uncommon adult infection is caused by an RNA paramyxovirus. Because of childhood immunization, up to 90 percent of adults are seropositive (Rubin, 2012). The virus primarily infects the salivary glands, and hence its name—mumps—is derived from Latin, “to grimace.” Infection also may involve the gonads, meninges, pancreas, and other organs. It is transmitted by direct contact with respiratory secretions, saliva, or through fomites. Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

Women who develop mumps in the first trimester may have an increased risk of spontaneous abortion. Infection in pregnancy is not associated with congenital malformations, and fetal infection is rare (McLean, 2013).

The live attenuated Jeryl-Lynn vaccine strain is part of the MMR vaccine—measles, mumps, and rubella—and is contraindicated in pregnancy according to the CDC (McLean, 2013). No malformations attributable to MMR vaccination in pregnancy have been reported, but pregnancy should be avoided for 30 days after mumps vaccination. The vaccine may be given to susceptible women postpartum, and breast feeding is not a contraindication.

Rubeola (Measles)

Measles is caused by a highly contagious RNA virus of the family Paramyxoviridae that only infects humans. Annual outbreaks occur in late winter and early spring, transmission is primarily by respiratory droplets, and the secondary attack rate among contacts exceeds 90 percent (Moss, 2012). Infection is characterized by fever, coryza, conjunctivitis, and cough. The characteristic erythematous maculopapular rash develops on the face and neck and then spreads to the back, trunk, and extremities. *Koplik spots* are small white lesions with surrounding erythema found within the oral cavity. Diagnosis is most commonly performed by serology, although RT-PCR tests are available. Treatment is supportive.

Pregnant women without evidence of measles immunity should be administered intravenous immune globulin (IVIG), 400 mg/kg within 6 days of a measles exposure (McLean, 2013). Active vaccination is not performed during pregnancy. However, susceptible women can be vaccinated routinely postpartum, and breast feeding is not contraindicated (Ohji, 2009).

The virus does not appear to be teratogenic (Siegel, 1973). However, an increased frequency of abortion, preterm delivery, and low-birthweight neonates is noted with maternal measles (American Academy of Pediatrics, 2006; Siegel, 1966). If a woman develops measles shortly before birth, there is considerable risk of serious infection developing in the neonate, especially in a preterm neonate.

Rubella—German Measles

This RNA togavirus typically causes infections of minor importance in the absence of pregnancy. *Rubella infection in the first trimester, however, poses significant risk for abortion and severe congenital malformations.* Transmission occurs via nasopharyngeal secretions, and the transmission rate is 80 percent to susceptible individuals. The peak incidence is late winter and spring.

Maternal rubella infection is usually a mild, febrile illness with a generalized maculopapular rash beginning on the face and spreading to the trunk and extremities. Other symptoms may include arthralgias or arthritis, head and neck lymphadenopathy, and conjunctivitis. The incubation period is 12 to 23 days. Viremia usually precedes clinical signs by about a week, and adults are infectious during viremia and through 5 to 7 days of the rash. Up to half of maternal infections are subclinical despite viremia that may cause devastating fetal infection (McLean, 2013; Zimmerman, 2012).

Diagnosis

Rubella may be isolated from the urine, blood, nasopharynx, and cerebrospinal fluid for up to 2 weeks after rash onset. The diagnosis is usually made, however, with serological analysis. Specific IgM antibody can be detected using enzyme-linked immunoassay from 4 to 5 days after onset of clinical disease, but it can persist for up to 6 weeks after appearance of the rash (Zimmerman, 2012). Importantly, rubella reinfection can give rise to transient low levels of IgM. Serum IgG antibody titers peak 1 to 2 weeks after rash onset. This rapid antibody response may complicate serodiagnosis unless samples are initially collected within a few days after the onset of the rash. If, for example, the first specimen was obtained 10 days after the rash, detection of IgG antibodies would fail to differentiate between very recent disease and preexisting immunity to rubella. IgG avidity testing is performed concomitant with the serological tests above. High-avidity IgG antibodies indicate an infection at least 2 months in the past.

Fetal Effects

Rubella is one of the most complete teratogens, and sequelae of fetal infection are worst during organogenesis (Adams Waldorf, 2013). Pregnant women with rubella infection and a rash during the first 12 weeks of gestation have a fetus with congenital infection in up to 90 percent of cases (Miller, 1982; Zimmerman, 2012). At 13 to 14 weeks' gestation, this incidence was 54 percent, and by the end of the second trimester, it was 25 percent. Defects are rare after 20 weeks (Miller, 1982). According to Reef and colleagues (2000),

congenital rubella syndrome includes one or more of the following:

- Eye defects—cataracts and congenital glaucoma
- Congenital heart defects—patent ductus arteriosus and pulmonary artery stenosis
- Sensorineural deafness—the most common single defect
- Central nervous system defects—microcephaly, developmental delay, mental retardation, and meningoencephalitis
- Pigmentary retinopathy
- Neonatal purpura
- Hepatosplenomegaly and jaundice
- Radiolucent bone disease

Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants and to susceptible adults who contact them.

The *extended rubella syndrome*, with progressive panencephalitis and type 1 diabetes, may not develop clinically until the second or third decade of life. As many as a third of neonates who are asymptomatic at birth may manifest such developmental injury (Webster, 1998).

Management and Prevention

There is no specific treatment for rubella. Droplet precautions for 7 days after the onset of the rash are recommended. Primary prevention relies on comprehensive vaccination programs (Coonrod, 2008). Although large epidemics of rubella have virtually disappeared in the United States because of immunization, up to 10 percent of women in the United States are susceptible (Zimmerman, 2012). Cluster outbreaks during the 1990s mainly involved persons born outside the United States, as congenital rubella is still common in developing nations (Banatvala, 2004; Reef, 2002).

To eradicate rubella and prevent congenital rubella syndrome completely, a comprehensive approach is recommended for immunizing the adult population (McLean, 2013). MMR vaccine should be offered to nonpregnant women of childbearing age who do not have evidence of immunity whenever they make contact with the health-care system. Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is important. Rubella vaccination should be avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus. Although there is a small overall theoretical risk of up to 2.6 percent, there is no observed evidence that the vaccine induces malformations (Badilla, 2007; McLean, 2013). MMR vaccination is not an indication for pregnancy termination. Prenatal serological screening for rubella is indicated for all pregnant women. Women found to be nonimmune should be offered the MMR vaccine postpartum.

Despite native or vaccine-induced immunity, subclinical rubella maternal *reinfection* may develop during outbreaks. And although fetal infection can rarely occur, no adverse fetal effects have been described.

Respiratory Viruses

More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis, laryngitis, bronchitis, and pneumonia.

Rhinovirus, coronavirus, and adenovirus are major causes of the common cold. The RNA-containing rhinovirus and coronavirus usually produce a trivial, self-limited illness characterized by rhinorrhea, sneezing, and congestion. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia.

Teratogenic effects of respiratory viruses are controversial. Women with a common cold had a four- to fivefold increased risk of fetal anencephaly in a 393-woman cohort in the Finnish Register of Congenital Malformations (Kurppa, 1991). In another population study, Shaw and coworkers (1998) analyzed California births from 1989 to 1991 and concluded that low attributable risks for neural-tube defects were associated with many illnesses in early pregnancy. Recently, amniotic fluid viral PCR studies were performed in 1191 women undergoing amniocentesis for fetal karyotyping. Viral PCR was positive in 6.5 percent, with adenovirus being the virus most frequently identified. There was an association with fetal-growth restriction, nonimmune hydrops, foot/hand abnormalities, and neural-tube defects (Adams, 2012).

Adenoviral infection is a known cause of childhood myocarditis. Towbin (1994) and Forsnes (1998) used PCR tests to identify and link adenovirus to fetal myocarditis and nonimmune hydrops.

Hantaviruses

These RNA viruses are members of the family Bunyaviridae. They are associated with a rodent reservoir, and transmission involves inhalation of virus excreted in rodent urine and feces. An outbreak in the Western United States occurred in 1993 due to Sin Nombre virus. The resulting Hantavirus pulmonary syndrome was characterized by severe adult respiratory distress syndrome with a case-fatality rate of 30 to 40 percent (Peters, 2012). Several outbreaks since then have occurred, the most recent in 2012.

Hantaviruses are a heterogeneous group of viruses with low and variable rates of transplacental transmission. Howard and associates (1999) reported the syndrome to cause maternal death, fetal demise, and preterm birth. They found no evidence of vertical transmission of the Sin Nombre virus. However, vertical transmission occurred inconsistently in association with hemorrhagic fever and renal syndrome caused by another Hantavirus species, the Hantaan virus.

Enteroviruses

These viruses are a major subgroup of RNA picornaviruses that include poliovirus, coxsackievirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the central nervous system, skin, heart, and lungs. Most maternal infections are subclinical yet can be fatal to the fetus-neonate (Goldenberg, 2003; Tassin, 2014). Hepatitis A is an enterovirus that is discussed in Chapter 55 (p. 1089).

Coxsackievirus

Infections with coxsackievirus group A and B are usually asymptomatic. Symptomatic infections—usually with group

B—include aseptic meningitis, polio-like illness, hand foot and mouth disease, rashes, respiratory disease, pleuritis, pericarditis, and myocarditis. No treatment or vaccination is available (Cohen, 2012). Coxsackievirus may be transmitted by maternal secretions to the fetus at delivery in up to half of mothers who seroconverted during pregnancy (Modlin, 1988). Transplacental passage has also been reported (Ornoy, 2006).

Congenital malformations may be increased slightly in pregnant women who had serological evidence of coxsackievirus (Brown, 1972). Viremia can cause fetal hepatitis, skin lesions, myocarditis, and encephalomyelitis, all of which may be fatal. Koro'lkova and colleagues (1989) have also described cardiac anomalies. There is evidence of increased low-birth-weight, preterm, and small-for-gestational-age newborns (Chen, 2010). Finally, a rare association between maternal coxsackievirus infection and insulin-dependent diabetes in offspring has been reported (Dahlquist, 1996; Hyoti, 1995; Viskari, 2012).

Poliovirus

Most of these highly contagious but rare infections are subclinical or mild. The virus is trophic for the central nervous system, and it can cause paralytic poliomyelitis (Cohen, 2012). Siegel (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Perinatal transmission has been observed, especially when maternal infection developed in the third trimester (Bates, 1955). Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto, 1989).

Parvovirus

Human parvovirus B19 causes *erythema infectiosum*, or *fifth disease*. The B19 virus is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors (Brown, 2012). This can lead to anemia, which is its primary fetal effect. Only individuals with the erythrocyte globoside membrane P antigen are susceptible. In women with severe hemolytic anemia—for example, sickle-cell disease—parvovirus infection may cause an aplastic crisis.

The main mode of parvovirus transmission is respiratory or hand-to-mouth contact, and the infection is common in spring months. The maternal infection rate is highest in women with school-aged children and in day-care workers but not usually in schoolteachers. Viremia develops 4 to 14 days after exposure. By adulthood, only 40 percent of women are susceptible. The annual seroconversion rate is 1 to 2 percent but is greater than 10 percent during epidemic periods (Brown, 2012). Secondary attack rates approach 50 percent.

Maternal Infection

In 20 to 30 percent of adults, infection is asymptomatic. Fever, headache, and flu-like symptoms may begin in the last

few days of the viremic phase. Several days later, a bright red rash with erythroderma affects the face and gives a slapped-cheek appearance. The rash becomes lacelike and spreads to the trunk and extremities. Adults often have milder rashes and develop symmetrical polyarthralgia that may persist several weeks. There is no evidence that parvovirus infection is altered by pregnancy (Valeur-Jensen, 1999). With recovery, there is production of IgM antibody 7 to 10 days postinfection, and this persists for 3 to 4 months. Several days after IgM is produced, IgG antibody is detectable and persists for life with natural immunity.

Fetal Infection

There is vertical transmission to the fetus in up to a third of maternal parvovirus infections (Bonvicini, 2011; de Jong, 2011; Lamont, 2011a). Fetal infection has been associated with abortion, nonimmune hydrops, and stillbirth (Enders, 2010; Lassen, 2012; McClure, 2009). In a review of 1089 cases of maternal B19 infection from nine studies, Crane (2002) reported an overall fetal loss rate of 10 percent. It was 15 percent for infections before 20 weeks but was only 2.3 percent after 20 weeks. Its role in later unexplained stillbirths is unclear because most data are from retrospective cohorts with incomplete maternal and fetal histological evaluations (Norbeck, 2002; Skjöldebrand-Sparre, 2000; Tolfvenstam, 2001). Currently, there are no data to support evaluating asymptomatic mothers and stillborn fetuses for parvovirus infection.

Parvovirus is the most frequent infectious cause of nonimmune hydrops in autopsied fetuses (Rogers, 1999). That said, this complication develops only in approximately 1 percent of infected women and usually is caused by infection in the first half of gestation (Crane, 2002; Enders, 2004; Puccetti, 2012).

Yaegashi (2000) has extensively investigated the development and pathophysiology of parvovirus B19 fetal hydrops. At least 85 percent of cases of fetal infection developed within 10 weeks of maternal infection, and the mean interval was 6 to 7 weeks. More than 80 percent of hydrops cases were found in the second trimester, with a mean gestational age of 22 to 23 weeks. The critical period for maternal infection leading to fetal hydrops was estimated to be between 13 and 16 weeks—coincidental with the period in which fetal hepatic hemopoiesis is greatest.

Diagnosis and Management

An algorithm for diagnosis of maternal parvoviral infection is illustrated in [Figure 64-2](#). Diagnosis is generally made by maternal serological testing for specific IgG and IgM antibodies (Bonvicini, 2011; Butchko, 2004; Enders, 2006). Viral DNA may be detectable by PCR in maternal serum during the prodrome and persist for months to years after infection. Fetal infection is diagnosed by detection of B19 viral DNA in amniotic fluid or IgM antibodies in fetal serum obtained by cordocentesis (de Jong, 2011; Weiffenbach, 2012). Fetal and maternal viral loads do not predict fetal morbidity and mortality (de Haan, 2007).

Most cases of parvovirus-associated hydrops develop in the first 10 weeks after infection (Enders, 2004). Thus, serial sonography every 2 weeks should be performed in women with recent infection (see [Fig. 64-2](#)). Middle cerebral artery (MCA)

Doppler interrogation can also be used to predict fetal anemia (Chap. 10, p. 221). Elevated peak systolic velocity values in the fetal MCA accurately predict fetal anemia (Chauvet, 2011; Cosmi, 2002; Delle Chiaie, 2001). Fetal blood sampling is warranted with hydrops to assess the degree of fetal anemia. Fetal myocarditis may induce hydrops with less severe anemia.

Depending on gestational age, fetal transfusion for hydrops may improve outcome in some cases (Enders, 2004; Schild, 1999; von Kaisenberg, 2001). Mortality rates as high as 30 percent have been reported in hydropic fetuses without transfusions. With transfusion, 94 percent of hydrops cases resolve within 6 to 12 weeks, and the overall mortality rate is < 10 percent. Most fetuses require only one transfusion because hemopoiesis resumes as infection resolves. The technique for fetal transfusion is described in Chapter 14 (p. 300).

Long-Term Prognosis

Reports describing neurodevelopmental outcomes in fetuses transfused for B19 infection-induced anemia are conflicting. Nagel and colleagues (2007) reviewed 25 transfusions in 24 hydropic fetuses. There was abnormal neurodevelopment in five of 16 survivors—32 percent—at 6 months to 8 years. Outcomes were not related to severity of fetal anemia or acidemia, and these investigators hypothesized that the infection itself induced cerebral damage. De Jong (2012) described long-term neurodevelopmental outcomes in 28 children treated with intrauterine transfusion. At a median age of 5 years, 11 percent had neurodevelopmental impairment. Conversely, Dembinski (2003) followed 20 children for a mean of 52 months after transfusion. They found no significant neurodevelopmental delay despite severe fetal anemia.

Prevention

There is currently no approved vaccine for human parvovirus B19, and there is no evidence that antiviral treatment prevents maternal or fetal infection (Broliden, 2006). Decisions to avoid higher-risk work settings are complex and require assessment of exposure risks. Pregnant women should be counseled that risks for infection approximate 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure such as for teachers; and 50 percent for close, frequent interaction such as in the home. Workers at day-care centers and schools need not avoid infected children because infectivity is greatest before clinical illness. Finally, infected children do not require isolation.

Cytomegalovirus

This ubiquitous DNA herpes virus eventually infects most humans. Cytomegalovirus (CMV) is the most common perinatal infection in the developed world. Specifically, some evidence of fetal infection is found in 0.2 to 2.5 percent of all neonates (Kenneson, 2007). The virus is secreted into all body fluids, and person-to-person contact with viral-laden saliva, semen, urine, blood, and nasopharyngeal and cervical secretions can transmit infection. The fetus may become infected by transplacental viremia, or the neonate is infected at delivery or during breast feeding. Moreover, acquisition

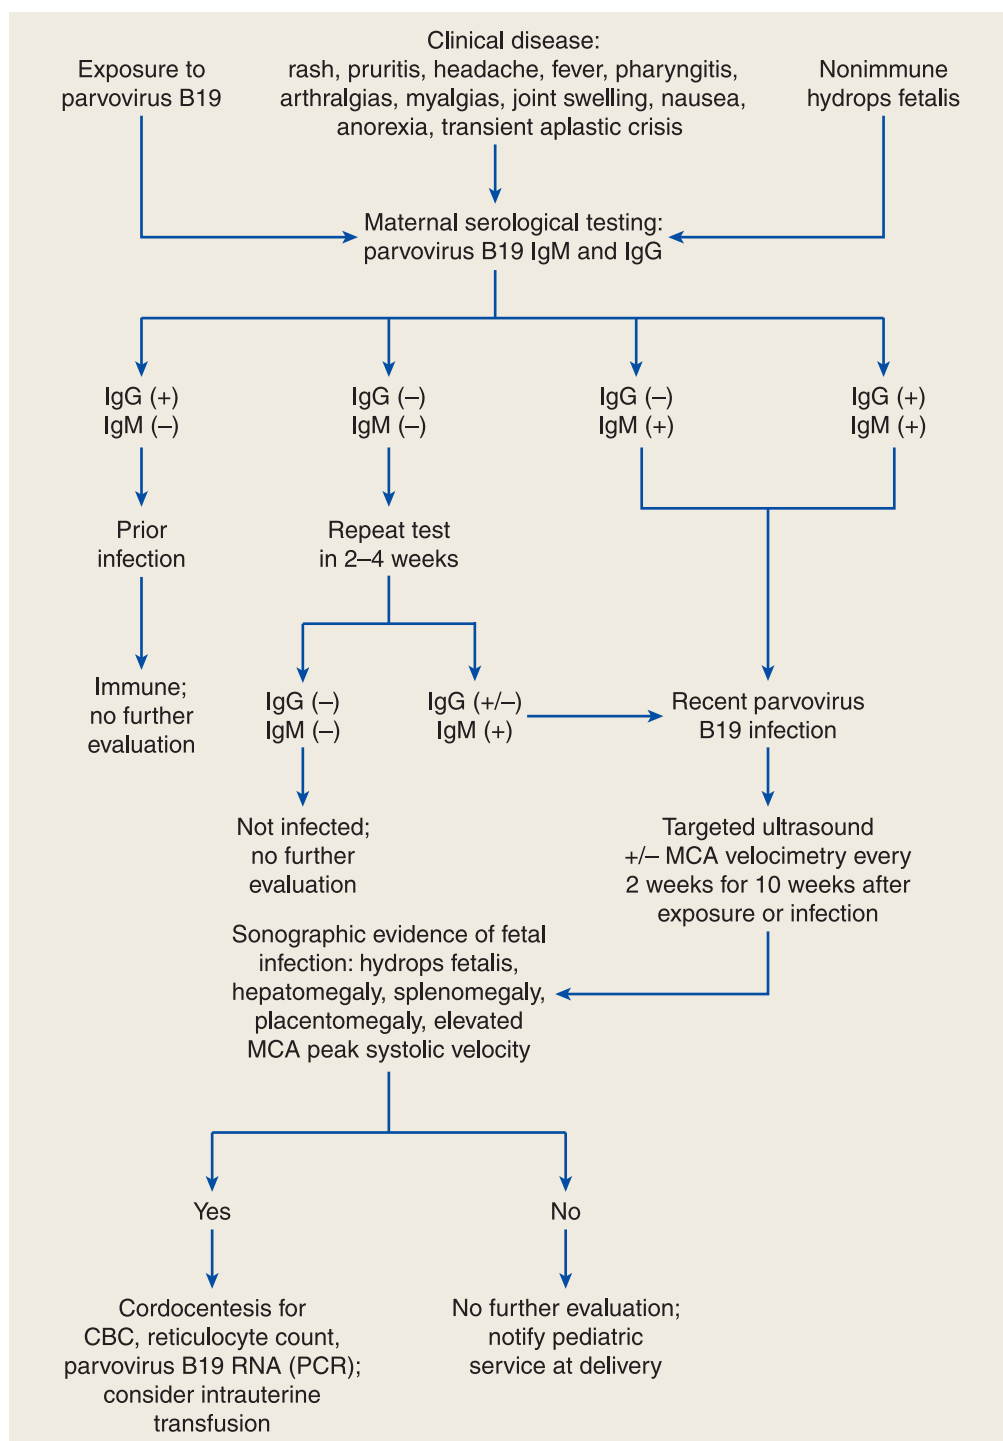

FIGURE 64-2 Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. CBC = complete blood count; IgG = immunoglobulin G; IgM = immunoglobulin M; MCA = middle cerebral artery; PCR = polymerase chain reaction; RNA = ribonucleic acid.

continues to accrue. Day-care centers, for example, are a frequent source, and by 2 to 3 years of age, many children have infected one another and may transmit infection to their parents (Demmler, 1991; Pass, 1991). Revello and coworkers (2008) reported that amniocentesis in women whose blood is positive for CMV DNA does not result in iatrogenic fetal transmission.

Up to 85 percent of women from lower socioeconomic backgrounds are seropositive by the time of pregnancy, whereas only

half of women in higher income groups are immune. Following primary CMV infection, and in a manner similar to other herpes virus infections, the virus becomes latent with periodic reactivation characterized by viral shedding. This occurs despite high serum levels of anti-CMV IgG antibody. These antibodies do not prevent maternal recurrence, reactivation, or reinfection, nor do they totally mitigate fetal or neonatal infection.

Women who are seronegative before pregnancy but who develop primary CMV infection during pregnancy are at

FIGURE 64-3 Sagittal (A) and coronal (B) cranial sonograms from a neonate with congenital cytomegalovirus infection. The arrows indicate periventricular calcifications.

greatest risk to have an infected fetus. It is estimated that 25 percent of congenital CMV infections in the United States are from primary maternal infection (Wang, 2011). Because most CMV infections are clinically silent, they are detected by seroconversion, and this may be as high as 1 to 7 percent (Hyde, 2010).

Maternal Infection

Pregnancy does not increase the risk or severity of maternal CMV infection. Most infections are asymptomatic, but 10 to 15 percent of infected adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritides. Immunocompromised women may develop myocarditis, pneumonitis, hepatitis, retinitis, gastroenteritis, or meningoencephalitis. Nigro and associates (2003) reported that most women in a cohort with primary infection had elevated serum aminotransferases or lymphocytosis. Reactivation disease usually is asymptomatic, although viral shedding is common.

Primary maternal CMV infection is transmitted to the fetus in approximately 40 percent of cases and can cause severe morbidity (Fowler, 1992; Liesnard, 2000). In contrast, recurrent maternal infection infects the fetus in only 0.15 to 1 percent of cases. A review of nine studies of CMV vertical transmission rates reported first-trimester transmission in 36 percent, second-trimester in 40 percent, and third-trimester in 65 percent (Picone, 2013). Naturally acquired immunity during pregnancy results in a 70-percent risk reduction of congenital CMV infection in future pregnancies (Fowler, 2003). However, as noted earlier, maternal immunity does not prevent recurrences, and maternal antibodies do not prevent fetal infection. Also, some seropositive women can be reinfected with a different viral strain that can cause fetal infection and symptomatic congenital disease (Ross, 2011).

Fetal Infection

When a newborn has apparent sequelae of in utero-acquired CMV infection, it is referred to as *symptomatic CMV infection*. Congenital infection is a syndrome that may include growth restriction, microcephaly, intracranial calcifications, chorio-

retinitis, mental and motor retardation, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura (Fig. 64-3). The pathogenesis of these outcomes has been reviewed by Cheeran and colleagues (2009). Of the estimated 40,000 infected neonates born each year, only 5 to 10 percent demonstrate this syndrome (Fowler, 1992). Thus, most infected infants are asymptomatic at birth, but some develop late-onset sequelae. They may include hearing loss, neurological deficits, chorioretinitis, psychomotor retardation, and learning disabilities.

Prenatal Diagnosis

Routine prenatal CMV serological screening is currently not recommended. Pregnant women should be tested for CMV if they present with a mononucleosis-like illness or if congenital infection is suspected based on abnormal sonographic findings. Primary infection is diagnosed using CMV-specific IgG testing of paired acute and convalescent sera. CMV IgM does not accurately reflect timing of seroconversion because IgM antibody levels may be elevated for more than a year (Stagno, 1985). Moreover, CMV IgM may be found with reactivation disease or reinfection with a new strain. Thus, specific CMV IgG avidity testing is valuable in confirming primary CMV infection (Fig. 64-4). High anti-CMV IgG avidity indicates primary maternal infection > 6 months before testing (Kanengisser-Pines, 2009). Finally, viral culture may be useful, although a minimum of 21 days is required before culture findings are considered negative.

Several fetal abnormalities associated with CMV infection may be seen with sonography, computed tomography, or magnetic resonance imaging. In some cases, they are found at the time of routine prenatal sonographic screening, but in others they are part of a specific evaluation in women with CMV infection. Findings include microcephaly, ventriculomegaly, and cerebral calcifications; ascites, hepatomegaly, splenomegaly, and hyperechoic bowel; hydrops; and oligohydramnios (Maling, 2003). Abnormal sonographic findings seen in combination with positive findings in fetal blood or amniotic fluid are predictive of an approximate 75-percent risk of symptomatic congenital infection (Enders, 2001).

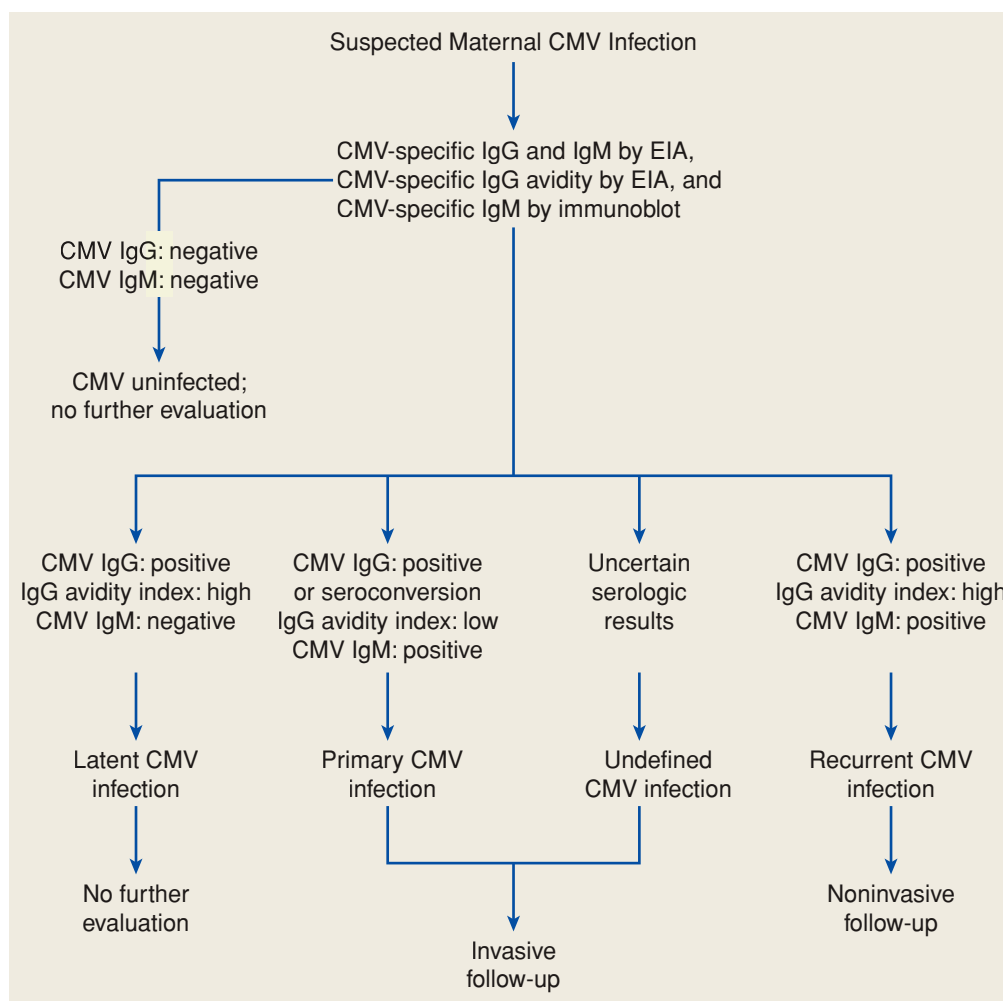

FIGURE 64-4 Algorithm for evaluation of suspected maternal primary cytomegalovirus (CMV) infection in pregnancy. EIA = enzyme immunoassay; IgG = immunoglobulin G; IgM = immunoglobulin M.

CMV nucleic acid amplification testing of amniotic fluid is considered the gold standard for the diagnosis of fetal infection. Sensitivities range from 70 to 99 percent and depend on amniocentesis timing (Nigro, 2005; Revello, 2004). Sensitivity is highest when amniocentesis is performed at least 6 weeks after maternal infection and after 21 weeks (Azam, 2001; Guerra, 2000). A negative amniotic fluid PCR does not exclude fetal infection and may need to be repeated if suspicion for fetal infection is high.

Management and Prevention

The management of the immunocompetent pregnant woman with primary or recurrent CMV is limited to symptomatic treatment. If recent primary CMV infection is confirmed, amniotic fluid analysis should be offered. Counseling regarding fetal outcome depends on the gestation age during which primary infection is documented. Even with the high infection rate with primary infection in the first half of pregnancy, most fetuses develop normally. However, pregnancy termination may be an option for some.

Kimberlin (2003) showed that intravenous ganciclovir administered for 6 weeks to neonates with symptomatic central nervous system disease prevents hearing deterioration at

6 months and possibly later. Conversely, antiviral chemotherapy given antepartum does not avert in utero CMV transmission. Passive immunization with CMV-specific hyperimmune globulin lowers the risk of congenital CMV infection when given to pregnant women with primary disease (Nigro, 2005, 2012; Visentin, 2012). Further clinical trials are necessary before this becomes standard treatment (McCarthy, 2011).

There is no CMV vaccine. Prevention of congenital infection relies on avoiding maternal primary infection, especially in early pregnancy. Basic measures such as good hygiene and hand washing have been promoted, particularly for women with toddlers in day-care settings (Fowler, 2000). Although there may be sexual transmission from infected partners, there are no data on the efficacy of preventive strategies.

BACTERIAL INFECTIONS

Group A Streptococcus

Infections caused by *Streptococcus pyogenes* are important in pregnant women. It is the most frequent bacterial cause of acute pharyngitis and is associated with several systemic and cutaneous infections. *S. pyogenes* produces numerous toxins and enzymes

responsible for the local and systemic toxicity associated with this organism. Pyrogenic exotoxin-producing strains are usually associated with severe disease (Mason, 2012; Wessels, 2012). In most cases, streptococcal pharyngitis, scarlet fever, and erysipelas are not life threatening. Treatment, usually with penicillin, is similar in pregnant and nonpregnant women (Shulman, 2012).

In the United States, *Streptococcus pyogenes* infrequently causes puerperal infection. Still, it remains the most common cause of severe maternal postpartum infection and death worldwide, and the incidence of these infections is increasing (Deutscher, 2011; Hamilton, 2013; Mason, 2012; Wessels, 2012). Puerperal infections are discussed in detail in Chapter 37 (p. 682). The early 1990s saw the rise of streptococcal toxic shock syndrome, manifested by hypotension, fever, and evidence of multiorgan failure with associated bacteremia. The case-fatality rate approximates 30 percent, and morbidity and mortality rates are improved with early recognition. Treatment includes clindamycin or penicillin therapy and often surgical debridement (Hamilton, 2013). No vaccine for group A streptococcus is commercially available.

■ Group B Streptococcus

Streptococcus agalactiae is a group B organism that can be found to colonize the gastrointestinal and genitourinary tract in 20 to 30 percent of pregnant women. Throughout pregnancy, group B *Streptococcus* (GBS) is isolated in a transient, intermittent, or chronic fashion. Although the organism is most likely always present in these same women, their isolation is not always homologous.

Maternal and Perinatal Infection

The spectrum of maternal and fetal GBS ranges from asymptomatic colonization to septicemia. *Streptococcus agalactiae* has been implicated in adverse pregnancy outcomes, including preterm labor, prematurely ruptured membranes, clinical and subclinical chorioamnionitis, and fetal infections. GBS can also cause maternal bacteriuria, pyelonephritis, osteomyelitis, postpartum mastitis, and puerperal infections. It remains the leading infectious cause of morbidity and mortality among infants in the United States (Centers for Disease Control and Prevention, 2010; Schrag, 2003; Wessels, 2012).

Neonatal sepsis has received the most attention due to its devastating consequences and available effective preventative measures. Infection < 7 days after birth is defined as *early-onset disease* and is seen in 0.24/1000 live births (Centers for Disease Control and Prevention, 2013a). Many investigators use a threshold of < 72 hours of life as most compatible with intrapartum acquisition of disease (Pulver, 2009; Wendel, 2002). We and others have also encountered several unexpected intrapartum stillbirths from GBS infections. Tudela and associates (2012) recently reported that newborns with early-onset GBS infection often had clinical evidence of fetal infection during labor or at delivery.

In many neonates, septicemia involves signs of serious illness that usually develop within 6 to 12 hours of birth. These include respiratory distress, apnea, and hypotension. At the outset, therefore, neonatal infection must be differentiated

from respiratory distress syndrome caused by insufficient surfactant production of the preterm neonate (Chap. 34, p. 653). The mortality rate with early-onset disease has declined to approximately 4 percent, and preterm newborns are disparately affected.

Late-onset disease caused by GBS is noted in 0.32 per 1000 live births and usually manifests as meningitis 1 week to 3 months after birth (Centers for Disease Control and Prevention, 2013a). The mortality rate, although appreciable, is less for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit devastating neurological sequelae.

Prophylaxis for Perinatal Infections

As GBS neonatal infections evolved beginning in the 1970s and before widespread intrapartum chemoprophylaxis, rates of early-onset sepsis ranged from 2 to 3 per 1000 live births. In 2002, the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics revised guidelines for perinatal prevention of GBS disease. They recommended universal rectovaginal culture screening for GBS at 35 to 37 weeks' gestation followed by intrapartum antibiotic prophylaxis for women identified to be carriers. Subsequent to implementation of these guidelines, the incidence of early-onset GBS neonatal sepsis has decreased to 0.24 cases per 1000 live births by 2012 (Centers for Disease Control and Prevention, 2013a). These guidelines were updated for early-onset GBS infection in 2010. They expanded laboratory identification criteria for GBS; updated algorithms for screening and intrapartum chemoprophylaxis for women with preterm prematurely ruptured membranes, preterm labor, or penicillin allergy; and described new dosing for penicillin G chemoprophylaxis.

Thus, during the past three decades, several strategies have been proposed to prevent perinatal acquisition of GBS infections (Ohlsson, 2013). These strategies have not been compared in randomized trials and are either culture-based or risk-based guidelines as subsequently discussed.

Culture-Based Prevention. The 2010 Centers for Disease Control and Prevention GBS Guidelines recommend a culture-based approach as shown in [Figure 64-5](#). Such a protocol was also adopted by the American College of Obstetricians and Gynecologists (2013c). This approach is designed to identify women who should be given intrapartum antimicrobial prophylaxis. Women are screened for GBS colonization at 35 to 37 weeks' gestation, and intrapartum antimicrobials are given to women with rectovaginal GBS-positive cultures. Selective enrichment broth followed by subculture improves detection. In addition, more rapid techniques such as DNA probes and nucleic acid amplification tests are being developed (Chan, 2006; Helali, 2012). A previous sibling with GBS invasive disease and identification of GBS bacteriuria in the current pregnancy are also considered indications for prophylaxis.

Risk-Based Prevention. A risk-based approach is recommended for women in labor and whose GBS culture results

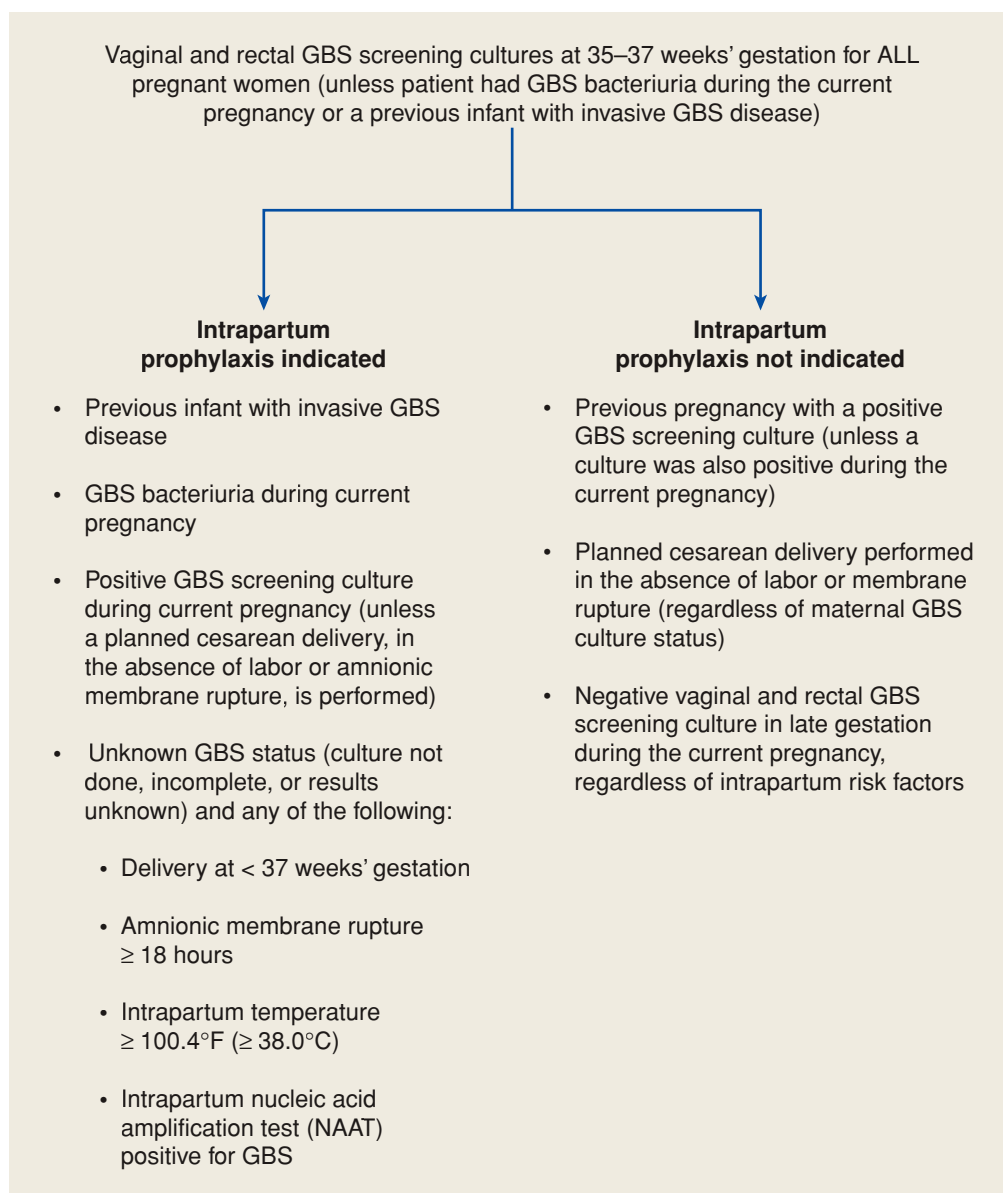

FIGURE 64-5 Indications for intrapartum prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures obtained at 35 to 37 weeks' gestation. (From Centers for Disease Control and Prevention, 2010.)

are not known. This approach relies on risk factors associated with intrapartum GBS transmission. Intrapartum chemoprophylaxis is given to women who have any of the following: delivery < 37 weeks, ruptured membranes ≥ 18 hours, or intrapartum temperature ≥ 100.4°F (≥ 38.0°C). Women with GBS during the current pregnancy and women with a prior infant with invasive early-onset GBS disease are also given chemoprophylaxis.

At Parkland Hospital in 1995—and prior to consensus guidelines—we adopted the risk-based approach for intrapartum treatment of women at high risk. In addition, all term neonates who were not given intrapartum prophylaxis were treated in the delivery room with aqueous penicillin G, 50,000 to 60,000 units intramuscularly. Rates of early-onset GBS infection and sepsis and of non-GBS sepsis decreased

to 0.4–0.66 per 1000 live births (Wendel, 2002). Non-GBS early-onset sepsis was identified in 0.24 per 1000 live births, and this was stable during the past two decades (Stafford, 2012). Thus, this approach has results similar to those reported by the Centers for Disease Control and Prevention (2010) for culture-based prevention.

Intrapartum Antimicrobial Prophylaxis

Prophylaxis administered 4 or more hours before delivery is highly effective (Fairlie, 2013). Regardless of screening method, penicillin remains the first-line agent for prophylaxis, and ampicillin is an acceptable alternative (Table 64-3). Women with a penicillin allergy and no history of anaphylaxis should be given cefazolin. Those at high risk for anaphylaxis should have antimicrobial susceptibility testing performed to

TABLE 64-3. Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease

Regimen	Treatment
Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 to 3.0 million units IV every 4 hours until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours or 2 g every 6 hours until delivery
Penicillin allergic	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery
Patients at high risk for anaphylaxis and with GBS susceptible to clindamycin	Clindamycin, 900 mg IV every 8 hours until delivery
Patients at high risk for anaphylaxis and with GBS resistant to clindamycin or susceptibility unknown	Vancomycin, 1 g IV every 12 hours until delivery

GBS = group B *Streptococcus*; IV = intravenous.

Adapted from the Centers for Disease Control and Prevention, 2010.

exclude clindamycin resistance. Clindamycin-sensitive but erythromycin-resistant isolates should have a D-zone test performed to assess for inducible clindamycin resistance. If clindamycin resistance is confirmed, vancomycin should be administered. *Erythromycin is no longer used for penicillin-allergic patients.*

Further recommendations for management of spontaneous preterm labor, threatened preterm delivery, or preterm prematurely ruptured membranes are shown in [Figure 64-6](#). Women undergoing cesarean delivery before labor onset with intact membranes do not need intrapartum GBS

chemoprophylaxis, regardless of GBS colonization status or gestational age.

Methicillin-Resistant *Staphylococcus Aureus*

Staphylococcus aureus is a pyogenic gram-positive organism and is considered the most virulent of the staphylococcal species. It primarily colonizes the nares, skin, genital tissues, and oropharynx. Approximately 20 percent of normal individuals are persistent carriers, 30 to 60 percent are intermittent carriers, and 20 to 50 percent are noncarriers (Gorwitz, 2008). Colonization

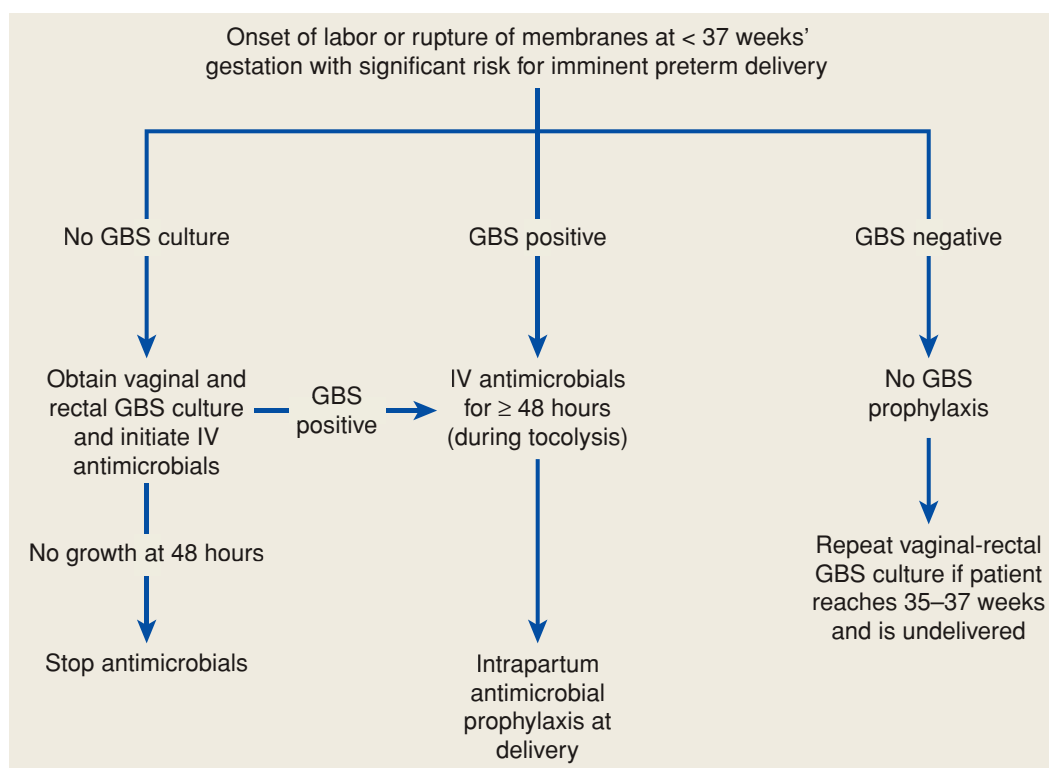

FIGURE 64-6 Sample algorithm for prophylaxis for women with group B streptococcal (GBS) disease and threatened preterm delivery. This algorithm is not an exclusive course of management, and variations that incorporate individual circumstances or institutional preferences may be appropriate. IV = intravenous. (Adapted from Centers for Disease Control and Prevention, 2010.)

is considered the greatest risk factor for infection (Sheffield, 2013). Methicillin-resistant *S aureus* (MRSA) colonizes only 2 percent of people but is a significant contributor to the health-care burden (Gorwitz, 2008). MRSA infections are associated with increased cost and higher mortality rates compared with those by methicillin-sensitive *S aureus* (MSSA) (Beigi, 2009; Butterly, 2010; Klevens, 2007).

Community-associated MRSA (CA-MRSA) is diagnosed when identified in an outpatient setting or within 48 hours of hospitalization in a person without traditional risk factors. The latter include prior MRSA infection, hospitalization, dialysis or surgery within the past year, and indwelling catheters or devices. Hospital-associated MRSA (HA-MRSA) infections are nosocomial. Most cases of MRSA in pregnant women are CA-MRSA.

MRSA and Pregnancy

Anovaginal colonization with *S aureus* is identified in 10 to 25 percent of obstetrical patients (Andrews, 2008; Creech, 2010; Top, 2010). MRSA has been isolated in 0.5 to 3.5 percent of these women. Skin and soft tissue infections are the most common presentation of MRSA in pregnant women (Fig. 64-7). Mastitis has been reported in up to a fourth of cases of MRSA complicating pregnancy (Laibl, 2005; Lee, 2010; Reddy, 2007). Perineal abscesses, wound infections at sites such as abdominal and episiotomy incisions, and chorioamnionitis are also associated with MRSA (Lareau, 2010; Pimentel, 2009; Rotas, 2007; Thurman, 2008). An increase in CA-MRSA infections has been reported in neonatal intensive care units and newborn nurseries. In these settings, infection is frequently associated with maternal and health-care worker MRSA skin infections and infected breast milk. Vertical transmission appears to be rare (Huang, 2009; Jimenez-Truque, 2012; Pinter, 2009).

Management

The Infectious Diseases Society of America has published guidelines for the treatment of MRSA infections (Liu, 2011).

FIGURE 64-7 Typical presentation of a skin lesion caused by infection with community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA). Patients often present with what they describe as an infected spider bite.

Uncomplicated superficial infections are managed by drainage and local wound care. The benefits of antibiotic treatment in this setting are unproven, and most studies have not shown improved outcomes with the addition of MRSA-appropriate antibiotics (Forcade, 2012; Laibl, 2005). Severe superficial infections, especially those that fail to respond to local care or those in patients with medical comorbidities, should be treated with MRSA-appropriate antibiotics. Purulent cellulitis should be treated empirically for CA-MRSA until culture results are available.

Most CA-MRSA strains are sensitive to trimethoprim-sulfamethoxazole. If clindamycin treatment is considered, inducible resistance must be excluded by a D-zone test for erythromycin-resistant, clindamycin-sensitive isolates. Rifampin rapidly develops resistance and should not be used for monotherapy. Linezolid, although effective against MRSA, is expensive, and there is little information regarding its use in pregnancy. Doxycycline, minocycline, and tetracycline, although effective for MRSA infections, should not be used in pregnancy. Vancomycin remains the first-line therapy for inpatient MRSA infections.

The control and prevention of HA-MRSA and CA-MRSA rely on appropriate hand hygiene and prevention of skin-to-skin contact or contact with wound dressings. Decolonization should be considered only in cases in which a patient develops recurrent superficial infections despite optimal hygiene measures or if ongoing transmission occurs among household or close contacts (Liu, 2011). Decolonization measures include nasal treatment with mupirocin, chlorhexidine gluconate baths, and oral rifampin therapy. Routine decolonization has not been shown to be effective in the obstetrical population. For women with culture-proven CA-MRSA infection during pregnancy, we add single-dose vancomycin to routine β -lactam perioperative prophylaxis for cesarean deliveries and fourth-degree perineal lacerations. Breast feeding in these women is not prohibited, but optimal hygiene and attention to minor skin breaks is encouraged.

Vulvar Abscess

Labia majora infections, which begin as cellulitis, have the potential for significant expansion and abscess formation. Risk factors include diabetes, obesity, perineal shaving, and immunosuppression. For early cellulitis, sitz baths and oral antibiotics are reasonable treatment. If present, a small abscess can be incised and drained, wound cultures obtained, abscess cavity packed, and surrounding cellulitis treated with oral antibiotics. These infections are typically polymicrobial, and suitable broad-spectrum antimicrobials are given along with coverage for MRSA (Thurman, 2008). For severe infections, especially in immunosuppressed or pregnant patients, hospitalization and intravenous antimicrobial therapy are often warranted due to increased risks for necrotizing fasciitis. Large abscesses are best drained in the operating room with adequate analgesia or anesthesia.

Cysts of the Bartholin gland duct are usually unilateral, sterile, and need no treatment during pregnancy. If a cyst is sufficiently large to obstruct delivery, then needle aspiration is an appropriate temporary measure. With gland duct infection, a localized unilateral vulvar bulge, tenderness, and erythema are present. Treatment is given with broad-spectrum

antimicrobials, and drainage is established. In addition to obtaining wound cultures, testing is done for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. For a small abscess, incision and placement of a Word catheter may be suitable. For larger abscesses with extensive cellulitis, drainage is best performed in the operating room. In these cases, the incised edges of the abscess cavity may be marsupialized.

Occasionally, abscesses of the periurethral glands develop. The largest of these, the Skene gland, may require drainage and broad-spectrum antimicrobial treatment if there is suppuration.

Listeriosis

Listeria monocytogenes is an uncommon but probably underdiagnosed cause of neonatal sepsis. This facultative intracellular gram-positive bacillus can be isolated from the feces of 1 to 5 percent of adults. Nearly all cases of listeriosis are thought to be food-borne (Silk, 2013). Outbreaks have been caused by raw vegetables, coleslaw, apple cider, melons, milk, fresh Mexican-style cheese, smoked fish, and processed foods, such as pâté, hummus, wieners, and sliced deli meats (Cartwright, 2013; Centers for Disease Control and Prevention, 2013i; Janakiraman, 2008; Varma, 2007; Voetsch, 2007).

Listerial infections are more common in the very old or young, pregnant women, and immunocompromised patients. The incidence of such infections appears to be increasing in several countries worldwide (Allenberger, 2010; Cartwright, 2013; Goulet, 2012). In 1651 cases reported in 2009 to 2011, the Centers for Disease Control and Prevention found that 14 percent were in pregnant women (Silk, 2013). And in a recent review, pregnant women had a significantly higher rate for listeriosis compared with nonpregnant reproductive-aged women (Pouillot, 2012). It is unclear why pregnant women still account for a significant number of these reported cases. One hypothesis is that pregnant women are susceptible because of decreased cell-mediated immunity (Baud, 2011; Jamieson, 2006b; Wing, 2002). Another is that placental trophoblasts are susceptible to invasion by *Listeria monocytogenes* (Le Monnier, 2007).

Maternal and Fetal Infection

Listeriosis during pregnancy may be asymptomatic or may cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis (Centers for Disease Control and Prevention, 2013i; Mylonakis, 2002). The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor (Boucher, 1986). Discolored, brownish, or meconium-stained amniotic fluid is common with fetal infection, even preterm gestations.

In 2011, a listerial outbreak associated with cantaloupes resulted in 147 infected individuals (Centers for Disease Control and Prevention, 2012b). Seven of these infections were related to pregnancy—four in pregnant women and three in newborns. Maternal listeriosis causes fetal infection that characteristically produces disseminated granulomatous lesions with *microabscesses* (Topalovski, 1993). Chorioamnionitis is common with maternal infection, and placental lesions include multiple, well-demarcated macroabscesses. Early- and late-onset neonatal

FIGURE 64-8 The pale placenta (A) and stillborn infant (B) resulted from maternal listeriosis.

infections are similar to GBS sepsis. In a review of 222 cases by Mylonakis (2002), infection resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns. Voetsch (2007) detailed similar findings. A stillbirth caused by listeriosis is shown in [Figure 64-8](#).

Treatment with ampicillin plus gentamicin is usually recommended because of synergism against *Listeria* species. Trimethoprim-sulfamethoxazole can be given to penicillin-allergic women. Maternal treatment in most cases is also effective for fetal infection (Chan, 2013). No vaccine is available, and prevention is by washing raw vegetables and cooking all raw food (Goulet, 2012; Silk, 2012). Pregnant women should also avoid the implicated foods listed previously.

Salmonellosis

Infections from *Salmonella* species continue to be a major and increasing cause of food-borne illness (Peques, 2012). Six serotypes account for most cases in the United States, including *Salmonella* subtypes *typhimurium* and *enteritidis*. Non-typhoid *Salmonella* gastroenteritis is contracted through contaminated food. Symptoms including nonbloody diarrhea, abdominal pain, fever, chills, nausea, and vomiting begin 6 to 48 hours after exposure. Diagnosis is made by stool studies. Intravenous crystalloid is given for rehydration. Antimicrobials are not given in uncomplicated infections because they do not commonly

shorten illness and may prolong the convalescent carrier state. If gastroenteritis is complicated by bacteremia, antimicrobials are given as discussed below. Rare case reports have linked *Salmonella* bacteremia with abortion (Coughlin, 2002).

Typhoid fever caused by *Salmonella typhi* remains a global health problem, although it is uncommon in the United States. Infection is spread by oral ingestion of contaminated food, water, or milk. In pregnant women, the disease is more likely to be encountered during epidemics or in those with HIV infection (Hedriana, 1995). In former years, antepartum typhoid fever resulted in abortion, preterm labor, and maternal or fetal death (Dildy, 1990).

Fluoroquinolones and third-generation cephalosporins are the preferred treatment. For enteric (typhoid) fever, antimicrobial susceptibility testing is important because of the development of drug-resistant strains (Peques, 2012). Typhoid vaccines appear to exert no harmful effects when administered to pregnant women and should be given in an epidemic or before travel to endemic areas.

■ Shigellosis

Bacillary dysentery caused by *Shigella* is a relatively common, highly contagious cause of inflammatory exudative diarrhea in adults. Shigellosis is more common in children attending day-care centers and is transmitted via the fecal-oral route. Clinical manifestations range from mild diarrhea to severe dysentery, bloody stools, abdominal cramping, tenesmus, fever, and systemic toxicity.

Although shigellosis may be self-limited, careful attention to treatment of dehydration is essential in severe cases. We have cared for pregnant women in whom secretory diarrhea exceeded 10 L/day! Antimicrobial therapy is imperative, and effective treatment during pregnancy includes fluoroquinolones, ceftriaxone, or azithromycin. Antimicrobial resistance is rapidly emerging, and antibiotic susceptibility testing can help guide appropriate therapy (Centers for Disease Control and Prevention, 2013c).

■ Hansen Disease

Also known as leprosy, this chronic infection is caused by *Mycobacterium leprae* and is rare in the United States (United States Department of Health and Human Services, 2011). Diagnosis is confirmed by PCR. Multidrug therapy with dapsone, rifampin, and clofazimine is recommended for treatment and is generally safe during pregnancy (Britton, 2004). Duncan (1980) reported an excessive incidence of low-birthweight newborns among infected women. The placenta is not involved, and neonatal infection apparently is acquired from skin-to-skin or drop-let transmission (Böddinghaus, 2007; Duncan, 1984). Vertical transmission is common in untreated mothers (Moschella, 2004).

■ Lyme Disease

Caused by the spirochete *Borrelia burgdorferi*, Lyme disease is the most commonly reported vector-borne illness in the United States (Centers for Disease Control and Prevention, 2012c). Lyme borreliosis follows tick bites of the genus *Ixodes*. Early infection causes a distinctive local skin lesion, *erythema*

migrans, which may be accompanied by a flu-like syndrome and regional adenopathy. If untreated, disseminated infection follows in days to weeks. Multisystem involvement is frequent, but skin lesions, arthralgia and myalgia, carditis, and meningitis predominate. If still untreated after several weeks to months, late or persistent infection manifests in perhaps half of patients. Native immunity is acquired, and the disease enters a chronic phase. Although some patients remain asymptomatic, others in the chronic phase develop various skin, joint, or neurological manifestations (Wormser, 2006). Although relapses were initially considered common, recent clinical and epidemiological evidence suggests that most cases of recurrent erythema migrans occurring after appropriate antimicrobial therapy are actually new infections (Nadelman, 2012).

Clinical diagnosis is important because serological and PCR testing has many pitfalls (Schoen, 2013). IgM and IgG serological testing is recommended in early infection and is followed by Western blotting for confirmation. Ideally, acute and convalescent serological evaluation is completed if possible. The false-positive and -negative rates are high, and more accurate tests are being developed (Radolf, 2012; Schoen, 2013; Steere, 2012).

Treatment and Prevention

Optimal treatment of Lyme disease was reviewed by Wormser (2006) for the Infectious Diseases Society of America. For early infection, treatment with doxycycline, amoxicillin, or cefuroxime is recommended for 14 days, although doxycycline is usually avoided in pregnancy. A 14- to 28-day course of IV ceftriaxone, cefotaxime, or penicillin G is given for complicated early infections that include meningitis, carditis, or disseminated infections. Chronic arthritis and post-Lyme disease syndrome are treated with prolonged oral or IV regimens, however, symptoms respond poorly to treatment (Steere, 2012).

No vaccine is commercially available. Avoiding areas with endemic Lyme disease and improving tick control in those areas is the most effective prevention. Self-examination with removal of unengorged ticks within 36 hours of attachment reduces infection risk (Hayes, 2003). For tick bites recognized within 72 hours, a single 200-mg oral dose of doxycycline may reduce infection development.

There are several reports of Lyme disease in pregnancy, although large series are lacking. Transplacental transmission has been confirmed, but no congenital effects of maternal borreliosis have been conclusively identified (Elliott, 2001; Maraspin, 2011; Walsh, 2006). Prompt treatment of maternal early infection should prevent most adverse pregnancy outcomes (Mylonas, 2011).

■ Tuberculosis

Diagnosis and management of tuberculosis during pregnancy is discussed in detail in Chapter 51 (p. 1019).

PROTOZOAL INFECTIONS

■ Toxoplasmosis

The obligate intracellular parasite *Toxoplasma gondii* has a life cycle with two distinct stages (Kim, 2012). The *feline* stage takes

place in the cat—the definitive host—and its prey. Unsporulated oocysts are secreted in feces. In the *nonfeline* stage, tissue cysts containing bradyzoites or oocysts are ingested by the intermediate host, including humans. Gastric acid digests the cysts to release bradyzoites, which infect small-intestinal epithelium. Here, they are transformed into rapidly dividing tachyzoites, which can infect all cells within the host mammal. Humoral and cell-mediated immune defenses eliminate most of these, but tissue cysts develop. Their lifelong persistence is the chronic form of toxoplasmosis.

Human infection is acquired by eating raw or undercooked meat infected with tissue cysts or by contact with oocysts from cat feces in contaminated litter, soil, or water. Prior infection is confirmed by serological testing, and its prevalence depends on geographic locale and parasite genotype. In the United States, there is a 5 to 30 percent seroprevalence in persons aged 10 to 19 years, and this can exceed 60 percent after age 50 (Kim, 2012). Thus, a significant segment of pregnant women in this country are susceptible to infection. The incidence of prenatal infection resulting in birth of a newborn with congenital toxoplasmosis has been estimated to vary from 0.8 per 10,000 live births in the United States to 10 per 10,000 in France (Dubey, 2000). Between 400 and 4000 cases of congenital toxoplasmosis are diagnosed annually in the United States. Globally, it is estimated that a third of the population has been exposed to this parasite (Verma, 2012).

Maternal and Fetal Infection

Most acute maternal infections in Europe and North America are subclinical and are detected only by prenatal or newborn serological screening. In some cases, maternal symptoms may include fatigue, fever, headache, muscle pain, and sometimes a maculopapular rash and posterior cervical lymphadenopathy. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, and reactivation may cause encephalitis, retinochoroiditis, or mass lesions. Maternal infection is associated with a fourfold increased preterm delivery rate before 37 weeks (Freeman, 2005). Even so, growth restriction is not increased. Toxoplasmosis serotype NE-II is most commonly associated with preterm birth and severe neonatal infection (McLeod, 2012).

The incidence and severity of fetal toxoplasmosis infection depend on gestational age at the time of maternal infection. Risks for fetal infection increase with pregnancy duration (Fig. 64-9). A metaanalysis estimated the risk to be 15 percent at 13 weeks, 44 percent at 26 weeks, and 71 percent at 36 weeks (SYROCOT Study Group, 2007). Conversely, the severity of fetal infection is much greater in early pregnancy, and these fetuses are much more likely to have clinical findings of infection.

Importantly, most infected fetuses are born without obvious stigmata of toxoplasmosis. Clinically affected neonates usually have generalized disease expressed as low birthweight, hepatosplenomegaly, jaundice, and anemia. Some primarily have neurological disease with intracranial calcifications and with hydrocephaly or microcephaly. Many eventually develop chorioretinitis and exhibit learning disabilities. This classic

FIGURE 64-9 Risk of congenital toxoplasmosis infection by gestational age at maternal seroconversion. (From Dunn, 1999, with permission.)

triad—chorioretinitis, intracranial calcifications, and hydrocephalus—is often accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications.

Screening and Diagnosis

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) do not recommend prenatal screening for toxoplasmosis in areas of low prevalence, including the United States. In areas of high toxoplasmosis prevalence—for example, France and Austria—routine screening has resulted in diminished congenital disease (Wallon, 2013). With IgG antibody confirmed before pregnancy, there is no risk for a congenitally infected fetus (Montoya, 2004). Screening should be performed in immunocompromised pregnant women, regardless of country of residence.

Pregnant women suspected of having toxoplasmosis should be tested. The parasite is rarely detected in tissue or body fluids. Anti-toxoplasma IgG develops within 2 to 3 weeks after infection, peaks at 1 to 2 months, and usually persists for life—sometimes in high titers. Although IgM antibodies appear by 10 days after infection and usually become negative within 3 to 4 months, they may remain detectable for years. Thus, IgM antibodies should not be used alone to diagnose acute toxoplasmosis. IgA and IgE antibodies are also useful in diagnosing acute infection. Best results are obtained with the Toxoplasma Serologic Profile performed at the Palo Alto Medical Foundation Research Institute (www.toxolab@pamf.org). Toxoplasma IgG avidity increases with time. Thus, if a high-avidity IgG result is found, infection in the preceding 3 to 5 months is excluded. Multiple commercial avidity tests are now available that provide a 100-percent positive-predictive value of high avidity confirming latent infection (Villard, 2013). PCR testing has a high sensitivity and specificity.

Prenatal diagnosis of toxoplasmosis is performed using DNA amplification techniques and sonographic evaluation. PCR of amniotic fluid or fetal blood has improved sensitivity compared with standard isolation techniques (Sterkers, 2012). The sensitivity varies with gestational age, and it is lowest at

< 18 weeks (Montoya, 2008). Sonographic evidence of intracranial calcifications, hydrocephaly, liver calcifications, ascites, placental thickening, hyperechoic bowel, and growth restriction has been used prenatally to help confirm diagnosis.

Management

No randomized clinical trials have been performed to assess the benefit and efficacy of treatment to decrease the risk for congenital infection. A systematic review of data from 1438 treated pregnancies found weak evidence for early treatment to reduce congenital toxoplasmosis risks (SYROCOT Study Group, 2007). Treatment has been associated with a reduction in rates of serious neurological sequelae and neonatal demise (Cortina-Borja, 2010).

Prenatal treatment is based on two regimens—spiramycin alone or a pyrimethamine–sulfonamide combination with folinic acid. These two regimens have also been used consecutively (Hotop, 2012). Little evidence supports the use of a specific regimen. That said, most experts will use spiramycin in women with acute infection early in pregnancy. Pyrimethamine–sulfadiazine with folinic acid is selected for maternal infection after 18 weeks or if fetal infection is suspected.

Prevention

There is no vaccine for toxoplasmosis, so avoidance of infection is necessary if congenital infection is to be prevented. Efforts include: (1) cooking meat to safe temperatures; (2) peeling or thoroughly washing fruits and vegetables; (3) cleaning all food preparation surfaces and utensils that have contacted raw meat, poultry, seafood, or unwashed fruits and vegetables; (4) wearing gloves when changing cat litter, or else delegating this duty; and (5) avoiding feeding cats raw or undercooked meat and keeping cats indoors. Although these preventive steps are recommended, there are no data to support their effectiveness (Di Mario, 2009). Vaccine development is actively being pursued (Verma, 2012).

Malaria

Malaria remains a global health crisis. In 2010, there were an estimated 219 million cases and 655,000 deaths, mainly in sub-Saharan Africa (Chico, 2012; World Health Organization, 2011). Malaria has been effectively eradicated in Europe and in most of North America, and worldwide mortality rates have fallen more than 25 percent. In the United States, most cases of malaria are imported—some in returning military personnel (Centers for Disease Control and Prevention, 2013j). Transmitted by infected *Anopheles* mosquitoes, five species of *Plasmodium* cause human disease—*falciparum*, *vivax*, *ovale*, *malariae*, and *knowlesi* (White, 2012).

Maternal and Fetal Infection

Clinical findings are fever, chills, and flu-like symptoms including headaches, myalgia, and malaise, which may occur at intervals. Symptoms are less severe with recurrences. Malaria may be associated with anemia and jaundice, and *falciparum* infections may cause kidney failure, coma, and death. That said, many otherwise healthy but infected adults in endemic areas are asymptomatic. Pregnant women, although often

FIGURE 64-10 Photomicrograph of placental malaria. **A.** Multiple infected red blood cells (long black arrow) are seen in the intervillous space of this placenta. Multiple villi cut in cross section are shown, and three are highlighted (short arrows). **B.** Increased magnification of image (A). Multiple infected erythrocytes are seen, and two are identified (arrows).

asymptomatic, are said to be more likely to develop traditional symptoms (Desai, 2007).

Malarial infections during pregnancy—whether symptomatic or asymptomatic—are associated with increased rates of perinatal morbidity and mortality (Menéndez, 2007; Nosten, 2007; Rogerson, 2007). Adverse outcomes include stillbirth, preterm birth, low birthweight, and maternal anemia. The latter two are documented most frequently (Machado Filho, 2014; McClure, 2013). Maternal infection is associated with 14 percent of low-birthweight newborns worldwide (Eisele, 2012). These adverse perinatal outcomes correlate with high levels of placental parasitemia (Rogerson, 2007). The latter occurs when parasitized erythrocytes, monocytes, and macrophages accumulate in the vascular areas of the placenta (Fig. 64-10). Infections with *P. falciparum* are the worst, and early infection increases the risk for abortion (Desai, 2007). The incidence of malaria increases significantly in the latter two trimesters and postpartum (Diagne, 2000). Overall, congenital malaria occurs in < 5 percent of neonates born to infected mothers.

Diagnosis

Identification of parasites by microscopical evaluation of a thick and thin blood smear remains the gold standard for diagnosis.

In women with low parasite densities, however, the sensitivity of microscopy is poor. Malaria-specific antigens are now being used for rapid diagnostic testing. Not only is their sensitivity still an issue in pregnancy, but these tests are not routinely available (Fowkes, 2012; Kashif, 2013; White, 2012).

Management

The most frequently used antimalarial drugs are not contraindicated in pregnancy. The World Health Organization recommends all infected patients living in or traveling from endemic areas be treated with an artemisinin-based regimen for uncomplicated falciparum malaria. Little is known about these regimens in pregnancy (Mutabingwa, 2013). The Centers for Disease Control and Prevention (2013g) recommends using atovaquone-proguanil or artemether-lumefantrine only if other treatment options are not available or tolerated.

The Centers for Disease Control and Prevention (2013g) recommends that pregnant women diagnosed with uncomplicated malaria caused by *P. vivax*, *P. malariae*, *P. ovale*, and chloroquine-sensitive *P. falciparum* should be treated with chloroquine or hydroxychloroquine. For women infected with chloroquine-resistant *P. falciparum*, mefloquine or quinine sulfate with clindamycin should be used. Chloroquine-resistant *P. vivax* should be treated with mefloquine. Chloroquine-sensitive *P. vivax* or *P. ovale* should be treated with chloroquine throughout pregnancy and then primaquine postpartum. Treatment regimens for uncomplicated and severe malarial infections in pregnancy are detailed at: www.cdc.gov/malaria/diagnosis_treatment/clinicians3.html. The CDC also maintains a malaria hotline for treatment recommendations (770-488-7788).

The World Health Organization (2011) allows for the use of intermittent preventative therapy during pregnancy. This consists of at least two treatment doses of sulfadoxine-pyrimethamine in the second and third trimesters. The rationale is that each dose will clear placental asymptomatic infections and provide up to 6 weeks of posttreatment prophylaxis. This ideally will decrease the rate of low-birthweight newborns in endemic areas (Harrington, 2013). A recent metaanalysis supported the use of at least three doses of intermittent preventative therapy to improve birthweight and decrease placental and maternal malarial infection at delivery (Kayentao, 2013).

Resistance to all the antimalarial drugs has been reported, including the recently added artemisinin. The World Health Organization recommends routine monitoring of antimalarial drug resistance and tailoring medication regimens.

Prevention and Chemoprophylaxis

Malaria control and prevention relies on chemoprophylaxis when traveling to or living in endemic areas. Vector control is also important. Insecticide-treated netting, pyrethroid insecticides, and *N,N*-diethyl-*m*-toluamide (DEET)-based insect repellent decrease malarial rates in endemic areas. These are well tolerated in pregnancy (Menéndez, 2007). If travel is necessary, chemoprophylaxis is recommended.

Chloroquine and hydroxychloroquine prophylaxis is safe and well tolerated in pregnancy. It decreases placental infection from 20 percent to 4 percent in asymptomatic infected

women in areas without chloroquine resistance (Cot, 1992). For travelers to areas with chloroquine-resistant *P. falciparum*, mefloquine remains the only chemoprophylaxis recommended. Primaquine and doxycycline are contraindicated in pregnancy, and there are insufficient data on atovaquone/proguanil to recommend them at this time. Likewise, amodiaquine is used in Africa, but data are limited in pregnant women. The latest chemoprophylaxis regimens for pregnancy can be obtained from the Centers for Disease Control and Prevention *Travelers' Health* website at: <http://www.cdc.gov/travel>. The Centers also publish *Health Information for International Travel* (The Yellow Book) at: www.cdc.gov/yellowbook.

Amebiasis

Most persons infected with *Entamoeba histolytica* are asymptomatic. Amebic dysentery, however, may take a fulminant course during pregnancy, with fever, abdominal pain, and bloody stools. Prognosis is worse if complicated by a hepatic abscess. Diagnosis is made by identifying *E. histolytica* cysts or trophozoites within a stool sample. Therapy is similar to that for the nonpregnant woman, and metronidazole or tinidazole is the preferred drug for amebic colitis and invasive disease. Noninvasive infections may be treated with paromomycin (Stanley, 2012).

MYCOTIC INFECTIONS

Disseminated fungal infection—usually pneumonitis—during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in Chapter 51 (p. 1019).

EMERGING INFECTIONS

These are collectively defined as infectious diseases that have newly appeared or increased in incidence or geographic spread (Jamieson, 2006a,b; Theiler, 2008). At this time, emerging infections include West Nile virus, coronavirus, and several influenza A strains. They also include many bioterrorism agents.

West Nile Virus

This mosquito-borne RNA flavivirus is a human neuropathogen. Since 1999, the reported numbers of human and animal infections have increased, and the geographical range of disease activity has expanded. The year 2012 was the second worst outbreak of total cases in the United States (Centers for Disease Control and Prevention, 2013b). West Nile viral infections are typically acquired through mosquito bites in late summer or perhaps through blood transfusion (Harrington, 2003). The incubation period is 2 to 14 days, and most persons have mild or no symptoms. Fewer than 1 percent of infected adults develop meningoencephalitis or acute flaccid paralysis (Granwehr, 2004). Presenting symptoms may include fever, mental status changes, muscle weakness, and coma (Chapa, 2003; Stewart, 2013).

Diagnosis of West Nile infection is based on clinical symptoms and the detection of viral IgG and IgM in serum and IgM in cerebrospinal fluid. There is no known effective antiviral treatment, and management is supportive. The primary strategy for preventing exposure in pregnancy is the use of insect repellent containing DEET. This is considered safe for use around pregnant women (Koren, 2003). Avoiding outdoor activity and stagnant water and wearing protective clothing are also recommended.

Adverse effects of West Nile viremia on pregnancy are unclear. Animal data suggest that embryos are susceptible, and a case report of human fetal infection at 27 weeks described chorioretinitis and severe temporal and occipital lobe leukomalacia (Alpert, 2003; Julander, 2006). Of 77 maternal infections initially reported to the West Nile Virus Pregnancy Registry, there were four miscarriages, two elective abortions, and 72 live births, of which 6 percent were preterm (O'Leary, 2006). Three of these 72 newborns were shown to have West Nile infection, and it could not be established conclusively that infection was acquired congenitally. Of three major malformations *possibly* associated with viral infection, none was definitively confirmed. Similar conclusions were reached by Pridjian and colleagues (2014), who analyzed data from the Centers for Disease Control and Prevention West Nile Virus Registry. Transmission of West Nile virus through breast feeding is rare (Hinckley, 2007).

■ Coronavirus Infections

Coronaviruses are single-stranded RNA viruses that are prevalent worldwide. They are associated with 10 to 35 percent of common colds, usually in the fall, winter, and early spring. In 2002, an especially virulent strain of coronavirus—*severe acute respiratory syndrome (SARS-CoV)* was first noted in China. It rapidly spread throughout Asia, Europe, and North and South America. Transmission is through droplets or contact with infected secretions, fluids, and wastes. The incubation period is 2 to 16 days, and there appears to be a triphasic pattern to its clinical progression. The first week is characterized by prodromal symptoms of fever, myalgias, headache, and diarrhea. During the second week, patients may suffer recurrent fever, watery diarrhea, and a dry nonproductive cough with mild dyspnea. These are coincident with IgG seroconversion and a declining viral load. Progression at this stage is thought to be due to an overexuberant host immune response. The third, and at times, lethal phase—seen in about 20 percent of patients—is progression to SARS (Christian, 2004; Peiris, 2003a,b). Radiographic lung findings include ground-glass opacities and airspace consolidations that can rapidly progress within 1 to 2 days. The case-fatality rate approached 10 percent in the nonpregnant population and was as high as 25 percent in pregnant women (Lam, 2004; Wong, 2004). Although there have been no confirmed cases since 2004, the Centers for Disease Control and Prevention (2013d) now lists SARS-CoV as a “select agent” that has the potential to pose a severe threat to public health and safety. Another novel coronavirus infecting humans with a high case-fatality rate was detected in the Middle East in 2012 (MERS-CoV).

TRAVEL PRECAUTIONS DURING PREGNANCY

Pregnant travelers face obstetrical risks, general medical risks, and potentially hazardous destination risks. The International Society for Tropical Medicines has comprehensive information available at: <http://www.istm.org>. Also, the Centers for Disease Control and Prevention have extensive travel information regarding pregnancy and breast feeding at its websites listed on page 1257.

BIOTERRORISM

Bioterrorism involves the deliberate release of bacteria, viruses, or other infectious agents to cause illness or death. These natural agents are often altered to increase their infectivity or their resistance to medical therapy. Clinicians should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. Clinicians are urged to contact their state health department or the Centers for Disease Control and Prevention for contemporary information and recommendations. The American College of Obstetricians and Gynecologists (2013b) has recently addressed disaster preparedness for obstetricians. It provides both general considerations and recommendations for hospital preparedness and obstetrics-specific recommendations.

■ Smallpox

The variola virus is considered a serious weapon because of high transmission and overall 30-percent case-fatality rate. The last case of smallpox in the United States was reported in 1949, and worldwide it was reported in Somalia in 1977. Transmission occurs with prolonged contact with infected persons, infected body fluids, or contaminated objects such as clothing. Smallpox presents with an acute-onset fever that is followed by a rash with firm, deep-seated vesicles or pustules. Nishiura (2006) and Suarez and Hankins (2002) have reviewed the severe perinatal and maternal morbidity and mortality caused by smallpox. The case-fatality rate of smallpox in pregnancy is 61 percent if the pregnant woman is unvaccinated. There is a significant increase in stillbirth, abortion, preterm labor and delivery, and neonatal demise in pregnancies complicated by smallpox infection.

Because the smallpox vaccine currently available is made with live vaccinia virus, pregnancy should be delayed for 4 weeks in recipients. It is generally not given to pregnant women because of the risk of fetal vaccinia, a rare but serious complication. Inadvertent smallpox vaccination during pregnancy has not, however, been associated with fetal malformations or preterm birth. Moreover, no cases of fetal vaccinia have been reported with second-generation smallpox vaccine exposure (Ryan, 2008a,b). The Smallpox Vaccine in Pregnancy Registry remains active, and vaccinated women are still being enrolled.

■ Anthrax

Bacillus anthracis is a gram-positive, spore-forming, aerobic bacterium. It can cause three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Holty, 2006;

Swartz, 2001; Sweeney, 2011). The bioterrorist anthrax attacks of 2001 involved inhalational anthrax (Inglesby, 2002). Spores are inhaled and deposited in the alveoli. They are engulfed by macrophages and germinate in mediastinal lymph nodes. The incubation period is usually less than 1 week but may be as long as 2 months. Initial symptoms are nonspecific and include low-grade fever, nonproductive cough, malaise, and myalgias. Within 1 to 5 days of symptom onset, the second stage is heralded by the abrupt onset of severe respiratory distress and high fevers. Mediastinitis and hemorrhagic thoracic lymphadenitis are common, and there is a widened mediastinum on chest radiograph. Case-fatality rates with inhalational anthrax are high, even with aggressive antibiotic and supportive therapy (Dixon, 1999; Holty, 2006).

Anthrax affecting pregnant women and its treatment were recently reviewed by Meaney-Delman and coworkers (2012, 2013). They reported data on 20 pregnant and postpartum women. The overall mortality rate was 80 percent, with a 60-percent fetal or neonatal loss rate. Of note, most cases were published before the advent of antibiotics.

Regimens for postexposure anthrax prophylaxis are given for 2 months. The American College of Obstetricians and Gynecologists (2009) and the Centers for Disease Control and Prevention (Wright, 2010) recommend that asymptomatic pregnant and lactating women with documented exposure to *B anthracis* be given postexposure prophylaxis with ciprofloxacin, 500 mg orally twice daily for 60 days. Amoxicillin, 500 mg orally three times daily, can be substituted if the strain is proven sensitive. In the case of ciprofloxacin allergy and either penicillin allergy or resistance, doxycycline, 100 mg orally twice daily, is given for 60 days. Risks from anthrax far outweigh any fetal risks from doxycycline (Meaney-Delman, 2013).

The anthrax vaccine (AVA) is an inactivated, cell-free product that requires five injections over 18 months. Vaccination is generally avoided in pregnancy because there are limited safety data. Reports of inadvertent vaccination of pregnant women with AVA have not found a significant increase in fetal malformations or miscarriage rates (Ryan, 2008c; Wiesen, 2002). Anthrax vaccine is an essential adjunct to postexposure antimicrobial prophylaxis, even in pregnancy (Wright, 2010).

Other Bioterrorism Agents

Other category A bioterrorism agents include *Francisella tularensis*—tularemia, *Clostridium botulinum*—botulism, *Yersinia pestis*—plague, and viral hemorrhagic fevers—for example, Ebola, Marburg, Lassa, and Machupo. Multiple agents are also listed as category B and C. The guidelines for these biological agents are evolving and are detailed at the Centers for Disease Control and Prevention Bioterrorism website: <http://www.emergency.cdc.gov/agent/agentlist-category>.

CHAPTER 65

Sexually Transmitted Infections

SYPHILIS	1265
GONORRHEA	1269
CHLAMYDIAL INFECTIONS	1270
HERPES SIMPLEX VIRUS	1271
CHANCROID	1274
HUMAN PAPILLOMAVIRUS	1275
VAGINITIS	1276
HUMAN IMMUNODEFICIENCY VIRUS	1276

Sexually transmitted infections or diseases are among the most common of all infectious diseases encountered during pregnancy. Because they may be injurious to both mother and fetus, they should be aggressively sought and treated. Importantly, education, screening, treatment, and prevention are essential components of prenatal care (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Sexually transmitted infections (STIs) that affect pregnant women and potentially affect the fetus include syphilis, gonorrhea, trichomoniasis, and chlamydia, hepatitis B, human immunodeficiency virus (HIV), herpes simplex virus-1 and -2 (HSV-1, -2), and human papillomavirus (HPV) infections. Recommended therapy for most adhere to guidelines provided by the Centers for Disease Control and Prevention (CDC)(2010b). Treatment of most STIs is clearly associated with improved pregnancy outcome and prevention of perinatal mortality (Goldenberg, 2003, 2008; Ishaque, 2011; Koumans, 2012).

SYPHILIS

Despite the availability of adequate therapy for almost 70 years, syphilis remains a major issue for both mother and fetus.

Syphilis rates reached an all-time low in 2000. But from 2001 through 2009 for the United States, there was a steady increase in primary and secondary syphilis rates, which then leveled in 2010 and 2011 (Centers for Disease Control and Prevention, 2013b). The primary and secondary syphilis rate among women in 2012 was 0.9 case per 100,000 persons, which is a 9-percent decrease from 2010. Congenital syphilis rates also decreased in 2012, mirroring the decline in primary and secondary syphilis rates among women since 2008. However, syphilis remains a significant global health problem, with many countries reporting high numbers of new infections (Lukehart, 2012).

Pathogenesis and Transmission

The causative agent for syphilis is *Treponema pallidum*. Minute abrasions on the vaginal mucosa provide an entry portal for the spirochete, and cervical eversion, hyperemia, and friability increase the transmission risk. Spirochetes replicate and then disseminate through lymphatic channels within hours to days. The incubation period averages 3 weeks—3 to 90 days—depending on host factors and inoculum size. The early stages of syphilis include primary, secondary, and early latent syphilis. These are associated with the highest spirochete loads and transmission rates of up to 30 to 50 percent. In late-stage disease, transmission rates are much lower because of smaller inoculum sizes.

The fetus acquires syphilis by several routes. Spirochetes readily cross the placenta to cause congenital infection. Because of immune incompetence prior to midpregnancy, the fetus generally does not manifest the immunological inflammatory response characteristic of clinical disease before this time (Silverstein, 1962). Although transplacental transmission is the most common route, neonatal infection may follow after contact with spirochetes through lesions at delivery or across the placental membranes. Increased maternal syphilis rates have been linked to substance abuse, especially crack cocaine; inadequate prenatal care and screening; and treatment

failures and reinfection (Johnson, 2007; Lago, 2004; Trepka, 2006; Warner, 2001; Wilson, 2007). A report from Maricopa County, Arizona, also cited minority race or ethnicity as a risk factor (Kirkcaldy, 2011).

Clinical Manifestations

Maternal syphilis can cause preterm labor, fetal death, fetal-growth restriction, and neonatal infection (Krakauer, 2012; Saloojee, 2004). Any stage of maternal syphilis may result in fetal infection, but risk is directly related to maternal spirochete load (Fiumara, 1952; Golden, 2003). Maternal syphilis is staged according to clinical features and disease duration:

1. *Primary syphilis* is diagnosed by the characteristic chancre, which develops at the inoculation site. It is usually painless, with a raised, red, firm border and a smooth base (Fig. 65-1). Nonsuppurative lymphadenopathy may develop. A chancre will usually resolve spontaneously in 2 to 8 weeks, even if untreated. Multiple lesions may be found, predominantly in HIV-1 co-infected women.
2. *Secondary syphilis* is diagnosed when the spirochete is disseminated and affects multiple organ systems. Manifestations develop 4 to 10 weeks after the chancre appears and include dermatological abnormalities in up to 90 percent of women. A diffuse macular rash, plantar and palmar targetlike lesions, patchy alopecia, and mucous patches may be seen (Figs. 65-2 and 65-3). Condylomata lata are flesh-colored papules and nodules found on the perineum and perianal area. They are teeming with spirochetes and are highly infectious. Most women with secondary syphilis will also express constitutional symptoms such as fever, malaise, anorexia, headache, myalgias, and arthralgias. Up to 40 percent will have cerebrospinal fluid abnormalities, although only 1 to 2 percent will develop clinically apparent aseptic meningitis. Hepatitis, nephropathy, ocular changes, anterior uveitis, and periostitis may also develop.

FIGURE 65-2 Target lesions on the palms of a pregnant woman with secondary syphilis.

3. *Latent syphilis* develops when primary or secondary syphilis is not treated. It is characterized by reactive serological testing, but resolved clinical manifestations. *Early latent syphilis* is latent disease acquired within the preceding 12 months. Disease diagnosed beyond 12 months is either *late latent syphilis* or *latent syphilis of unknown duration*.
4. *Tertiary or late syphilis* is a slowly progressive disease affecting any organ system but is rarely seen in reproductive-aged women.

As noted, congenital infection is uncommon before 18 weeks. Once fetal syphilis develops, however, it manifests as a continuum of involvement. Fetal hepatic abnormalities are followed by anemia and thrombocytopenia, then ascites and

FIGURE 65-1 Primary syphilis. Photograph of a chancre with a raised, firm border and smooth, red base.

FIGURE 65-3 Mucous patches around the mouth of a pregnant woman with secondary syphilis.

FIGURE 65-4 Congenital syphilis. **A.** Fetogram of a stillborn infant infected with syphilis showing the “moth-eaten” appearance of the femurs (arrow). **B.** Enlarged hydropic placenta of a syphilis-infected neonate.

hydrops (Hollier, 2001). Stillbirth remains a major complication (Di Mario, 2007; Hawkes, 2011; Rac, 2014b). The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, nephrosis, or long-bone involvement.

With syphilitic infection, the placenta becomes large and pale (Fig. 65-4). Microscopically, villi lose their characteristic arborization and become thicker and clubbed (Kapur, 2004). Sheffield and colleagues (2002c) described such large villi in more than 60 percent of syphilitic placentas. Blood vessels markedly diminish in number, and in advanced cases, they almost entirely disappear as a result of endarteritis and stromal cell proliferation. Likely related, Lucas and coworkers (1991) demonstrated increased vascular resistance in uterine and umbilical arteries of infected pregnancies. In a study of 25 untreated women, Schwartz and associates (1995) reported that necrotizing funisitis was present in a third. Spirochetes were detected in almost 90 percent using silver and immunofluorescent staining.

■ Diagnosis

The United States Preventative Services Task Force has reaffirmed its recommendation that clinicians screen all pregnant women for syphilis to treat and prevent congenital infection (Wolff, 2009). Testing is now required by law in all states and should be performed at the first prenatal visit. In populations in which the prevalence of syphilis is high, serological testing should be performed in the third trimester and again at delivery (Centers for Disease Control and Prevention, 2010b).

Treponema pallidum cannot be cultured from clinical specimens. Definitive diagnosis of early-stage lesions is made using dark-field examination and direct immunofluorescent antibody staining of lesion exudates (Centers for Disease Control and Prevention, 2010b). In asymptomatic patients or for screening purposes, serological testing is used. There are two types. The first type is nontreponemal testing that includes the Venereal Disease Research Laboratory (VDRL) and the rapid plasma

reagin (RPR). These tests are quantified and expressed as titers. Because titers reflect disease activity, they increase during early syphilis and often exceed levels of 1:32 in secondary syphilis. Following treatment of primary and secondary syphilis, serological testing at 3 to 6 months usually confirms a fourfold drop in VDRL or RPR titers (Rac, 2014a). Those with treatment failure or reinfection may lack this decline. Because VDRL titers do not correspond directly to RPR titers, consistent use of the same test for surveillance is recommended.

The other type of testing is treponemal-specific and includes the fluorescent treponemal-antibody absorption tests (FTA-ABS), the microhemagglutination assay for antibodies to *T pallidum* (MHA-TP), or the *Treponema pallidum* passive particle agglutination (TP-PA) test. These treponemal-specific tests generally remain positive throughout life.

Each of the serological tests has limitations including false-positive results. Traditionally, nontreponemal tests have been used for screening in the United States, and results are then confirmed by a specific treponemal test. Several laboratories have recently implemented a reverse screening algorithm, that is, screening with a treponemal test (Binnicker, 2012; Park, 2011). Both approaches are effective if appropriate screening, follow-up, and treatment are implemented. Patel and colleagues (2012) described missed opportunities for preventing and treating congenital syphilis in New York City. They found that 63 percent of mothers with newborns diagnosed with congenital syphilis had a missed opportunity for prevention. Most of these did not receive serological testing.

Rapid syphilis testing for “point of care” diagnosis is currently being developed and may be useful in settings with limited prenatal care (Centers for Disease Control and Prevention, 2010b; Greer, 2008). Treponemal immunochromatographic strip (ICS) tests and enzyme immunoassays (EIAs) are increasingly being used for screening and confirmatory testing (Henrich, 2011; Lukehart, 2012).

The prenatal diagnosis of congenital syphilis is difficult because an infected fetus often has a normal sonographic

examination. Some findings, however, may be suggestive or even diagnostic—hydrops fetalis, ascites, hepatomegaly, placental thickening, elevated middle cerebral artery Doppler velocimetry measurements, and hydramnios all suggest infection (Rac, 2014b). Polymerase chain reaction (PCR) is specific for detection of *T pallidum* in amniotic fluid, and treponemal DNA has been found in 40 percent of pregnancies infected before 20 weeks (Nathan, 1997; Wendel, 1991). Fetal syphilis has also been verified by amniotic fluid dark-field examination or rabbit infectivity testing in 64 percent of a cohort of women with untreated syphilis (Hollier, 2001). Although prenatal diagnosis can be made by funipuncture or amniocentesis, its clinical utility is not clear.

Treatment

Syphilis therapy during pregnancy is given to eradicate maternal infection and to prevent or treat congenital syphilis. Parenteral penicillin G remains the preferred treatment for all stages of syphilis during pregnancy. Currently recommended treatment guidelines are shown in Table 65-1 and are the same as for nonpregnant adults. For pregnant women, authorities recommend that a second dose of benzathine penicillin G be given 1 week after the initial dose.

In retrospective analyses, benzathine penicillin G has been shown to be highly effective for early maternal infection. In a study of 340 pregnant women so treated, Alexander and associates (1999) reported six cases—1.8 percent—of congenital syphilis. Four of these six neonates were from a group of 75 women with secondary syphilis. The other two were identified in those delivered from a group of 102 women with early latent syphilis. Congenital syphilis was generally confined to neonates of women treated after 26 weeks and is likely related to the duration and severity of fetal infection. Sheffield and coworkers (2002b) reported that high maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks for failure of maternal treatment to prevent neonatal infection. There are no proven alternatives to penicillin therapy during pregnancy. Erythromycin and azithromycin may be curative for the mother, but because of limited

transplacental passage, these drugs do not prevent all congenital disease (Berman, 2004; Centers for Disease Control and Prevention, 2010b; Wendel, 1988; Zhou, 2007). In several countries, macrolide resistant strains of *T pallidum* are now prevalent (Stamm, 2010). Cephalosporins may prove useful, but data are limited (Augenbraun, 1999, 2002; Zhou, 2007). Tetracyclines, including doxycycline, are effective for treatment of syphilis in the nonpregnant woman. These are generally not recommended during pregnancy, however, because of the risk of yellow-brown discoloration of fetal deciduous teeth (Chap. 12, p. 248).

Penicillin Allergy

Women with a history of penicillin allergy should have either a oral stepwise penicillin dose challenge or skin testing performed to confirm the risk of immunoglobulin E (IgE)-mediated anaphylaxis. If confirmed, penicillin desensitization is recommended, as shown in Table 65-2, and then followed by benzathine penicillin G treatment (Chisholm, 1997; Wendel, 1985).

In most women with primary syphilis and approximately half with secondary infection, penicillin treatment causes a *Jarisch-Herxheimer reaction*. Uterine contractions frequently develop with this reaction and may be accompanied by decreased fetal movement and late fetal heart rate decelerations (Klein, 1990). In a study of 50 pregnant women who received benzathine penicillin for syphilis, Myles and colleagues (1998) reported a 40-percent incidence of a Jarisch-Herxheimer reaction. Of the 31 women monitored electronically, 42 percent developed regular uterine contractions with a median onset of 10 hours, and 39 percent developed variable decelerations with a median onset of 8 hours. All contractions resolved within 24 hours of therapy. Lucas and associates (1991) used Doppler velocimetry and demonstrated acutely increased vascular resistance during this time. Beta-lactam antibiotics for group B streptococcus intrapartum prophylaxis can also trigger this reaction in a woman with untreated syphilis (Rac, 2010).

All women with syphilis should be offered counseling and testing for HIV (Koumans, 2000). For women with concomitant HIV infection, the Centers for Disease Control and

TABLE 65-1. Recommended Treatment for Pregnant Women with Syphilis

Category	Treatment
Early syphilis ^a	Benzathine penicillin G, 2.4 million units intramuscularly as a single injection—some recommend a second dose 1 week later
More than 1-year duration ^b	Benzathine penicillin G, 2.4 million units intramuscularly weekly for three doses
Neurosyphilis ^c	Aqueous crystalline penicillin G, 3–4 million units intravenously every 4 hours for 10–14 days or Aqueous procaine penicillin, 2.4 million units intramuscularly daily, plus probenecid 500 mg orally four times daily, both for 10–14 days

^aPrimary, secondary, and latent syphilis of less than 1-year duration.
^bLatent syphilis of unknown or more than 1-year duration; tertiary syphilis.
^cSome recommend benzathine penicillin, 2.4 million units intramuscularly after completion of the neurosyphilis treatment regimens.
From the Centers for Disease Control and Prevention, 2010b.

14	80,000	8.0	640,000	1,296,700

^aInterval between doses: 15 minutes. Elapsed time: 3 hours and 45 minutes. Cumulative dose: 1.3 million units. Observation period: 30 minutes before parenteral administration of penicillin.

^bThe specific amount of drug was diluted in approximately 30 mL of water and administered orally. From Wendel, 1985, with permission.

Prevention (2010b) recommend the same treatment as for HIV-negative persons. Clinical and serological surveillance to detect treatment failures is also recommended at 3, 6, 9, 12, and 24 months in HIV-positive patients.

GONORRHEA

Gonorrhea remains the second most commonly reported notifiable disease in the United States. The incidence of gonorrhea in the United States for 2012 was 107.5 cases per 100,000 persons, which is an increase of 4 percent since 2011 (Centers for Disease Control and Prevention, 2013b). The highest rates in women of any ethnicity were in the groups aged 20 to 24 years (578.5) and 15 to 19 years (521.2). Its prevalence in prenatal clinics in 2011 among women aged 15 to 24 years was 0.8 percent, although inner-city STI clinics have reported a prenatal prevalence of 5 to 10 percent (Berggren, 2011; Johnson, 2007). Risk factors include single marital status, adolescence, poverty, drug abuse, prostitution, other STIs, and lack of prenatal care (Berggren, 2011; Gorgos, 2011). Gonococcal infection is also a marker for concomitant chlamydial infection in up to 40 percent of infected women (Christmas, 1989; Miller, 2004). In most pregnant women, gonococcal infection is limited to the lower genital tract—the cervix, urethra, and periurethral and vestibular glands. Acute salpingitis is rare in pregnancy, but pregnant women account for a disproportionate number of disseminated gonococcal infections (Bleich, 2012; Ross, 1996; Yip, 1993).

Gonococcal infection may have deleterious effects in any trimester. There is an association between untreated gonococcal cervicitis and septic abortion as well as infection after voluntary abortion (Burkman, 1976). Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are reported to be more common in women infected with *Neisseria gonorrhoeae* (Alger, 1988; Johnson, 2011). Bleich and coworkers (2012) reviewed outcomes of 32 pregnant women admitted to Parkland Hospital for disseminated gonococcal infection. Although all the women promptly responded to appropriate antimicrobial therapy, one stillbirth was attributed to gonococcal sepsis.

Screening and Treatment

The U.S. Preventative Services Task Force recommends gonorrhea screening for all sexually active women, including pregnant women, if they are at increased risk (Meyers, 2008). Risk factors include age < 25 years, prior gonococcal infection, other STIs, prostitution, new or multiple sexual partners, drug use, and inconsistent condom use. For women who test positive, screening for syphilis, *Chlamydia trachomatis*, and HIV should precede treatment, if possible. If chlamydial testing is unavailable, presumptive therapy is given. Screening for gonorrhea in women is by culture or nucleic acid amplification tests (NAATs). Rapid tests for gonorrhea, although available, do not yet reach the sensitivity or specificity of culture or NAAT (Greer, 2008).

Gonorrhea treatment has evolved during the past decade due to the ability of *N gonorrhoeae* to rapidly develop antimicrobial resistance (Centers for Disease Control and Prevention, 2011b,c; Dionne-Odom, 2011; Ram, 2012; Unemo, 2011). Rapid development of fluoroquinolone resistance caused the CDC to remove that therapeutic class from its treatment guidelines in 2007. The Gonococcal Isolate Surveillance Project, a national sentinel surveillance system established to monitor trends in gonococcal antimicrobial resistance, has reported decreasing susceptibility to cephalosporins. This is the one remaining class of antimicrobial agents currently recommended for gonorrhea treatment (Bolan, 2012; Centers for Disease Control and Prevention, 2010b, 2012). This global public health threat has led the CDC in 2012 to change the gonorrhea treatment recommendations.

Listed in Table 65-3 are the updated recommendations for treatment of uncomplicated gonococcal infection during pregnancy. The increased ceftriaxone dose of 250 mg should be given along with 1 gram of azithromycin. The latter provides

TABLE 65-3. Treatment of Uncomplicated Gonococcal Infections During Pregnancy

Ceftriaxone, 250 mg intramuscularly as a single dose
plus
 Azithromycin, 1 gram orally as a single dose

From the Centers for Disease Control and Prevention, 2010b.

another drug with a different mechanism of action against *N gonorrhoeae* and treats chlamydial co-infections. Cefixime tablets should be reserved for situations that preclude ceftriaxone treatment. If they are used, a test-of-cure should be performed 1 week after treatment. Azithromycin, 2 grams orally as a single dose, can be used in cephalosporin-allergic women. However, this treatment should be limited due to emerging macrolide resistance (Centers for Disease Control and Prevention, 2011c). Treatment is also recommended for sexual contacts. A test-of-cure is unnecessary if symptoms resolve, but because gonococcal reinfection is common, a second screening in late pregnancy should be considered for women treated earlier (Blatt, 2012).

■ Disseminated Gonococcal Infections (DGI)

Gonococcal bacteremia may cause disseminated infections that manifest as petechial or pustular skin lesions, arthralgias, septic arthritis, or tenosynovitis. For treatment, the Centers for Disease Control and Prevention (2010b) has recommended ceftriaxone, 1000 mg intramuscularly or intravenously (IV) every 24 hours. Treatment should be continued for 24 to 48 hours after improvement, and therapy is then changed to an oral agent to complete 1 week of therapy. Prompt recognition and antimicrobial treatment will usually result in favorable outcomes in pregnancy (Bleich, 2012). Meningitis and endocarditis rarely complicate pregnancy, but they may be fatal (Bataskov, 1991; Burgis, 2006; Ram, 2012). For gonococcal *endocarditis*, ceftriaxone 1000 to 2000 mg IV every 12 hours should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days (Centers for Disease Control and Prevention, 2010b).

CHLAMYDIAL INFECTIONS

Chlamydia trachomatis is an obligate intracellular bacterium that has several serotypes, including those that cause lymphogranuloma venereum. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection. It is the most commonly reported infectious disease in the United States, with 1.4 million cases reported in 2012. It is estimated, however, that there are approximately 2.8 million new cases annually, although most are undiagnosed (Centers for Disease Control and Prevention, 2008). In 2012, the incidence of chlamydial infection among women was 2½ times greater than among men. Selective prenatal screening clinics in 2011 reported a median chlamydial infection rate of 7.7 percent (Centers for Disease Control and Prevention, 2013b).

Although most pregnant women have asymptomatic infection, a third have urethral syndrome, urethritis, or Bartholin gland infection (Peipert, 2003). Mucopurulent cervicitis may be due to chlamydial or gonococcal infection or both. It may also represent normal, hormonally stimulated endocervical glands with abundant mucus production. Other chlamydial infections not usually seen in pregnancy are endometritis, salpingitis, peritonitis, reactive arthritis, and Reiter syndrome.

The role of chlamydial infection in pregnancy complications remains controversial. A few studies have reported a direct association between *C trachomatis* and miscarriage, whereas most show no correlation (Baud, 2011; Coste, 1991; Paukku, 1999; Sugiura-Ogasawara, 2005). It is disputed whether untreated cervical infection increases the risk of preterm delivery, preterm ruptured membranes, and perinatal mortality (Andrews, 2000, 2006; Baud, 2008; Blas, 2007; Silva, 2011). Johnson and colleagues (2011) reported a twofold risk for low-birthweight infants.

Chlamydial infection has not been associated with an increased risk of chorioamnionitis or with pelvic infection after cesarean delivery (Blanco, 1985; Gibbs, 1987). Conversely, delayed postpartum uterine infection has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postpartum metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, lower abdominal pain, and uterine tenderness.

There is vertical transmission to 30 to 50 percent of neonates delivered vaginally from infected women. Perinatal transmission to newborns can cause pneumonia. Moreover, *C trachomatis* is the most commonly identifiable infectious cause of ophthalmia neonatorum (Chap. 32, p. 631).

■ Screening and Treatment

Prenatal screening for *C trachomatis* is a complex issue, although there is little evidence for its effectiveness in asymptomatic women who are not in high-risk groups (Kohl, 2003; Meyers, 2007; Peipert, 2003). Identification and treatment of asymptomatic infected women may prevent neonatal infections, but evidence of adverse pregnancy outcome prevention is lacking. Currently, the U.S. Preventive Services Task Force (2007) and the CDC recommend prenatal screening at the first prenatal visit for women at increased risk for chlamydial infection, and again during the third trimester if high-risk behavior continues. In a systematic review of repeat chlamydial infection among women, Hosenfeld and coworkers (2009) reported a reinfection rate of 14 percent, and most recurred within the first 8 to 10 months. Interestingly, in another study, Sheffield and colleagues (2005) found that almost half of pregnant women with asymptomatic cervical chlamydia underwent spontaneous resolution of infection.

Diagnosis is made predominantly by culture or NAAT. Cultures are more expensive and less accurate than newer NAATs, including PCR (Greer, 2008). Roberts and associates (2011) evaluated nucleic acid amplification testing of urine compared with cervical secretions in more than 2000 pregnant women and found them to be equivalent.

Currently recommended treatment regimens for chlamydial infections are shown in Table 65-4. Azithromycin is first-line treatment and has been found to be safe and effective in pregnancy. The fluoroquinolones and doxycycline are avoided in pregnancy, as is erythromycin estolate because of drug-related hepatotoxicity. Repeat chlamydial testing 3 to 4 weeks after completion of therapy is recommended.

TABLE 65-4. Treatment of *Chlamydia trachomatis* Infections During Pregnancy

Regimen	Drug and Dosage
Preferred choice	Azithromycin, 1000 mg orally as a single dose <i>or</i> Amoxicillin, 500 mg orally three times daily for 7 days
Alternatives	Erythromycin base, 500 mg orally four times daily for 7 days <i>or</i> Erythromycin ethylsuccinate, 800 mg orally four times daily for 7 days <i>or</i> Erythromycin base, 250 mg orally four times daily for 14 days <i>or</i> Erythromycin ethylsuccinate, 400 mg orally four times daily for 14 days

From the Centers for Disease Control and Prevention, 2010b.

■ Lymphogranuloma Venereum

L_1 , L_2 , and L_3 serovars of *C trachomatis* cause *lymphogranuloma venereum* (LGV). The primary genital infection is transient and seldom recognized. Inguinal adenitis may develop and at times lead to suppuration. It may be confused with chancroid. Ultimately, the lymphatics of the lower genital tract and perirectal tissues may be involved. Here, sclerosis and fibrosis can cause vulvar elephantiasis and severe rectal stricture. Fistula formation involving the rectum, perineum, and vulva also may evolve.

For treatment during pregnancy, erythromycin base, 500 mg orally four times daily, is given for 21 days (Centers for Disease Control and Prevention, 2010b). Although data regarding efficacy are scarce, some authorities recommend azithromycin, 1000 mg orally weekly for 3 weeks.

HERPES SIMPLEX VIRUS

Genital herpes simplex virus infection is one of the most common sexually transmitted diseases according to the Centers for Disease Control and Prevention (2010a,b). An estimated 50 million adolescents and adults are currently affected. In 2012, there were 228,000 initial office visits for genital herpes (Centers for Disease Control and Prevention, 2013b). Although most women are unaware of their infection, approximately one in six has serological evidence for HSV-2 infection. This incidence is as high as one in two for non-Hispanic black pregnant women (Corey, 2012). As most cases of HSV are transmitted by persons who are asymptomatic or unaware of their disease, herpes infections have become a major public health concern. It is estimated that 0.5 to 2 percent of pregnant women acquire HSV-1 or -2 during pregnancy (Brown, 1997).

■ Pathogenesis and Transmission

Two types of HSV have been distinguished based on immunological and clinical differences. Type 1 is responsible for most nongenital infections. However, more than half of new cases of genital herpes in adolescents and young adults are caused by HSV-1 infection. This is thought to be due to an increase in

oral-genital sexual practices (Mertz, 2003; Pena, 2010; Roberts, 2003). Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted by sexual contact. Most recurrences—greater than 90 percent—are secondary to HSV-2. There is a large amount of DNA sequence homology between the two viruses, and prior infection with one type attenuates a primary infection with the other type.

Neonatal transmission is by three routes: (1) intrauterine in 5 percent, (2) peripartum in 85 percent, or (3) postnatal in 10 percent (Kimberlin, 2004b). The fetus becomes infected by virus shed from the cervix or lower genital tract. It either invades the uterus following membrane rupture or is transmitted by contact with the fetus at delivery. The overall transmission rate is 1 in 3200 to 1 in 30,000 births depending on the population studied (Corey, 2012; Mahnert, 2007; Whitley, 2007). Neonatal herpes is caused by both HSV-1 and HSV-2, although HSV-2 infection predominates. Most infected infants are born to mothers with no reported history of HSV infection (Gardella, 2010).

The risk of neonatal infection correlates with the presence of HSV in the genital tract, the HSV type, invasive obstetrical procedures, and stage of maternal infection (Brown, 2005, 2007). Infants born to women who acquire genital HSV near the time of delivery have a 30- to 50-percent risk of infection. This is attributed to higher viral loads and the lack of transplacental protective antibodies (Brown, 1997; Brown, 2000). Women with recurrent HSV have less than a 1-percent risk of neonatal infection (Pasternak, 2010; Prober, 1987).

■ Clinical Manifestations

Once transmitted by genital-genital or oral-genital contact, HSV-1 or -2 replicates at the entry site. Following mucocutaneous infection, the virus moves retrograde along sensory nerves. It then remains latent in cranial nerves or dorsal spinal ganglia. HSV infections may be categorized into three groups:

1. *First episode primary infection* describes cases in which HSV-1 or -2 is isolated from genital secretions in the absence of HSV-1 or -2 antibodies. Only a third of newly acquired HSV-2 genital infections are symptomatic (Langenberg,

FIGURE 65-5 First-episode primary genital herpes simplex virus infection. On the left labium majora and mons, both vesicles and ulcers are seen.

1999). The typical incubation period of 6 to 8 days (range 1 to 26 days) may be followed by a “classic presentation.” This is characterized by a papular eruption with itching or tingling, which then becomes painful and vesicular. Multiple vulvar and perineal lesions may coalesce, and inguinal adenopathy may be severe (Fig. 65-5). Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Hepatitis, encephalitis, or pneumonia may develop, although disseminated disease is rare. Cervical involvement is common, but it may be inapparent clinically. Some cases are severe enough to require hospitalization. In 2 to 4 weeks, all signs and symptoms of infection disappear. Many women do not present with the typical lesions—instead, a pruritic or painful abraded area or knifeflit may be present. The incidence of asymptomatic primary infections may be as high as 80 percent (Centers for Disease Control and Prevention, 2010a,b).

2. *First episode nonprimary infection* is diagnosed when HSV is isolated in women who have only the other serum HSV-type antibody present. For example, HSV-2 is isolated from genital secretions in women already expressing serum HSV-1 antibodies. In general, these infections are characterized by fewer lesions, fewer systemic manifestations, less pain, and briefer duration of lesions and viral shedding. This is likely because of some immunity from cross-reacting antibodies, for example, from childhood-acquired HSV-1 infection. In many cases, it may be impossible to differentiate clinically between the two types of first infection. Thus, serological confirmation may be beneficial.
3. *Reactivation disease* is characterized by isolation of HSV-1 or -2 from the genital tract in women with the same serotype antibodies. During the latency period, in which viral particles reside in nerve ganglia, reactivation is common and mediated through variable but poorly understood stimuli. Reactivation is termed *recurrent infection* and results

in herpes-virus shedding. Most recurrent genital herpes is caused by type 2 virus (Centers for Disease Control and Prevention, 2010a,b; Corey, 2012). These lesions generally are fewer in number, are less tender, and shed virus for shorter periods—2 to 5 days—than those of primary infection. Typically, they recur at the same sites. Recurrences are most common in the first year after initial infection, and rates slowly decline over several years.

Asymptomatic viral shedding is defined by HSV as detected by culture or PCR in the absence of clinical findings. Most infected women shed virus intermittently, and most HSV transmission to a partner occurs during periods of asymptomatic viral shedding. Gardella and coworkers (2005) reported an HSV culture-positive rate of 0.5 percent and a PCR-positive rate of 2.7 percent in asymptomatic women presenting for delivery. More data are needed to determine the effect of asymptomatic shedding on neonatal transmission.

Most primary and first-episode infections in early pregnancy are probably not associated with an increased rate of spontaneous abortion or stillbirth (Eskild, 2002). In their review, Fagnant and Monif (1989) found only 15 cases of congenital herpetic infection that were acquired during early pregnancy. Brown and Baker (1989) reported that late-pregnancy primary infection may be associated with preterm labor and fetal-growth restriction.

Newborn infection may manifest in a number of ways. Infection may be localized to the skin, eye, or mouth—SEM disease—in about 40 percent of cases. Central nervous system disease with encephalitis is seen in 30 percent of cases. Disseminated disease as shown in Figure 65-6 with involvement of multiple major organs is found in 32 percent. Localized infection is usually associated with a good outcome. Conversely, even with acyclovir treatment, disseminated infection has a mortality rate of nearly 30 percent (Corey, 2009; Kimberlin, 2004a,b, 2011). Importantly, serious developmental and central nervous system morbidity is seen in 20 to 50 percent of survivors with disseminated or cerebral infection.

FIGURE 65-6 Cross-section showing necrotic brain tissue from a newborn who died from disseminated herpesvirus infection.

Diagnosis

According to the Centers for Disease Control and Prevention (2010a), clinical diagnosis of genital herpes is both insensitive and nonspecific and should be confirmed by laboratory testing. HSV tests available are either virological or type-specific serological tests.

Virological tests are performed on a specimen from a mucocutaneous lesion. Cell culture and PCR are the preferred tests. The sensitivity of HSV isolation is relatively low for viral culture as vesicular lesions ulcerate and then crust. Viral isolation results sometimes are not available for 1 to 2 weeks. PCR assays are more sensitive, the results generally are available in 1 to 2 days, and specimen handling is easier. The major limitation of PCR is cost and laboratory availability. The PCR assay is the preferred test for HSV detection in spinal fluid. Regardless of the test performed, HSV viral type should be differentiated because HSV type influences counseling and long-term prognosis. *A negative culture or PCR result does not exclude infection.* False-positive results are rare.

Several serological assay systems are available to detect antibody to HSV glycoproteins G1 and G2 (Anzivino, 2009; Centers for Disease Control and Prevention, 2010a). These proteins evoke type-specific antibody responses to HSV-1 and HSV-2 infection, respectively, and they reliably differentiate the two. This permits confirmation of clinical infection and identification of asymptomatic carriers. The Food and Drug Administration (FDA) has approved type-specific tests that are enzyme-linked immunosorbent assay (ELISA) or blot-style tests. Providers should request type-specific glycoprotein G-based assays when serology is being performed. Sensitivity approaches 90 to 100 percent and specificity 99 to 100 percent (Wald, 2002). IgG antibodies usually are detected 1 to 2 weeks after a primary infection. IgM antibody detection is not a useful test.

Point-of-care testing is being increasingly requested by practitioners to help guide management intrapartum or near delivery. There are type-specific serological tests available that use capillary blood or serum. Sensitivity varies from 80 to 98 percent with specificity ≥ 96 percent. False-positive and false-negative results may occur. Real-time quantitative PCR of genital tract secretions has recently been developed by Gardella and colleagues (2010). They reported sensitivity of 99.6 percent and specificity of 96.7 percent with a turnaround time of 2 hours. These features would prove valuable to guide clinical decision making at delivery.

Routine serological screening for herpes in pregnancy is not recommended by the American College of Obstetricians and Gynecologists (2012) due to cost and limited data on efficacy in reducing the incidence of neonatal herpes. Cost-decision analysis for prenatal type-specific antibody screening and suppressive therapy for partners has been found to be unacceptably expensive (Barnabas, 2002; Rouse, 2000; Thung, 2005). In contrast, it was found to be potentially cost-effective by Baker and associates (2004). Cleary and coworkers (2005) calculated that universal prenatal screening would reduce rates of perinatal death and severe sequelae from neonatal HSV. But they also found that it would require treatment of 3849 women

to prevent one case of neonatal death or disease with severe sequelae. Universal screening would identify previously undiagnosed women who could then be counseled regarding safe practices and antepartum antiviral suppression, but a concrete benefit remains unproven.

Management

Antiviral therapy with acyclovir, famciclovir, or valacyclovir has been used for treatment of first-episode genital herpes in non-pregnant patients. Oral or parenteral preparations attenuate clinical infection and the viral shedding duration. Suppressive therapy has also been given to limit recurrent infections and to reduce heterosexual transmission (Corey, 2004, 2012). For intense discomfort, oral analgesics and topical anesthetics may provide some relief, and urinary retention is treated with an indwelling bladder catheter. Acyclovir appears to be safe for use in pregnant women (Briggs, 2011; Stone, 2004). The manufacturers of acyclovir and valacyclovir, in cooperation with the Centers for Disease Control and Prevention, maintained a registry of outcomes following exposure to these drugs during pregnancy through 1999. More than 700 neonates exposed during the first trimester were evaluated, and no increased adverse effects were found (Stone, 2004). At this time, there are insufficient data with famciclovir exposure, although a pregnancy registry is being maintained (1-888-669-6682).

Women with a primary outbreak during pregnancy may be given antiviral therapy to attenuate and decrease the duration of symptoms and viral shedding (Table 65-5). Women with HIV co-infection may require a longer duration of treatment. Those with severe or disseminated HSV are given IV acyclovir, 5 to 10 mg/kg, every 8 hours for 2 to 7 days until clinically improved. This is followed by oral antiviral therapy to complete at least 10 days of total therapy (Centers for Disease Control and Prevention, 2010b). Recurrent HSV infections during pregnancy are treated for symptomatic relief only (see Table 65-5). Acyclovir resistance has been reported, predominantly with HSV-2 and in immunocompromised patients (Corey, 2012).

Peripartum Shedding Prophylaxis

Several studies have shown that acyclovir or valacyclovir suppression initiated at 36 weeks' gestation will decrease the number of HSV outbreaks at term, thus decreasing the need for cesarean delivery (Hollier, 2008). Such suppressive therapy will also decrease viral shedding defined by both culture and PCR techniques (Scott, 2002; Sheffield, 2006; Watts, 2003). A systematic review of studies of acyclovir prophylaxis given from 36 weeks to delivery was reported by Sheffield and colleagues (2003). They found that delivery suppressive therapy was associated with significantly decreased rates of clinical HSV recurrence, cesarean deliveries for HSV recurrences, total HSV detection, and asymptomatic shedding. Subsequent studies using valacyclovir suppression have shown similar results (Andrews, 2006; Sheffield, 2006). Because of these studies, the American College of Obstetricians and Gynecologists (2012) recommends viral therapy at or beyond 36 weeks for women

TABLE 65-5. Antiviral Medications for Herpesvirus Infection in Pregnancy

Indication	Pregnancy Recommendation
Primary or first episode infection	Acyclovir, 400 mg orally three times daily for 7–10 days
	or
Symptomatic recurrent infection (episodic therapy)	Valacyclovir, 1 g orally twice daily for 7–10 days
	Acyclovir, 400 mg orally three times daily for 5 days
	or
	Acyclovir, 800 mg orally twice daily for 5 days
	or
Daily suppression	Valacyclovir, 500 mg orally twice daily for 3 days
	or
	Valacyclovir, 1 g orally once daily for 5 days
	Acyclovir, 400 mg orally three times daily from 36 weeks until delivery
	or
	Valacyclovir, 500 mg orally twice daily from 36 weeks until delivery

Adapted from the Centers for Disease Control and Prevention, 2010b.

who have any recurrence during pregnancy. It is unclear whether suppression is needed for women with outbreaks before but not during pregnancy. There have been several case reports of atypical neonatal herpes disease following maternal antiviral suppression. Thus, suppression does not prevent all cases of neonatal disease (Pinninti, 2012).

On presentation for delivery, a woman with a history of HSV should be questioned regarding prodromal symptoms such as vulvar burning or itching. A careful examination of the vulva, vagina, and cervix should be performed, and suspicious lesions should be cultured or PCR tested. Currently, there is no approved point-of-care test to guide management. Cesarean delivery is indicated for women with active genital lesions or prodromal symptoms (American College of Obstetricians and Gynecologists, 2012). Of note, 10 to 15 percent of neonates with HSV are born to women undergoing cesarean delivery. Cesarean delivery is not recommended for women with a history of HSV infection but no active genital disease at the time of delivery. Moreover, an active lesion in a nongenital area is not an indication for cesarean delivery. Instead, an occlusive dressing is placed, and vaginal delivery is allowed.

There is no evidence that external lesions cause ascending fetal infection with preterm ruptured membranes. Major and associates (2003) described expectant management of preterm premature membrane rupture in 29 women < 31 weeks. There were no cases of neonatal HSV, and the maximum infection risk was calculated to be 10 percent. Antiviral treatment use in this setting is reasonable, but of unproven efficacy. For women with a clinical recurrence at delivery, there is not an absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 2013). Women with active HSV may breast feed if there are no active HSV breast lesions. Strict hand washing is advised. Valacyclovir and acyclovir may be used during breast feeding, as drug concentrations in breast milk are low. One study

found the acyclovir concentration to be only 2 percent of that used for therapeutic dosing of the neonate (Sheffield, 2002a).

Other antiviral agents are under development. One is *pritelivir*, a viral helicase-primase complex that reduces HSV-2 shedding (Wald, 2014). Also, HSV-2 vaccine development is currently being aggressively pursued. Two glycoprotein D-based subunit vaccine trials have shown benefit in discordant couples by decreasing HSV-2 acquisition (Stanberry, 2002). Interestingly, a recent randomized controlled trial of a newer glycoprotein D-based HSV-2 vaccine showed it to be effective in women in preventing HSV-1, but not HSV-2, genital disease (Belshe, 2012). Further research is needed to better understand these challenging and contradictory results (Johnson, 2011).

CHANCROID

Haemophilus ducreyi can cause painful, nonindurated genital ulcers termed soft chancres that at times are accompanied by painful suppurative inguinal lymphadenopathy. Although common in some developing countries, it had become rare in the United States by the 1970s. There was an increase in the late 1980s, but only fifteen cases were reported in the United States in 2012. This marked decrease likely represents a true decline as well as diagnostic difficulties that led to underdiagnosis (Centers for Disease Control and Prevention, 2013b). Importantly, the ulcerative lesion is a high-risk cofactor for HIV transmission.

Diagnosis by culture is difficult because appropriate media are not widely available. Instead, clinical diagnosis is made when typical painful genital ulcer(s) are dark-field negative for spirochetes and herpes-virus test results are negative. No FDA-cleared PCR test is yet available. Recommended treatment in pregnancy is azithromycin, 1 g orally as a single dose; erythromycin base, 500 mg orally three times daily for 7 days; or ceftriaxone, 250 mg in a single intramuscular dose (Centers for Disease Control and Prevention, 2010b).

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is one of the most common sexually transmitted infections, and more than 40 types infect the genital tract. Most reproductive-aged women become infected within a few years of becoming sexually active, although most infections are asymptomatic and transient. Oncogenic or high-risk HPV types 16 and 18 are associated with dysplasia and are discussed in Chapter 63 (p. 1222). Mucocutaneous external genital warts termed condyloma acuminata are usually caused by HPV types 6 and 11 but may also be caused by intermediate- and high-oncogenic-risk HPV.

The National Health and Nutrition Examination Survey (NHANES) 2003 to 2006 reported an overall HPV prevalence of 43 percent in females aged 14 to 59 years (Hariri, 2011). A 27-percent seroprevalence was also reported for subjects 18 through 25 years in the National Longitudinal Study of Adolescent Health (Manhart, 2006). Similar rates of HPV positivity have been reported for pregnant women (Aydin, 2010; Gajewska, 2005; Hernandez-Giron, 2005; Rama, 2010). Prevalence is highest in younger age groups.

External Genital Warts—Condyloma Acuminata

For unknown reasons, genital warts frequently increase in number and size during pregnancy. Acceleration of viral replication by the physiological changes of pregnancy might explain perineal lesion growth and progression of some to cervical neoplasm (Fife, 1999; Rando, 1989). These lesions may sometimes grow to fill the vagina or cover the perineum, thus making vaginal delivery or episiotomy difficult (Fig. 65-7). Because HPV infection may be subclinical and multifocal, most women with vulvar lesions also have cervical infection, and vice versa (Ault, 2003; Kroupis, 2011; Reichman, 2012).

Treatment

There may be an incomplete response to treatment during pregnancy, but lesions commonly improve or regress rapidly following delivery. Consequently, wart eradication during pregnancy is usually not necessary. Therapy is directed toward minimizing treatment toxicity to the mother and fetus and debulking symptomatic genital warts. There are several agents available, but pregnancy limits their use. There is no definitive evidence that any one of the subsequently discussed treatments is superior to another (Centers for Disease Control and Prevention, 2010b; Wiley, 2002).

Trichloroacetic or bichloroacetic acid, 80- to 90-percent solution, applied topically once a week, is an effective regimen for external warts. Some prefer *cryotherapy*, *laser ablation*, or *surgical excision* (Arena, 2001; Centers for Disease Control and Prevention, 2010b). Agents not recommended in pregnancy because of concerns for maternal and fetal safety include podophyllin resin, podofilox 0.5-percent solution or gel, imiquimod 5-percent cream, interferon therapy, and sinecatechins.

Neonatal Infection

Juvenile-onset recurrent respiratory papillomatosis is a rare, benign neoplasm of the larynx. It can cause hoarseness and

FIGURE 65-7 Extensive external genital warts in a postpartum woman.

respiratory distress in children and is often due to HPV types 6 or 11. In some cases, maternal genital HPV infection is associated with laryngeal papillomatosis, but studies differ in their findings of neonatal transmission rates. Although some have reported rates as high as 50 percent, it is likely that these findings are from maternal contamination or transient HPV infection (Campisi, 2010; Winer, 2004). A Danish population-based study indicated a neonatal transmission risk of 7 per 1000 infected women (Silverberg, 2003). Prolonged rupture of membranes was associated with a twofold increased risk, but risk was not associated with delivery mode. This low transmission risk has been confirmed in subsequent studies (Heim, 2007; Smith, 2004). Finally, long-term follow-up studies are consistent with a very low vertical transmission risk (Manns, 1999; Smith, 2004). The benefit of cesarean delivery to decrease transmission risk is unknown, and thus it is currently not recommended solely to prevent HPV transmission (Centers for Disease Control and Prevention, 2010b). HPV vaccination may decrease the rate over time (Hawkes, 2008; Kim, 2008).

Immunization

Two HPV inactivated vaccines are currently licensed in the United States. These are a quadrivalent vaccine (Gardasil) containing HPV types 6, 11, 16, and 18 and a bivalent vaccine (Cervarix) containing HPV types 16 and 18. The vaccines are both a three-dose series and are licensed for females and males aged ≤ 26 years. They are effective for males (Giuliano, 2011).

The vaccines are not recommended for pregnant women, however, inadvertent exposures do occur. Garland and coworkers (2009) analyzed data on these exposures from five Phase III clinical trials of Gardasil. They found no adverse pregnancy outcomes associated with the vaccine. Wacholder and associates (2010) pooled data from two multicenter Phase III trials and found no association between HPV vaccination and miscarriage risk. Postlicensure surveillance is ongoing using a manufacturer pregnancy registry (American College of Obstetricians and Gynecologists, 2010a). Women who are breast feeding may receive the vaccine. If a woman is found to be pregnant after starting the vaccination series, the remaining doses should be delayed until after delivery.

VAGINITIS

Pregnant women commonly develop increased vaginal discharge, which in many instances is not pathological (Chap. 4, p. 50). The vaginal microbial flora provides protection against vaginal infection. Elucidation of the composition and function of the normal vaginal microflora is currently underway with the human microbiome project (Lamont, 2011).

Bacterial Vaginosis

Not an infection in the ordinary sense, bacterial vaginosis (BV) is a maldistribution of normal vaginal flora. Numbers of lactobacilli are decreased, and overrepresented species are anaerobic bacteria that include *Gardnerella vaginalis*, *Mobiluncus*, and some *Bacteroides* species. As many as 30 percent of childbearing-aged women have bacterial vaginosis (Allsworth, 2007; Koumans, 2007; Simhan, 2008). Vitamin D deficiency has been identified as a risk factor for vaginosis in pregnancy. Moreover, douching, multiple partners, young age, smoking, and black race are associated with vaginosis in both pregnant and nonpregnant women (Bodnar, 2009; Desseauve, 2012; Hensel, 2011). In pregnancy, it is associated with preterm birth, early and late miscarriage, low birthweight, and increased neonatal morbidity (Goldenberg, 2008; Laxmi, 2012). Treatment is reserved for symptomatic women, who usually complain of a fishy-smelling discharge. Preferred treatment is metronidazole, 500 mg twice daily orally for 7 days; 250 mg three times daily orally for 7 days; or clindamycin 300 mg orally twice daily for 7 days (Centers for Disease Control and Prevention, 2010b). Unfortunately, although eradication is possible, treatment does not reduce preterm birth rates, and routine screening is not recommended (McDonald, 2007).

Trichomoniasis

Trichomonas vaginalis can be identified during prenatal examination in up to 20 percent of women. Symptomatic vaginitis is much less prevalent, and it is characterized by foamy leukorrhea, pruritus, and irritation. Trichomonads are seen readily in fresh vaginal secretions as flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes.

Metronidazole, administered orally in a single 2-g dose, is effective in eradicating *T vaginalis* (Centers for Disease Control

and Prevention, 2010b). It may be used at any gestational age—multiple studies have not shown an association between metronidazole use in any trimester of pregnancy and neonatal effects, including malformations (Briggs, 2011). Some studies have linked trichomonal infection with preterm birth, however, treatment has not decreased this risk (Gulmezoglu, 2011; Wendel, 2007). Thus, screening and treatment of asymptomatic women is not recommended during pregnancy.

Candidiasis

Candida albicans or other *Candida* species can be identified by culture from the vagina during pregnancy in approximately 25 percent of women. Asymptomatic colonization requires no treatment. However, the organism may sometimes cause an extremely profuse, irritating discharge associated with a pruritic, tender, edematous vulva. Effective treatment is given with a number of azole creams that include 2-percent butoconazole, 1-percent clotrimazole, 2-percent miconazole, and 0.4- or 0.8-percent terconazole applied for 7 days (Centers for Disease Control and Prevention, 2010b). Topical treatment is recommended, but as described in Chapter 12 (p. 247), oral azoles are generally considered safe (Pitsouni, 2008). In some women, infection is likely to recur and require repeated treatment during pregnancy. In these cases, symptomatic infection usually subsides after pregnancy (Sobel, 2007).

HUMAN IMMUNODEFICIENCY VIRUS

Acquired immunodeficiency syndrome (AIDS) was first described in 1981, and it is currently one of the worst global health pandemics in recorded history. Worldwide, it was estimated in 2012 that there were 35.3 million infected persons with HIV/AIDS; 2.3 million new cases of HIV infection; and 1.6 million HIV-related deaths (UNAIDS, 2013). In the United States through 2011, the Centers for Disease Control and Prevention (2013a) estimated that there were more than 1.1 million infected individuals and more than 636,000 deaths (Centers for Disease Control and Prevention, 2013a). In 2010, women accounted for 20 percent of all HIV/AIDS cases among adults and adolescents, most of which resulted from heterosexual contact. Comparing 2008 with 2011, HIV incidence decreased in women, primarily black/African American women and women acquiring HIV through heterosexual contact.

The estimated number of perinatally acquired AIDS cases has decreased dramatically during the past two decades (Fig. 65-8). This is predominantly due to the implementation of prenatal HIV testing and antiviral therapy given to the pregnant woman and then to her neonate (De Cock, 2012). In addition, *highly active antiretroviral therapy (HAART)* has led to an increasing number of people living with chronic HIV infection and thus the associated comorbidities also affecting pregnancy (Fenton, 2007).

Etiopathogenesis

Causative agents of AIDS are RNA retroviruses termed *human immunodeficiency viruses*, *HIV-1* and *HIV-2*. Most cases worldwide are caused by HIV-1 infection. Transmission is

FIGURE 65-8 Estimated number of perinatally acquired AIDS cases by year of diagnosis, 1985 to 2010, in the United States and dependent areas. (Data from the Centers for Disease Control and Prevention, 2011a.)

similar to hepatitis B virus, and sexual intercourse is the major mode. The virus also is transmitted by blood or blood-contaminated products, and infected mothers may infect their fetuses perinatally or by their breast milk. The primary determinant of HIV-1 transmission is the plasma HIV-1 viral load.

The common denominator of clinical illness with AIDS is profound immunodeficiency that gives rise to various opportunistic infections and neoplasms. Sexual transmission occurs when mucosal dendritic cells bind to the HIV envelope glycoprotein gp120. These dendritic cells then present the viral particle to thymus-derived lymphocytes, that is, T lymphocytes. These lymphocytes are defined phenotypically by the cluster of differentiation 4 (CD4) glycoprotein surface antigens. The CD4 site serves as a receptor for the virus. Coreceptors are necessary for viral entry into the cell, and two chemokine receptors—CCR5 and CXCR4—are the most frequently identified (Fauci, 2012; Sheffield, 2007). The CCR5 coreceptor is found on the cell surface of CD4 positive (CD4⁺) cells in high progesterone states such as pregnancy, possibly aiding viral entry (Sheffield, 2009).

After initial infection, the level of viremia usually decreases to a set point, and patients with the highest viral burden at this time progress more rapidly to AIDS and death (Fauci, 2007, 2012). And as shown in [Figure 65-9](#), viral burden and neonatal infection incidence are directly related. Over time, the number of T cells drops insidiously and progressively, resulting eventually in profound immunosuppression. Although it is thought that pregnancy has minimal effects on CD4⁺ T-cell counts and HIV RNA levels, the latter are often higher 6 months postpartum than during pregnancy. Higher levels of inflammatory cytokines and a decrease in regulatory T cells in late pregnancy may contribute to maternal and fetal morbidity (Richardson, 2011).

Clinical Manifestations

The incubation period from exposure to clinical disease is days to weeks, and the average is 3 to 6 weeks. Acute HIV infection is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms include fever and night sweats, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, nausea, vomiting, and diarrhea. After symptoms abate, the set point of chronic viremia is established. The progression from asymptomatic viremia to AIDS has a median time of approximately 10 years (Fauci, 2008). Route of infection, the pathogenicity of the infecting viral strain, the initial viral inoculum, and the immunological status of the host all affect the rapidity of progression.

Several clinical and laboratory manifestations will herald disease progression. Generalized lymphadenopathy, oral hairy leukoplakia, aphthous ulcers, and thrombocytopenia are common. A number of opportunistic infections associated with

FIGURE 65-9 Incidence of perinatal human immunodeficiency virus (HIV) infection plotted against plasma HIV-1 RNA levels in 1542 neonates born to mothers in the Women and Infants Transmission Study. (Data from Cooper, 2002.)

AIDS include esophageal or pulmonary candidiasis; persistent herpes simplex or zoster lesions; condyloma acuminata; pulmonary tuberculosis; cytomegaloviral pneumonia, retinitis, or gastrointestinal disease; molluscum contagiosum; *Pneumocystis jiroveci* pneumonia; toxoplasmosis; and others. Neurological disease is common, and approximately half of patients have central nervous system symptoms. A CD4⁺ count < 200/mm³ is also considered definitive for the diagnosis of AIDS.

There are unique gynecological issues for women with HIV, such as menstrual abnormalities, contraceptive needs, and genital neoplasia, that are discussed in *Williams Gynecology*, 2nd edition (Werner, 2012). Some of these as well as other STIs may persist into pregnancy (Cejtin, 2003; Stuart, 2005). Repeated pregnancy has no significant effect on the clinical or immunological course of viral infection (Minkoff, 2003).

■ Prenatal HIV Screening

The Centers for Disease Control and Prevention (2006, 2010a), The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2011), and the United States Preventive Services Task Force (2012) recommend prenatal HIV screening using an *opt-out approach*. This means that the woman is notified that HIV testing is included in a comprehensive set of antenatal tests, but that testing may be declined. Women are given information regarding HIV but are not required to sign a specific consent. Through the use of such *opt-out* strategies, HIV testing rates have increased. Each provider should be aware of specific state laws concerning screening.

In areas in which the incidence of HIV or AIDS is 1 per 1000 person-years or greater, or in women at high risk for acquiring HIV during pregnancy, repeat testing in the third trimester is recommended (American College of Obstetricians and Gynecologists, 2011). High-risk factors include injection drug use, prostitution, a suspected or known HIV-infected sexual partner, multiple sexual partners, or a diagnosis of another sexually transmitted disease. Several states also recommend or require HIV testing at delivery.

Screening is performed using an enzyme-linked immunoassay with a sensitivity > 99.5 percent. A positive test is confirmed with either a Western blot or immunofluorescence assay

(IFA), both of which have high specificity. According to the Centers for Disease Control and Prevention (2001), antibody can be detected in most patients within 1 month of infection, and thus, antibody serotesting may not exclude early infection. For acute primary HIV infection, identification of viral p24 core antigen or viral RNA or DNA is possible. False-positive confirmatory results are rare (Centers for Disease Control and Prevention, 2010b).

Women with limited prenatal care or with undocumented HIV status at delivery should have a “rapid” HIV test performed. These tests can detect HIV antibody in 60 minutes or less and have sensitivities and specificities comparable with those of conventional ELISAs (Chetty, 2012). A negative rapid test result does not need to be confirmed. However, in a woman exposed to HIV within the last 3 months, repeat testing is recommended. A positive rapid test result should be confirmed with a Western blot or IFA test. As shown in Table 65-6, peripartum and neonatal interventions to reduce perinatal transmission are based on the initial rapid testing results, and this can be discontinued if the confirmatory test is negative (American College of Obstetricians and Gynecologists, 2011; Centers for Disease Control and Prevention, 2010b). A detailed list of the rapid HIV tests currently available in the United States can be found at <http://www.cdc.gov/hiv/topics/testing/resources/factsheets/rt-lab.htm> (Centers for Disease Control and Prevention, 2007). The Mother-Infant Rapid Intervention at Delivery (MIRIAD) multicenter study indicated that rapid HIV testing can be used to identify infected women so that peripartum antiretroviral prophylaxis can be administered to mother and infant (Bulterys, 2004).

■ Maternal and Perinatal Transmission

Transplacental HIV transmission can occur early, and the virus has even been identified in specimens from elective abortion (Lewis, 1990). In most cases, however, mother-to-child transmission at the time of delivery is the most common cause of pediatric HIV infections. Between 15 and 40 percent of neonates born to non-breast-feeding, untreated, HIV-infected mothers are infected. Kourtis and colleagues (2001) have proposed a model for estimation of the temporal distribution of

TABLE 65-6. Strategy for Rapid Human Immunodeficiency Virus (HIV) Testing of Pregnant Women in Labor

If the rapid HIV test result in labor and delivery is positive, the obstetrical provider should take the following steps:

1. Tell the woman she may have HIV infection and that her neonate also may be exposed
2. Explain that the rapid test result is preliminary and that false-positive results are possible
3. Assure the woman that a second test is being performed to confirm the positive rapid test result
4. To reduce the risk of transmission to the infant, immediate initiation of antiretroviral prophylaxis should be recommended without waiting for the results of the confirmatory test
5. Once the woman gives birth, discontinue maternal antiretroviral therapy pending receipt of confirmatory test results
6. Tell the women that she should postpone breast feeding until the confirmatory result is available because she should not breast feed if she is infected with HIV
7. Inform pediatric care providers (depending on state requirements) of positive maternal test results so that they may institute the appropriate neonatal prophylaxis

Summarized from American College of Obstetricians and Gynecologists, 2011.

vertical transmission. They estimate that 20 percent of transmission occurs before 36 weeks' gestation, 50 percent in the days before delivery, and 30 percent intrapartum. Transmission rates for breast feeding may be as high as 30 to 40 percent and are associated with systemic HIV viral burden (Kourtis, 2006, 2007a; Slyker, 2012). Vertical transmission is more common with preterm births, especially with prolonged membrane rupture. Analyzing data from the Perinatal AIDS Collaborative Transmission Study, Kuhn and coworkers (1999) reported a nearly fourfold increased risk with preterm delivery. Although an increased risk of perinatal transmission has been associated with membrane rupture in the past, recent analyses in the setting of combination antiviral therapy have not found this to be a risk factor with an HIV viral load < 1000 copies/mL (Cotter, 2012).

In nonpregnant individuals, there is an association between concomitant STIs and horizontal HIV transmission. There is also evidence that vertical perinatal transmission may be increased with STIs (Schulte, 2001; Watts, 2012). Women with maternal HSV-2 antibody have a significant 50-percent increased risk of intrapartum HIV-1 maternal-to-child transmission (Cowan, 2008). They attributed up to 25 percent of vertical transmission to maternal HSV-2 co-infection. Elevated cytokine and chemokine levels in the placenta, reflecting inflammation, are associated with in utero transmission (Kumar, 2012). A recent Cochrane analysis, however, has failed to show that sexually transmitted infection control is an effective HIV prevention strategy (Ng, 2011).

Perinatal HIV transmission is most accurately correlated with maternal plasma HIV RNA burden (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Watts, 2002). As shown in Figure 65-9, cohort neonatal infection was 1 percent with < 400 copies/mL, and it was > 30 percent when maternal viral RNA levels were > 100,000 copies/mL. *Transmission of HIV infection, however, has been observed at all HIV RNA levels, including those that were non-detectable by current assays.* This may be attributed to discordance between the viral load in plasma and that in the genital secretions. Because of these findings, the viral load should not be used to determine whether to initiate antiretroviral therapy in pregnancy.

■ Preconceptional Counseling

Effective contraception should be discussed if pregnancy is undesired. Certain antiviral medications decrease hormonal contraception efficacy and are discussed in Chapter 38 (p. 708). Recommendations are also available at <http://AIDSinfo.nih.gov> and are updated frequently as new data become available. Counseling also includes education for decreasing high-risk sexual behaviors to prevent transmission and to decrease the acquisition of other sexually transmitted diseases. Currently used antiretroviral medications are reviewed to avoid those with high teratogenic potential should the woman become pregnant. A specific example is efavirenz, which has significant teratogenic effects on primate fetuses (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). Preference should also include those that decrease HIV RNA viral load effectively before pregnancy.

■ Management During Pregnancy

These women need special attention and are seen in consultation by physicians with special interest in this field. At Parkland Hospital, the initial assessment of an HIV-infected pregnant woman includes:

- Standard prenatal laboratory surveys that include serum creatinine, hemogram, and bacteriuria screening (Chap. 9, p. 171)
- Plasma HIV RNA quantification—"viral load," CD4⁺ T-lymphocyte count, and antiretroviral resistance testing
- Serum hepatic aminotransferase levels
- HSV-1 and -2, cytomegalovirus, toxoplasmosis, and hepatitis C serology screening
- Baseline chest radiograph
- Tuberculosis skin testing—purified protein derivative (PPD) or interferon-gamma release assay
- Evaluation of need for pneumococcal, hepatitis B, hepatitis A, Tdap, and influenza vaccines
- Sonographic evaluation to establish gestational age.

Antiretroviral Therapy

Treatment is recommended for all HIV-infected pregnant women. This may be a departure for those not receiving treatment when nonpregnant because they did not meet certain criteria. Treatment reduces the risk of perinatal transmission regardless of CD4⁺ T-cell count or HIV RNA level. Antiretroviral therapy is complicated, and pregnancy only adds to the complexity. In general, HAART is begun if the woman is not already receiving one of the regimens. Antiretroviral agents are grouped into several classes and used to design antiretroviral regimens (Table 65-7). The 2012 Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission classify each agent into five use categories: preferred, alternative, use in special circumstances, not recommended, and insufficient data to recommend use. The woman is counseled regarding risks and benefits of antiretroviral agents to make an informed decision as to her treatment regimen. Regardless of what regimen is begun, adherence is important because the risk of viral drug resistance is lessened.

The Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission (2012) has issued guidelines that detail management of different scenarios during pregnancy (Table 65-8). Women already taking HAART at pregnancy onset are encouraged to continue the regimen if there is adequate viral suppression. The neural-tube defect risk associated with efavirenz is restricted to the first 6 weeks of pregnancy. Thus, efavirenz can be continued if the woman presents after this time and if adequate virological suppression is documented. Until recently, addition of zidovudine to all regimens was recommended. Currently, however, in women with adequate viremia suppression with a regimen not containing zidovudine, continuation of the current regimen is appropriate. Zidovudine is given intravenously during labor and delivery to women with an HIV RNA viral load > 400 copies/mL or who have an unknown viral load near delivery (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal

TABLE 65-7. Classes of Antiretroviral Drugs

Drug Class	Category ^a
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors	
Lamivudine	Preferred
Zidovudine	Preferred
Abacavir	Alternative
Emtricitabine	Alternative
Tenofovir	Alternative
Didanosine	Special circumstances
Stavudine	Special circumstances
Non-nucleoside Reverse Transcriptase Inhibitors	
Nevirapine	Preferred
Efavirenz	Special circumstances
Etravirine	Insufficient data ^b
Rilpivirine	Insufficient data ^b
Protease Inhibitors	
Ritonavir	Preferred
Atazanavir	Preferred
Lopinavir/ritonavir	Preferred
Saquinavir	Alternative
Darunavir	Alternative
Indinavir	Special circumstances
Nelfinavir	Special circumstances
Fosamprenavir	Special circumstances
Tipranavir	Special circumstances
Entry Inhibitors	
Enfuvirtide	Insufficient data ^b
Maraviroc	Insufficient data ^b
Integrase Inhibitors	
Raltegravir	Special circumstances

^bInsufficient data to recommend use.

Transmission, 2012). A 2 mg/kg load is infused over 1 hour followed by zidovudine 1 mg/kg/hr until delivery.

Women who have never received antiretroviral therapy—*antiretroviral naïve*—fall into two categories. First, women who meet the criteria for antiretroviral therapy initiation in nonpregnant adults are given HAART regardless of trimester. Because of an increased risk of hepatotoxicity, *nevirapine* is reserved for women with a CD4⁺ cell count < 250 cells/mm³. In general, the starting HAART regimen is two nucleoside reverse transcriptase inhibitors (NRTIs) plus a non-nucleoside reverse transcriptase inhibitor (NNRTI) or protease inhibitor(s). At Parkland Hospital as of 2014, our standard regimen in treatment-naïve women is lopinavir/ritonavir—formulated as *Kaletra*—plus zidovudine/lamivudine—formulated as *Combivir*. The lopinavir/ritonavir regimen should be increased in the late second and third trimester. Atazanavir, another protease inhibitor, is also now listed as a preferred agent and can be used in place of lopinavir/ritonavir. If used, it is combined with low-dose ritonavir boosting.

The second category contains treatment-naïve HIV-infected pregnant women who do not meet nonpregnant adult indications for antiretroviral therapy. These women are counseled regarding the benefits of initiating therapy to prevent perinatal viral transmission. Because of potential teratogenic effects, women may delay therapy until the second trimester. That said, however, earlier initiation may be more effective in reducing perinatal transmission (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Read, 2012).

Women who have previously received antiretroviral therapy but are currently not taking medications should undergo HIV resistance testing because antiretroviral use increases their risk of drug resistance. Regimens may then be tailored based on prior medication use and response as well as current resistance patterns. The final group includes women who present in labor and who are taking no medications. These women are given intravenous zidovudine intrapartum (see Table 59-8). The National Perinatal HIV Hotline (1-888-448-8765) is a federally funded service that provides free consultation to providers.

Laboratory Assessment

CD4⁺ T-lymphocyte count, HIV RNA viral load measurement, complete blood count, and liver function tests are done 4 weeks after beginning or changing therapy to assess response and exclude toxicity. Thereafter, HIV RNA viral loads are measured monthly until RNA levels are undetectable. CD4 T-lymphocyte and HIV RNA levels can then be measured every trimester. If the HIV RNA viral load increases or does not decrease appropriately, then medication compliance and antiretroviral drug resistance are assessed. Poor adherence to therapy is a significant problem in pregnancy.

Although there was an association of early studies with glucose intolerance and protease inhibitor use, this has not been corroborated (Hitti, 2007; Tang, 2006). Standard serum glucose screening should be performed at 24 to 28 weeks unless indicated earlier. In addition, careful surveillance is important for interactions between antiretroviral drugs as well as therapies for opportunistic infection, hepatitis B and C, and tuberculosis (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Piscitelli, 2001).

Complications of HIV Infection

Management of some HIV complications may be altered by pregnancy. If the CD4⁺ T-cell count is < 200/mm³, primary prophylaxis for *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia is recommended with sulfamethoxazole-trimethoprim or dapsone. Pneumonitis is treated with oral or IV sulfamethoxazole-trimethoprim or dapsone-trimethoprim. Other symptomatic opportunistic infections that may develop are from latent or newly acquired toxoplasmosis, herpes virus, mycobacteria, and candida. The National Institutes of Health, Centers for Disease Control and Prevention, and Infectious Diseases Society of America (2013) have published guidelines for prevention and treatment of opportunistic infections. Maternal HIV infection has also been associated with fetal-growth restriction, preeclampsia, and preterm membrane rupture (Ndirangu, 2012; Rollins, 2007; Suy, 2006).

TABLE 65-8. Recommendations for Antiviral Drug Use During Pregnancy

Clinical Scenario	Recommendations
HIV-infected woman taking antiretroviral therapy who becomes pregnant	Continue current medication if viral suppression adequate and patient tolerating If virus detectable, order HIV antiretroviral drug-resistance testing If first trimester, continue medications; if stopped, stop all medications and then reinstate in the second trimester Start IV ZDV in labor if HIV RNA level > 400 copies/mL or unknown near delivery
HIV-infected woman who is antiretroviral naïve	Order HIV antiretroviral drug-resistance testing Initiate HAART: – Avoid efavirenz in the early first trimester – Use one or more NRTIs—ZDV, lamivudine, emtricitabine, tenofovir, or abacavir—if feasible – Avoid nevirapine in women with a CD4 ⁺ count > 250 cells/mm ³ HAART should be initiated as early as possible for maternal indications; if high CD4 T-lymphocyte count and low HIV RNA level, can consider delaying initiation of HAART until the second trimester Start IV ZDV in labor if HIV RNA level > 400 copies/mL or unknown near delivery
HIV-infected woman previously taking antiretroviral medications but not on medications currently	Order HIV antiretroviral drug-resistance testing Initiate HAART with regimen based on prior therapy history and resistance testing Avoid efavirenz in the early first trimester Use one or more NRTIs—ZDV, lamivudine, emtricitabine, tenofovir, or abacavir—if feasible Avoid nevirapine in women with a CD4 ⁺ count > 250 cells/mm ³ Start IV ZDV in labor if HIV RNA level > 400 copies/mL or unknown near delivery
HIV-infected woman on no antiretroviral medication who presents in labor	Order initial HIV laboratory assessment (p. 1279) Start IV ZDV during labor—2 mg/kg IV load over 1 hour, then 1 mg/kg/hr until delivery

CD4 = cluster of differentiation 4; HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus; IV = intravenous; NRTIs = nucleoside reverse transcriptase inhibitors; ZDV = zidovudine.

Adapted from the Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012.

Perinatal Outcomes

Even with treatment, the incidence of perinatal complications in HIV-infected women is increased, although the newer drug regimens may diminish these rates. Multiple studies reviewed in the 2012 Perinatal Treatment Guidelines address the association of antiretroviral medications with preterm delivery. Most of those have shown a small but significantly increased risk. Kourtis and colleagues (2007b) performed a metaanalysis of 14 European and U.S. studies and found no overall greater risk for preterm delivery. They did find, however, that women taking regimens that included a protease inhibitor had a small increased risk—1.3-fold—that was nevertheless significant. Antiretroviral medication use in the second half of pregnancy was shown by Lopez and associates (2012) to increase iatrogenic preterm birth but did not affect spontaneous preterm birth rates. This slightly increased frequency of preterm birth clearly is outweighed by the benefits of decreasing perinatal HIV transmission.

Medication Toxicity

At least two follow-up studies of children from the Pediatric AIDS Clinical Trial Group (PACTG) 076 Study found no adverse effects at 18 months and up to a mean of 5.6 years after zidovudine

exposure (Culnane, 1999; Sperling, 1998). Prenatal exposure to HAART may increase the risk for neonatal neutropenia and anemia, although no long-term hematological or hepatic toxicities have been documented (Bae, 2008; Dryden-Peterson, 2011). Preliminary data also show a possible effect on infant mitochondrial DNA proliferation and/or expression with maternal antiretroviral drug treatment (Cote, 2008; Hernandez, 2012; Jitratkosol, 2012). For these reasons, long-term follow-up is recommended for all infants exposed in utero to antiviral medications.

Prenatal HIV Transmission

Maternal HAART treatment along with intrapartum zidovudine prophylaxis has dramatically reduced the perinatal HIV transmission risk from approximately 25 percent to 2 percent or less. HAART during pregnancy was reported to be associated with a decreased incidence of placental villitis, which may partially account for the lower HIV transmission rate in treated women (Stewart, 2014a). Optimal management of labor is uncertain, but if labor is progressing with intact membranes, artificial rupture and invasive fetal monitoring are avoided. Labor augmentation is used when needed to shorten the interval to delivery to further decrease the transmission risk. Operative delivery with forceps or

vacuum extractor is avoided if possible. Postpartum hemorrhage is managed with oxytocin and prostaglandin analogues. Methergine and other ergot alkaloids adversely interact with reverse transcriptase and protease inhibitors to cause severe vasoconstriction.

Cesarean delivery has been recommended to decrease HIV prenatal transmission. An earlier metaanalysis of 15 prospective cohort studies by the International Perinatal HIV Group (1999) included 8533 mother-neonate pairs. Vertical HIV transmission was shown to be reduced by about half when cesarean was compared with vaginal delivery. When antiretroviral therapy was given in the prenatal, intrapartum, and neonatal periods along with cesarean delivery, the likelihood of neonatal transmission was reduced by 87 percent compared with vaginal delivery and without antiretroviral therapy. The European Mode of Delivery Collaboration (1999) has reported similar findings.

Based on these observations, the American College of Obstetricians and Gynecologists (2010b) concluded that scheduled cesarean delivery should be discussed and recommended for HIV-infected women whose HIV-1 RNA load exceeds 1000 copies/mL. Scheduled delivery is recommended at 38 weeks' gestation in these women. Although data are insufficient to estimate such benefits for women whose HIV RNA levels are < 1000 copies/mL, it is unlikely that scheduled cesarean delivery would confer additional risk reduction if the woman has been taking antiviral therapy (Jamieson, 2007; Read, 2005). If cesarean delivery is performed for obstetrical indications, it should be performed at 39 weeks with standard perioperative antimicrobials for prophylaxis. HIV-infected women undergoing a scheduled cesarean delivery should be given IV zidovudine as a loading dose followed by 2 more hours of continuous maintenance therapy—a total of 3 hours of infused zidovudine.

■ Breast Feeding

Vertical transmission is increased by breast feeding, and it generally is not recommended for HIV-positive women in the United States (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2012; Read, 2003). The probability of HIV transmission per liter of breast milk ingested is estimated to be similar in magnitude to heterosexual transmission with unsafe sex in adults (Richardson, 2003). As with other exposures, risk is related to the maternal HIV RNA level, HIV disease status, breast health, and duration of breast feeding (De Cock, 2000; John-Stewart, 2004). Most transmission occurs in the first 6 months, and as many as two thirds of infections in breast-fed infants are from breast milk. In the Petra Study Team (2002) from Africa, the prophylactic benefits of short-course perinatal antiviral regimens were diminished considerably by 18 months of age due to breast feeding. The World Health Organization (2010) has recommended exclusive breast feeding the first 6 months of life for infants of women living in developing countries in which infectious diseases and malnutrition are the primary causes of infant deaths. Breast feeding can be continued for 12 months until a nutritionally adequate diet is available.

■ Postpartum Management

Many otherwise healthy women with normal CD4⁺ T-cell counts and low HIV RNA levels may discontinue treatment after

delivery and be closely monitored according to adult guidelines. The exception is the woman who plans another pregnancy in the near future. Stewart and colleagues (2014b) showed that inter-pregnancy viral load suppression is associated with less vertical transmission in a subsequent pregnancy. Psychosocial support is essential during this time, especially while awaiting diagnostic testing for pediatric infection. Contraceptive needs are complex and also may entail condoms in discordantly infected couples. As discussed in Chapter 38 (p. 708), antiretroviral drugs may affect oral contraceptive hormone levels and possibly of injectable agents (Stuart, 2012). Intrauterine devices may be an acceptable choice in some women with normal immunocompetence and a low risk for STIs. The Centers for Disease Control and Prevention has recently revised the recommendations for the use of hormonal contraception among women at high risk for HIV infection or infected with HIV (Tepper, 2012). It reaffirmed prior recommendations that hormonal contraception use is safe for these women and that condom use should be encouraged regardless of contraceptive method.

Glomerular filtration rate (GFR) (mL/min)	106–132 ^d	131–166	135–170	117–182	19, 22, 50
Filtration fraction (%)	16.9–24.7 ^f	14.7–21.6	14.3–21.9	17.1–25.1	19, 22, 50
Osmolarity, urine (mOsm/kg)	500–800	326–975	278–1066	238–1034	61
24-hr albumin excretion (mg/24 hr)	< 30	5–15	4–18	3–22	27, 61
24-hr calcium excretion (mmol/24 hr)	< 7.5 ^e	1.6–5.2	0.3–6.9	0.8–4.2	66
24-hr creatinine clearance (mL/min)	91–130	69–140	55–136	50–166	22, 66
24-hr creatinine excretion (mmol/24 hr)	8.8–14 ^e	10.6–11.6	10.3–11.5	10.2–11.4	61
24-hr potassium excretion (mmol/24 hr)	25–100 ^e	17–33	10–38	11–35	66
24-hr protein excretion (mg/24 hr)	< 150	19–141	47–186	46–185	27
24-hr sodium excretion (mmol/24 hr)	100–260 ^e	53–215	34–213	37–149	17, 66

^aUnless otherwise specified, all normal reference values are from the seventeenth edition of *Harrison's Principles of Internal Medicine* (37).

^bRange includes references with and without iron supplementation.

^cReference values are from *Laboratory Reference Handbook*, Pathology Department, Parkland Hospital, 2005.

^dNormal reference range is specific range for females.

^eReference values are from the 15th edition of *Harrison's Principles of Internal Medicine* (12).

^fRange is for premenopausal females and varies by menstrual cycle phase.

^gReference values are from Cerneca et al: Coagulation and fibrinolysis changes in normal pregnancy increased levels of procoagulants and reduced levels of inhibitors during pregnancy induce a hypercoagulable state, combined with a reactive fibrinolysis (15).

^hReference values are from Cerneca et al and Choi et al: Tissue plasminogen activator levels change with plasma fibrinogen concentrations during pregnancy (15, 16).

ⁱReference values are from Mannucci et al: Changes in health and disease of the metalloprotease that cleaves von Willebrand factor (44A).

^jReference values are from Bacq et al: Liver function tests in normal pregnancy: a prospective study of 102 pregnant women and 102 matched controls (5).

^kReference values are from Leiserowitz et al: Creatine kinase and its MB isoenzyme in the third trimester and the peripartum period (41).

^lReference values are from Dunlop: Serial changes in renal haemodynamics during normal human pregnancy (19). Appendix courtesy of Dr. Mina Abbassi-Ghanavati and Dr. Laura G. Greer.

APPENDIX II. Maternal Echocardiographic Measurements

Left Ventricle	Pregnancy			Postpartum
	1st Trimester	2nd Trimester	3rd Trimester	
Geometry				
IVS _d (mm)	7.3 ± 1.0	7.4 ± 1.1	7.8 ± 1.2	7.1 ± 0.9
LVEDD (mm)	45–47.8	47–48.9	47–49.6	46–48.8
LVESD (mm)	28–30	29–30.1	30–30.8	28–30.6
PW _d	6.3 ± 0.7	6.6 ± 0.7	6.9 ± 1.0	6.1 ± 0.6
RWT	0.26–0.36	0.27–0.37	0.28–0.38	0.25–0.35
LV mass (g)	111–121	121–135	136–151	114–119
LV mass (g/m ²)	66 ± 13	70 ± 12	76 ± 16	67 ± 11
Systolic function				
FS (%)	37–38	76–78	80–85	67–69
SW thickening (%)	47 ± 17	53 ± 16	51 ± 15	54 ± 19
PW thickening (%)	66 ± 16	72 ± 16	74 ± 16	71 ± 14
VCFC (circ/sec)	1.15–0.3	1.18–0.16	1.18–0.12	1.18–0.12
ESS (g/cm ²)	59 ± 9	53 ± 11	52 ± 11	66 ± 12
Diastolic function				
Heart rate	75–76	76–78	80–85	67–69
Mitral E wave (m/sec)	0.85 ± 0.13	0.84 ± 0.16	0.77 ± 0.15	0.77 ± 0.11
Mitral A wave (m/sec)	0.5 ± 0.09	0.5 ± 0.1	0.55 ± 0.1	0.46 ± 0.1
Deceleration time (ms)	176 ± 44	188 ± 40	193 ± 33	201 ± 48
IVRT (ms)	90 ± 19	79 ± 18	72 ± 16	69 ± 10
E wave duration (ms)	263 ± 50	276 ± 43	282 ± 37	288 ± 48
E and A wave duration (ms)	454 ± 121	412 ± 79	375 ± 63	523 ± 88

Values are ranges or means ± SD.

Circ = circumference; d = diastolic; ESS = end-systolic wall stress; FS = fractional shortening; IVRT = isovolumic relaxation time; IVS_d = interventricular septum-diastole; LV = left ventricle; LVEDD = left ventricular end-diastolic dimension; LVESD = left ventricular end-systolic dimension; PW = posterior wall; RWT = relative wall thickening; SW = septal wall; VCFC = rate-adjusted mean velocity of circumferential fiber thickening.

Data from Savu (62A) and Vitarelli (71A).

APPENDIX III. Fetal Sonographic Measurements

TABLE III-1. Mean Gestational Sac Diameter and Crown-Rump Length and Corresponding Menstrual Age

Menstrual Age (day)	Menstrual Age (wk)	Gestational Sac Size (mm)	Crown-Rump Length (cm)
30	4.3

teratogenicity of, 246–247
- Antidepressant(s)
for mental disorders in pregnancy, 1208*t*
and oral contraceptives, interactions, 708*t*
- Antidigoxin antibody Fab (DIF), 763
- Anti-D immunoglobulin, 306, 309
administration of, 955
after delivery, 677
in alloimmunized pregnancy, 309
for Rh D alloimmunization, 311–312
in threatened abortion, 355
- Antiemetics, in hyperemesis gravidarum, 1072
- Antiepileptic monotherapy, first-trimester, 158*t*
- Antifungal agents, teratogenicity of, 247
- Anti-Fy^a, 307
- Antihistamine(s)
in dermatological disorders, 1217
in pemphigoid gestationis, 1216
and topical emollients, in pruritus, 1085
- Antihypertensive(s)
for chronic hypertension, 1005–1007
for gestational hypertension, 761–763
and oral contraceptives, interactions, 708*t*
in preeclampsia, 749
- Antiinflammatory agent(s)
leflunomide, 247–248
nonsteroidal antiinflammatory drugs, 247
and oral contraceptives, interactions, 708*t*
teratogenicity of, 247–248
- Antiinflammatory component, of pregnancy, 56
- Anti-Jk^k, 307
- Antiileukotrienes, for asthma, 1014
- Antimicrobial drug(s)
aminoglycosides, 248
for asymptomatic bacteriuria in pregnancy, 1053*t*
before cesarean delivery, 590
chloramphenicol, 248
nitrofurantoin, 248
pyelonephritis and, 1055
sulfonamides, 248
teratogenicity of, 248
tetracyclines, 248
- Antineoplastic agent(s)
cyclophosphamide, 248
methotrexate, 248–249
tamoxifen, 249
teratogenicity of, 248–249
trastuzumab, 249
- Antineutrophil cytoplasmic antibodies, 1149
- Antinuclear antibodies, 1170
- Antioxidants, in preeclampsia, 749
- Antiphospholipid antibodies, 259, 1174
and pregnancy, 1174
and thromboembolism, 1033
- Antiphospholipid antibody syndrome (APS), 259, 1173–1176
clinical features, 1173, 1173*t*
diagnosis, 1174
and fetal-growth restriction, 878–879
against natural anticoagulants, 1174
specific, 1173–1174
- Antiphospholipid syndrome, 1033
- Antipsychotics
for mental disorders in pregnancy, 1208*t*
teratogenicity of, 250, 251
- Antiretroviral drugs, classes of, 1280*t*
- Antiretroviral therapy, 1279
- Anti-ribonucleoprotein, 1172
- Antithrombin, 57, 1030
deficiency, 1030
heparin in, 1031
pregnancies outcomes in, 1030–1031
in pregnancy, 1030–1031
prevalence of, 1030
type I, 1030
type II, 1030
function of, 1030
- Antithrombin III, functional
in nonpregnant adult, 1288
in uncomplicated pregnancy, 1288
- Antithrombotic agents, in preeclampsia, 749
- Antiviral agents
recommendations for, 1281*t*
teratogenicity of, 249
- Antiviral medications, 1274
- Anxiety disorder(s), 1210
in pregnancy, 1210
treatment of, 1208*t*, 1210
- Aortic coarctation, 993–994
- Aortic dissection, 992–993
- Aortic insufficiency, 983
- Aortic stenosis, 983
- Aortic valvuloplasty, for critical aortic stenosis, 331
- Apgar scoring system, 627–628, 627*t*
low, and neurological impairment, 639, 642
- Aplastic anemia, 1106–1107
- Apnea, in neonates, 625
- Apolipoprotein A-I, normal laboratory values
in nonpregnant adult, 1291
in uncomplicated pregnancy, 1291
- Apolipoprotein B, normal laboratory values
in nonpregnant adult, 1291
in uncomplicated pregnancy, 1291
- Apolipoprotein H, 1173
- Aponeuroses, 16
- Appendiceal computed tomography, 1079
- Appendicitis, 1078–1080
computed tomography in, 1079
diagnosis of, 1079
incidence of, 1078–1079
laparoscopic surgery in pregnancy for, 1079
management of, 1079
MR imaging in, 1079, 1079*f*
postpartum, 1080
pregnancy outcomes, 1079–1080
sonography in, 1079
- Aquaporins, 410
- Aqueductal stenosis, 224*f*
- Arachnoiditis, spinal (subarachnoid) block and, 512
- Arcuate uterus (class VI), 41
- Argatroban, for heparin-induced thrombocytopenia, 1040
- Arginine vasopressin (AVP), 144
from fetal pituitary gland, 141
- Arias-Stella reaction, 49
- Aromatase deficiency of
and adult growth pattern, 110
fetal-placental, 110
- Arrest disorder, 459
- Arrest of descent
- Arrest of dilatation, 446
- Arrhythmia(s), 991–992
bradyarrhythmias, 991–992
cardiac, 481–482
medical therapy in, 321–323
bradyarrhythmias, 322–323
premature atrial contractions, 321
tachyarrhythmias, 321–322
prolonged QT-interval, 992
supraventricular tachycardias, 992
ventricular tachycardia, 992
- Arrhythmogenic right ventricular dysplasia, 990
- Arterial thromboembolism, rFVIIa use and, 817
- Arteriovenous malformations (AVMs), 1194
bleeding from, 1194
in pregnancy, 1194
treatment of, 1194
- Arteriovenous oxygen, maternal, 63
- Asherman syndrome, 258–259
- Ashkenazi Jewish descent
preconceptional counseling of, 161
recessive diseases in, 297
Tay-Sachs disease in, 296–297

- Aspartate aminotransferase (AST)
normal laboratory values
in nonpregnant adult, 1289
in uncomplicated pregnancy, 1289
- Asphyxia neonatorum, 638
- Aspiration, 519–520
fasting, 519–520
pathophysiology of, 520
treatment of, 520
- Aspirin
low-dose
plus heparin in preeclampsia, 749
for preeclampsia prevention, 749, 749*t*
and oral contraceptives, interactions, 708*t*
in thrombocytosis, 1115
- Assisted reproductive technology (ART), and
monozygotic twinning, 892
- Asthma, 1011–1015
acute, management of, 1015
chronic, management of, 1014–1015
clinical evaluation of, 1014
clinical stages of, 1012–1014, 1012*f*
environmental allergic stimulant and, 1012
fetal effects of drugs, 1014
fetal response to maternal hypoxemia, 1014
forced expiratory volume at 1 second in, 1014
and labor and delivery, 1015
pathophysiology of, 1012
pregnancy and, 1013–1014
effects of, 1013
outcomes of, 1013, 1014
severity classification, 1012*t*
treatment of
antileukotrienes for, 1014
cromones for, 1014
inhaled β -agonists for, 1014–1015
inhaled corticosteroids for, 1014–1015
stepwise approach to, 1014*f*
theophylline for, 1015
- Asymptomatic viral shedding, 1272
- Asynclitism, 439, 441*f*
anterior, 439, 441*f*
posterior, 439, 441*f*
- Atazanavir, 1280
- Atelectasis, and puerperal fever, 682
- Atopic eruption of pregnancy (AEP), 1216
- Atosiban, for preterm labor, 853
- Atrial flutter, 322*f*
- Atrial isomerism, 209
- Atrial natriuretic peptide (ANP), 422–423
normal laboratory values
in nonpregnant adult, 1291
in uncomplicated pregnancy, 1291
in phase 2 of parturition, 522–523
in preeclampsia, 739
- Atrial natriuretic peptide converting enzyme,
876
- Atrial septostomy, for hypoplastic left heart,
331
- Atrophy, of lower extremity, 1240*f*
- Atypical glandular cells of undetermined
significance (AGUS), 1221
- Autism spectrum disorders, 643
- Autoimmune adrenalitis, 1161
- Autoimmune hemolysis, 1104–1105
- Autoimmune hepatitis, 1092
- Autologous transfusion, 817
- Autonomic dysreflexia, 1198

 techniques used for, 364*t*
 trauma seldom and, 353
- First-trimester screening
 for Down syndrome, 289–290
 combined, 290
 nuchal translucency, 289–290
 serum analytes, 290
 unexplained abnormalities of, 290
- First-trimester sonography, 195–197
 fetal anomaly detection, 196–197, 197*t*
 indications for, 195*t*
 nuchal translucency, 196, 196*t*
- FISH. *See* Fluorescence in situ hybridization; Fluorescence in situ hybridization (FISH)
- Fish oil supplementation, for preeclampsia prevention, 749
- Flexible sigmoidoscopy, 1069
- Fluid attenuated inversion recovery (FLAIR), 223
- Fluid therapy, for acute respiratory distress syndrome, 945–946
- Fluorescence in situ hybridization (FISH), 276, 276*f*, 302, 665, 1148
 of microdeletion syndromes, 266*t*
- Fluorescence polarization assay, 655
- Fluoride, in pregnancy, 180
- Fluoroquinolones, for salmonellosis, 1254
- Flying foetus, 559
- Foam stability test, 655
- Focal nodular hyperplasia, 1094
- Focal seizures, 1189. *See also* Seizures
 causes of, 1189
 with dyscognitive features, 1189
 without dyscognitive features, 1189
- Folate
 red blood cell, normal laboratory values
 in nonpregnant adult, 1287
 in uncomplicated pregnancy, 1287
 serum, normal laboratory values
 in nonpregnant adult, 1287
 in uncomplicated pregnancy, 1287

- Folic acid
deficiency of. *See* Megaloblastic anemia
in inflammatory bowel disease, 1076, 1077
in pregnancy, 1104
- Folic acid metabolism, 245
- Follicle-stimulating hormone (FSH)
in ovarian cycle, 81–82, 82f
in ovarian-endometrial cycle, 81f
- Follicular development
controlled by transforming growth factor- β , 81
endocrine effects and, 83
- Fondaparinux, for heparin-induced
thrombocytopenia, 1040
- Forceps delivery, 574
blade application and delivery, 578–580,
579f–581f
classification of, 575, 576t
face presentation forceps delivery, 582–583
forceps design, 578
fenestrated/pseudofenestrated, 578, 578f
Kielland forceps, 578, 578f
Simpson/Elliott forceps, 578, 578f
Tucker-McLane forceps, 578, 578f
indications for, 574
maternal morbidity with, 575–576
for occiput posterior position, 580–582, 581f
for occiput transverse positions, 582
and pelvic floor disorders, 576
perinatal injuries with, 576
training for, 576–577
- Forebag
of amniotic fluid, 415
cervical dilatation during labor, 427f
- Founder effect, 294
- Fractures, newborn, 648
- Fragile X mental retardation 1 (FMR1) gene, 272
- Fragile X syndrome, 272–273
- Fragile X tremor ataxia syndrome (FXTAS), 273
- Fragmin. *See* Dalteparin
- Fraser syndrome, 208
- Fraternal twins. *See* Dizygotic twins
- Fresh-frozen plasma (FFP), 816t, 817

 prognosis for, 907
 staging system for, 907
- Two-Day method, 713
- Type 1 (insulin-dependent) diabetes, 1125
 etiological classification of, 1126 ϵ
 inheritance of, 1131
 maternal death, 1131
 preeclampsia with, 1131, 1131 f
 thyroid disorders with, 1147
- Type 2 (noninsulin-dependent) diabetes, 1125
 etiological classification of, 1126 ϵ
 inheritance of, 1131
- Typhoid fever, 1254
- Tyrosine kinase inhibitors, 1220
- Tysabri, in multiple sclerosis, 1196
- Ulipristal acetate, 715
- Ultrasound, 194
- Ultrasound Doppler principle, 474, 476 f
- Umbilical artery aneurysm, 124
- Umbilical artery Doppler velocimetry, 219–220, 220 f , 344
 in growth-restricted fetus evaluation, 881–882, 882 f
- Umbilical artery systolic-diastolic (S/D) ratio, 344
- Umbilical cord, 97 f , 100–101, 100 f
 abnormalities of, 121–124
 coiling, 121–122
 remnants and cysts, 122
 vascular, 124
 care of, 632–633
 development of, 100
 function of, 101
 funic presentation of, 124
 insertion of, 122–123
 furcate, 122–123
 velamentous, 122, 123 f
 length of, 121
 loops of, 124
 strictures of, 124
 structure of, 100
 true knots of, 123–124
 umbilical artery aneurysm, 124
 vessel number of, 122
 vessel thromboses, 124
- Umbilical cord clamping, 539
 delayed, 539
- Umbilical cord occlusion, in sheep fetus, 486 f
- Umbilical vein varix, 124
- Unfractionated heparin, in deep-vein thrombosis, 1037–1038, 1037 ϵ
- Unicornuate uterus (class II), 40–41
- Uniparental disomy, 273–274
 isodisomy, 274
 mechanism of, 273 f
- United States Medical Eligibility Criteria (US MEC), 695
- uNK cells. *See* Uterine natural killer (uNK) cells
- Upper extremity paralysis, breech presentation and, 561
- Upper gastrointestinal bleeding, 1074
- Upper gastrointestinal endoscopy, 1069
- Upper uterine segments, myometrium of, 412–413
- Urea nitrogen, normal laboratory values
 in nonpregnant adult, 1289
 in uncomplicated pregnancy, 1289
- Ureaplasma urealyticum*
 postpartum infection risk from, 683
 in preterm labor induction, 838–839
- Ureteral injury, cesarean delivery and, 588
- Ureteral obstruction, and oliguria, 1064, 1064 f
- Ureteropelvic junction obstruction, 215–216
- Ureteroscopy, during pregnancy, 1052
- Urethral diverticulum, 1064
- Urethritis, 1054
- Uric acid, normal laboratory values
 in nonpregnant adult, 1289
 in uncomplicated pregnancy, 1289
- Urinary bladder function, during first-stage labor, 451
- Urinary incontinence, operative vaginal delivery and, 576
- Urinary infections
 diaphragm use and, 713
 and puerperal fever, 682
- Urinary shunt placement, 330–331
- Urinary stress incontinence, 49
- Urinary system
 embryology of, 36–37
 physiology of, 63–66
 bladder, 66
 kidney, 63–65
 ureters, 65–66
- Urinary tract infections (UTI), 1052–1056
 acute pyelonephritis, 1054–1056
 asymptomatic bacteriuria, 1053–1054, 1054 ϵ
 causative organisms, 1052
 cystitis, 1054
 in puerperium, risk factors for, 1053
 reflux nephropathy, 1056
 urethritis, 1054
 vesicoureteral reflux and, 1056
- Urogenital sinus, 146 f
 types of, 36–37
- Ursodeoxycholic acid, in pruritus, 1085
- Uterine abnormalities, 40–42
 arcuate uterus (class VI), 41
 bicornuate uterus (class IV), 41
 septate uterus (class V), 41
 treatment with cerclage, 42
 unicornuate uterus (class II), 40–41
 uterine didelphys (class III), 41
- Uterine activation, in phase 2 of parturition, 423–424
- Uterine activity
 intrapartum surveillance of, 497–500
 Montevideo units concept for, 498
 normal, 499
 patterns of, 498–499
- Uterine artery Doppler velocimetry, 220–221, 345
 for preeclampsia prediction, 746–747
- Uterine artery ligation, 818–819, 818 f , 819 f
- Uterine atony
 after placental delivery, 784–785
 bimanual compression for, 786, 786 f
 evaluation and management of, 785
 hemorrhage with, 784–785
 high parity and, 785
 labor induction/augmentation and, 785
 and manual removal of placenta, 784, 784 f
 overdistended uterus and, 785
 postpartum hemorrhage from, 524
 primiparity and, 785
 risk factors for, 785
 surgical procedures to control hemorrhage from, 787
 uterotonic agents for, 785–786
 bleeding unresponsive to, 786–787
- Uterine cavity synechiae, B-Lynch sutures and, 819
- Uterine changes, during pregnancy, 168–169
- Uterine compression sutures, 818–819, 819 f
- Uterine contractility, 47
- Uterine contractions
 and cervical ripening, 410
 during first-stage labor, 450
 during labor, 412–413
 new terminology for, 499–500
 origin and propagation of, 499
