Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These were outlined by Spiegelberg (1878): (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the uteroovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically amid the placental tissue (Fig. 19-12). Risk factors are similar to those for tubal pregnancies, but ART or IUD failure seems to be disproportionately associated (Ko, 2012). Presenting complaints and findings mirror tubal ectopic pregnancy. Although the ovary can accommodate the expanding pregnancy more easily than the fallopian tube, rupture at an early stage is the usual consequence.

TVS use has resulted in a more frequent diagnosis of unruptured ovarian pregnancies. Sonographically, an internal anechoic area is surrounded by a wide echogenic ring, which in turn is surrounded by ovarian cortex (Comstock, 2005). In their review of 49 cases, Choi and associates (2011) noted that the diagnosis may not be made until surgery as many cases are presumed tubal ectopic pregnancy. Moreover, at surgery, an early ovarian pregnancy may be considered to be a hemorrhagic corpus luteum cyst or a bleeding corpus luteum.

Evidence-based management accrues mainly from case reports (Hassan, 2012; Scutiero, 2012). Classically, management for ovarian pregnancies has been surgical. Small lesions have been managed by ovarian wedge resection or cystectomy, whereas larger lesions require oophorectomy. Finally, systemic or locally injected methotrexate has been used successfully to treat small unruptured ovarian pregnancies (Pagidas, 2013). With conservative surgery or medical management, β -hCG levels should be monitored to exclude remnant trophoblast.

CERVICAL PREGNANCY

Diagnosis

This ectopic pregnancy is defined by cervical glands noted histologically opposite the placental attachment site and by part or all of the placenta found below the entrance of the uterine vessels or below the peritoneal reflection on the anterior uterus. In a typical case, the endocervix is eroded by trophoblast, and the pregnancy develops in the fibrous cervical wall. The more cephalad that the trophoblast is implanted along the cervical canal, the greater is its capacity to grow and hemorrhage. The incidence of cervical pregnancy lies between 1 in 8600 and 1 in 12,400 pregnancies, but the incidence is increasing as a result of ART (Ginsburg, 1994). Another risk according to Jeng and colleagues (2007) is previous dilation and curettage.

Painless vaginal bleeding is reported by 90 percent of women with a cervical pregnancy—a third of these have massive hemorrhage (Ushakov, 1997). As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus can be felt. Identification of cervical pregnancy is based on speculum examination, palpation, and TVS. Sonographic findings typical of cervical pregnancy are shown and described in Figure 19-13. MR imaging and 3-D sonography have also been used to confirm the diagnosis (Jung, 2001; Sherer, 2008).

Management

Cervical pregnancy may be treated medically or surgically. In many centers, including ours, methotrexate has become the first-line therapy in stable women, and administration follows protocols listed in Table 19-2 (Verma, 2011; Zakaria, 2011). The drug has also been injected directly into the gestational sac, alone or with systemic doses (Jeng, 2007; Kirk, 2006). Others describe methotrexate infusion combined

FIGURE 19-12 Ovarian pregnancy. **A.** Transvaginal sonogram shows a gestational sac containing fetal parts of a 16-week gestation. The placenta is marked by a red asterisk. **B.** Due to concern for extensive parasitic blood supply to the pregnancy, exploratory laparotomy was performed. Here, the right ovary is lifted by the surgeon, and the fallopian tube is the cordlike structure stretched across the top of the mass. Due to mass size and vascularity and scant normal ovarian stroma, this patient was treated by right salpingo-oophorectomy. (Photograph contributed by Dr. Kyler Elwell.)

FIGURE 19-13 Cervical pregnancy. Transvaginal sonographic findings may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix (black arrow); (3) absent intrauterine gestational tissue (white arrows); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. (Image contributed by Dr. Elysia Moschos.)

with uterine artery embolization (Xiaolin, 2010). With methotrexate regimens, resolution and uterine preservation are achieved for gestations < 12 weeks in 91 percent of cases (Kung, 1997). In selecting appropriate candidates, Hung and colleagues (1996) noted higher risks of systemic methotrexate treatment failure in those with a gestational age > 9 weeks, β -hCG levels > 10,000 mIU/mL, crown-rump length > 10 mm, and fetal cardiac activity. For this reason, many induce fetal death with intracardiac or intrathoracic injection of potassium chloride. With a single-dose intramuscular methotrexate protocol, a dose between 50 and 75 mg/m² BSA is typical. For women in whom fetal cardiac activity is detectable, a sonographically guided fetal intracardiac injection of 2 mL (2 mEq/mL) potassium chloride solution can be given (Verma, 2009). If β -hCG levels do not decline more than 15 percent after 1 week, a second dose of methotrexate can be given. Song and associates (2009) described management of 50 cases and observed that sonographic resolution lagged far behind serum β -hCG regression.

As an adjunct to medical or surgical therapy, uterine artery embolization has been described either as a response to bleeding or as a preprocedural preventive tool (Hirakawa, 2009; Nakao, 2008; Zakaria, 2011). The specifics of this interventional radiological technique are detailed in Chapter 41 (p. 820). Also in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect hemostasis by vessel tamponade and to monitor uterine drainage. The balloon remains inflated for 24 to 48 hours and is gradually decompressed over a few days (Ushakov, 1997).

Although conservative management is feasible for many women with cervical pregnancies, suction curettage or hysterectomy may be selected. Moreover, hysterectomy may be required with bleeding uncontrolled by conservative methods. Unfortunately, due to

the close proximity of the ureters to the ballooned cervix, urinary tract injury rates are of concern with hysterectomy.

Suction curettage may be especially favored in rare cases of a heterotopic pregnancy composed of a cervical and a desired uterine pregnancy (Moragianni, 2012). If cervical curettage is planned, intraoperative bleeding may be lessened by preoperative uterine artery embolization, by ligation of the descending branches of the uterine arteries, by vasopressin injection, or by a cerclage placed at the internal cervical os to compress feeding vessels (Davis, 2008; De La Vega, 2007; Trojano, 2009; Wang, 2011). Of these, cervical branches of the uterine artery can effectively be ligated with placement of hemostatic cervical sutures on the lateral aspects of the cervix at 3 and 9 o'clock. Cerclage placement is described in Chapter 18 (p. 361). Following curettage, a Foley balloon is placed to tamponade bleeding and is managed as described earlier.

CESAREAN SCAR PREGNANCY

This term describes implantation within the myometrium of a prior cesarean delivery scar. Its incidence approximates 1 in 2000 normal pregnancies and has increased alongside the cesarean delivery rate (Ash, 2007; Rotas, 2006). The pathogenesis of cesarean scar pregnancy (CSP) has been likened to that for placenta accreta and carries similar risk for serious hemorrhage (Timor-Tritsch, 2012a). It is unknown if the incidence increases with multiple cesarean deliveries or if it is affected by either one- or two-layer uterine incision closure.

Women with CSP usually present early, and pain and bleeding are common. However, up to 40 percent of women are asymptomatic, and the diagnosis is made during routine sonographic examination (Rotas, 2006). Rarely, early rupture can lead to an abdominal pregnancy (Teng, 2007).

Sonographically, differentiating between a cervicoisthmic intrauterine pregnancy and CSP can be difficult, and several investigators have described sonographic findings (Jurkovic, 2003; Moschos, 2008a). According to Godin (1997), there are four sonographic criteria that should be satisfied for the diagnosis, which are shown and described in Figure 19-14. Although TVS is the typical first-line imaging tool, MR imaging is useful when sonography is equivocal or inconclusive before intervention (Osborn, 2012).

Treatment standards are lacking, and several options are available. Hysterectomy is an acceptable initial choice in those desiring sterilization. It is sometimes a necessary option with heavy uncontrolled bleeding. Fertility-preserving options include systemic or locally injected methotrexate, either alone or combined with conservative surgery (Shen, 2012; Timor-Tritsch, 2012b; Yang, 2010). Surgeries include visually guided suction curettage or transvaginal aspiration, hysteroscopic removal, or isthmic excision. These are completed solely or more typically with adjunctive methotrexate (Michener, 2009; Seow, 2004, 2013; Timor-Tritsch, 2012a; Wang, 2009, 2012; Yang, 2009). Often uterine artery embolization is used preoperatively to minimize hemorrhage risk (Zhang, 2012; Zhuang, 2009).

FIGURE 19-14 Cesarean scar pregnancy. **A.** Transvaginal sonogram of a uterus with a cesarean scar pregnancy (CSP) in a sagittal plane. An empty uterine cavity is identified by a bright hyperechoic endometrial stripe (long, white arrow). An empty cervical canal is similarly identified (short, white arrow). Last, an intrauterine mass is seen in the anterior part of the uterine isthmus (red arrows). Healthy myometrium between the bladder and gestational sac is absent. (Image contributed by Dr. Elysia Moschos.) **B.** Hysterectomy specimen containing a cesarean scar pregnancy. **C.** This same hysterectomy specimen is transversely sectioned at the level of the uterine isthmus and through the gestational sac. The uterine body lies to the left, and the cervix is on the right. A metal probe is placed through the endocervical canal to show the eccentric development of this gestation. Only a thin layer of myometrium overlies this pregnancy, which pushes anteriorly through the uterine wall. (Photographs contributed by Drs. Sunil Balgobin, Manisha Sharma, Rebecca Stone.)

OTHER SITES OF ECTOPIC PREGNANCY

Ectopic placental implantations in less expected sites have been described in case reports and include the omentum, spleen, liver, and retroperitoneum, among others (Chin, 2010; Chopra, 2009; Gang, 2010; Martínez-Varea, 2011). Also, intramural uterine implantations at sites other than a cesarean scar have been noted in women with prior uterine surgeries, ART, or adenomyosis (Memtsa, 2013; Wu, 2013). Although laparotomy is preferred by many for these ectopic sites, laparoscopic excision in hemodynamically stable patients by those with suitable skills is gaining acceptance.

CHAPTER 20

Gestational Trophoblastic Disease

HYDATIDIFORM MOLE—MOLAR PREGNANCY 396

PATHOGENESIS 397

DIAGNOSIS 399

MANAGEMENT 400

GESTATIONAL TROPHOBLASTIC NEOPLASIA 401

DIAGNOSIS, STAGING, AND PROGNOSTIC SCORING . . . 402

TREATMENT 403

SUBSEQUENT PREGNANCY 404

Gestational trophoblastic disease (GTD) is the term used to encompass a group of tumors typified by abnormal trophoblast proliferation. Trophoblast produce human chorionic gonadotropin (hCG), thus the measurement of this peptide hormone in serum is essential for GTD diagnosis, management, and surveillance. GTD histologically is divided into *hydatidiform moles*, which are characterized by the presence of villi, and non-molar trophoblastic neoplasms, which lack villi.

Hydatidiform moles are excessively edematous immature placentas (Benirschke, 2012). These include the benign *complete hydatidiform mole* and *partial hydatidiform mole* and the malignant *invasive mole*. Invasive mole is deemed malignant due to its marked penetration into and destruction of the myometrium as well as its ability to metastasize.

Nonmolar trophoblastic neoplasms include choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These three are differentiated by the type of trophoblast they contain.

The malignant forms of gestational trophoblastic disease are termed *gestational trophoblastic neoplasia (GTN)*. These include invasive mole, choriocarcinoma, placental site trophoblastic

tumor, and epithelioid trophoblastic tumor. Other terms applied to GTN are *malignant gestational trophoblastic disease* and *persistent gestational trophoblastic disease*. These malignancies develop weeks or years following any type of pregnancy, but frequently occur after a hydatidiform mole.

Each of the GTN tumor types is histologically distinct and varies in its propensity to invade and metastasize. However, histological confirmation is typically not available. Instead, measurement of serum hCG levels combined with clinical findings—rather than a histological specimen—is used to diagnose and treat this malignancy. Accordingly, GTN is often identified and effectively treated as a group.

In the past, these metastatic tumors had a prohibitively high mortality rate. However, with chemotherapy, currently most tumors are highly curable (Goldstein, 2010). Early-stage GTN is typically cured with single-agent chemotherapy, whereas later-stage disease usually responds to combination chemotherapy.

HYDATIDIFORM MOLE—MOLAR PREGNANCY

The classic histological findings of molar pregnancy include villous stromal edema and trophoblast proliferation (Fig. 20-1). The degree of histological changes, karyotypic differences, and the absence or presence of embryonic elements are used to classify them as either *complete* or *partial moles*. These two also vary in associated risks for developing medical comorbidities and postevacuation GTN. Of the two, GTN more frequently follows complete hydatidiform mole.

A complete mole has abnormal chorionic villi that grossly appear as a mass of clear vesicles. These vary in size and often hang in clusters from thin pedicles. In contrast, a partial molar pregnancy has focal and less advanced hydatidiform changes and contains some fetal tissue. Although both forms of moles usually fill the uterine cavity, they rarely may be tubal or other forms of ectopic pregnancy (Sebire, 2005).

FIGURE 20-1 Complete hydatidiform mole. **A.** Gross specimen with characteristic vesicles of variable size. (Image contributed by Dr. Brian Levenson.) **B.** Low-magnification photomicrograph shows generalized edema and cistern formation (*black asterisks*) within avascular villi. Haphazard trophoblastic hyperplasia is marked by a yellow asterisk on the right. (Image contributed by Dr. Erika Fong.)

Epidemiology and Risk Factors

There is an ethnic predisposition to hydatidiform mole, which has increased prevalence in Asians, Hispanics, and American Indians (Drake, 2006; Lee, 2011; Smith, 2006). The incidence in the United States and Europe has been relatively constant at 1 to 2 per 1000 deliveries (Lee, 2011; Lybol, 2011; Salehi, 2011).

The strongest risk factors are age and a history of prior hydatidiform mole. Women at both extremes of reproductive age are most vulnerable. Specifically, adolescents and women aged 36 to 40 years have a twofold risk, but those older than 40 have an almost tenfold risk (Altman, 2008; Sebire, 2002a). For those with a prior complete mole, the risk of another mole

is 1.5 percent. With a previous partial mole, the rate is 2.7 percent (Garrett, 2008). After two prior molar pregnancies, Berkowitz and associates (1998) reported that 23 percent of women had a third mole.

Pathogenesis

With rare exceptions, molar pregnancies arise from chromosomally abnormal fertilizations. Complete moles most often have a diploid chromosomal composition ([Table 20-1](#)). These usually are 46,XX and result from *androgenesis*, meaning both sets of chromosomes are paternal in origin. As shown in [Figure 20-2A](#), an ovum is fertilized by a haploid sperm, which

TABLE 20-1. Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype^a	69,XXX or 69,XXY	46,XX
Clinical Presentation		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	Large for dates
Theca-lutein cysts	Rare	25–30% of cases
Initial hCG levels	< 100,000 mIU/mL	> 100,000 mIU/mL
Medical complications ^b	Rare	Uncommon
Rate of subsequent GTN	1–5% of cases	15–20% of cases
Pathology		
Embryo-fetus	Often present	Absent
Amnion, fetal erythrocytes	Often present	Absent
Villous edema	Focal	Widespread
Trophoblastic proliferation	Focal, slight to moderate	Slight to severe
Trophoblast atypia	Mild	Marked
p57 ^{KIP2} immunostaining	Positive	Negative

^aTypical karyotypes.

^bThese include anemia, hyperthyroidism, hyperemesis gravidarum, preeclampsia, and infection.

GTN = gestational trophoblastic neoplasia; hCG = human chorionic gonadotropin.

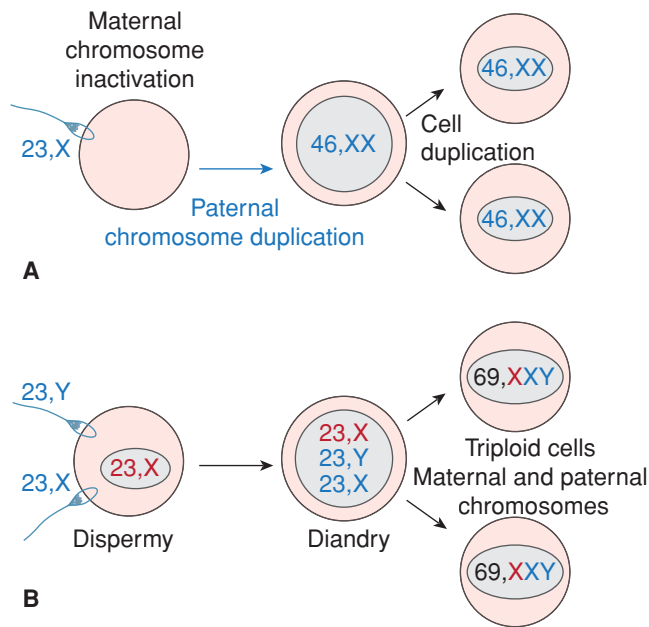

FIGURE 20-2 Typical pathogenesis of complete and partial moles. **A.** A 46,XX complete mole may be formed if a 23,X-bearing haploid sperm penetrates a 23,X-containing haploid egg whose genes have been “inactivated.” Paternal chromosomes then duplicate to create a 46,XX diploid complement solely of paternal origin. **B.** A partial mole may be formed if two sperm—either 23,X- or 23,Y-bearing—both fertilize (*dispermy*) a 23,X-containing haploid egg whose genes have not been inactivated. The resulting fertilized egg is triploid with two chromosome sets being donated by the father (*diandry*).

then duplicates its own chromosomes after meiosis. The chromosomes of the ovum are either absent or inactivated. Less commonly, the chromosomal pattern may be 46,XY or 46,XX and due to fertilization by two sperm, that is, *dispermic fertilization* or *dispermy* (Lawler, 1991; Lipata, 2010).

Partial moles usually have a triploid karyotype—69,XXX, 69,XXY—or much less commonly, 69,XYY. These are each composed of two paternal haploid sets of chromosomes contributed by dispermy and one maternal haploid set (see Fig. 20-2B). Less frequently, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm. These triploid zygotes result in some embryonic development, however, it ultimately is a lethal fetal condition. Fetuses that reach advanced ages have severe growth restriction, multiple congenital anomalies, or both.

Twin Pregnancy Comprised of a Normal Fetus and Coexistent Complete Mole

Rarely, in some twin pregnancies, one chromosomally normal fetus is paired with a complete diploid molar pregnancy. These are recognized in only 1 in 22,000 to 100,000 pregnancies (Steller, 1994). It is important that these cases be distinguished from a single partial molar pregnancy with its abnormal associated fetus. Amniocentesis done for fetal karyotyping is used to confirm the diagnosis.

There are a number of unique pregnancy complications with this twin pregnancy. And, many women may choose

to terminate the pregnancy, if diagnosed early. In those with continuing pregnancy, survival of the normal fetus is variable and dependent on complications that commonly develop from the molar component. The most worrisome are preeclampsia or hemorrhage, which frequently necessitate preterm delivery. Wee and Jauniaux (2005) reviewed outcomes in 174 women of whom 82 chose termination. Of the remaining 92 pregnancies, 42 percent either miscarried or had a perinatal death; approximately 60 percent delivered preterm; and only 40 percent delivered at term.

Another concern for those continuing their pregnancy is the possible risk for developing subsequent GTN. Sebire and colleagues (2002b) reviewed such twin pregnancies and reported that in those not terminated, 21 percent of mothers subsequently required chemotherapy. But, this was not significantly different from a rate of 16 percent among women who chose termination. Others have reported rates up to 50 percent following continuation (Massardier, 2009). At this time, most data indicate that women with these twin pregnancies are not at greater risk for subsequent neoplasia than those with a singleton complete mole (Niemann, 2007b). Postdelivery surveillance is conducted as for any molar pregnancy and is discussed on page 401.

Clinical Findings

The clinical presentation of women with a molar pregnancy has changed remarkably over the past several decades because prenatal care is sought much earlier and because sonography is virtually universal. As a result, most molar pregnancies are detected when they are small and before complications ensue (Kerkmeijer, 2009; Mangili, 2008).

Typically, there are usually 1 to 2 months of amenorrhea before discovery. In 41 women with a complete mole diagnosed at a mean of 10 weeks, Gerner and colleagues (2000) reported that 41 percent were asymptomatic and 58 percent had vaginal bleeding. Moreover, only 2 percent had anemia or hyperemesis, and none had other manifestations that in the past were common in these women.

As gestation advances, symptoms generally tend to be more pronounced with complete compared with partial moles (Niemann, 2007a). Untreated molar pregnancies will almost always cause uterine bleeding that varies from spotting to profuse hemorrhage. Bleeding may presage spontaneous molar abortion, but more often, it follows an intermittent course for weeks to months. In more advanced moles with considerable concealed uterine hemorrhage, moderate iron-deficiency anemia develops. Many women have uterine growth that is more rapid than expected. The enlarged uterus has a soft consistency, but typically no fetal heart motion is detected. Nausea and vomiting may become significant. The ovaries contain multiple theca-lutein cysts in 25 to 60 percent of women with a complete mole (Fig. 20-3). These likely result from overstimulation of lutein elements by sometimes massive amounts of hCG. Because theca-lutein cysts regress following pregnancy evacuation, expectant management is preferred. Occasionally a larger cyst may undergo torsion, infarction, and hemorrhage. However, oophorectomy is not performed unless there is extensive infarction that persists after untwisting.

FIGURE 20-3 Sonographic image of an ovary with theca-lutein cysts in a woman with a hydatidiform mole.

The thyrotropin-like effects of hCG frequently cause serum free thyroxine (fT_4) levels to be elevated and thyroid-stimulating hormone (TSH) levels to be decreased. Despite this, clinically apparent thyrotoxicosis is unusual and, in our experience, can be mimicked by bleeding and sepsis from infected products. Moreover, the serum free T_4 levels rapidly normalize after uterine evacuation. Despite this, a case of presumed “thyroid storm” has been reported (Moskovitz, 2010).

Severe preeclampsia and eclampsia are relatively common with large molar pregnancies. However, these are seldom seen today because of early diagnosis and evacuation. An exception is in the case of a normal fetus coexisting with a complete mole, described earlier. In those cases in which pregnancy is not terminated, severe preeclampsia frequently mandates preterm delivery. The predilection for preeclampsia is explained by the hypoxic trophoblastic mass, which releases

antiangiogenic factors that activate endothelial damage (Chap. 40, p. 733).

Diagnosis

Most women initially have amenorrhea that is followed by irregular bleeding that almost always prompts pregnancy testing and sonography. Some women will present with spontaneous passage of molar tissue.

Serum β -hCG Measurements

With a complete molar pregnancy, serum β -hCG levels are commonly elevated above those expected for gestational age. With more advanced moles, values in the millions are not unusual. Importantly, these high values can lead to erroneous false-negative *urine* pregnancy test results because of oversaturation of the test assay by excessive β -hCG hormone (Chap. 9, p. 169). In these cases, *serum* β -hCG determinations with or without sample dilution will clarify the conundrum. With a partial mole, β -hCG levels may also be significantly elevated, but more commonly concentrations fall into ranges expected for gestational age.

Sonography

Although sonographic imaging is the mainstay of trophoblastic disease diagnosis, not all cases are confirmed initially. Sonographically, a complete mole appears as an echogenic uterine mass with numerous anechoic cystic spaces but without a fetus or amniotic sac. The appearance is often described as a “snowstorm” (Figure 20-4). A partial mole has features that include a thickened, multicystic placenta along with a fetus or at least fetal tissue. In early pregnancy, however, these sonographic characteristics are seen in fewer than half of hydatidiform moles (Fowler, 2006). The most common misdiagnosis is incomplete or missed abortion. Occasionally, molar pregnancy may be confused for a multifetal pregnancy or a uterine leiomyoma with cystic degeneration.

FIGURE 20-4 Sonograms of hydatidiform moles. **A.** Sagittal view of a uterus with a complete hydatidiform mole. The characteristic “snowstorm” appearance is due to an echogenic uterine mass that has numerous anechoic cystic spaces. Notably, a fetus and amniotic sac are absent. **B.** In this image of a partial hydatidiform mole, the fetus is seen above a multicystic placenta. (Image contributed by Dr. Elysia Moschos.)

Pathological Diagnosis

Surveillance for subsequent neoplasia following molar pregnancy is crucial. Thus, moles must be histologically distinguished from other types of pregnancy failure that have hydropic placental degeneration, which can mimic molar villous changes. Some distinguishing histological characteristics are shown in Table 20-1.

In pregnancies before 10 weeks, classic molar changes may not be apparent because villi may not be enlarged and molar stroma may not yet be edematous and avascular (Paradinas, 1996). In such situations, other techniques are used to differentiate. One takes advantage of the differing ploidy to distinguish partial (triploid) moles from diploid entities. Complete moles and nonmolar pregnancies with hydropic placental degeneration are both diploid.

Another technique involves histological immunostaining to identify the p57^{KIP2} nuclear protein. Because the gene that expresses p57^{KIP2} is paternally imprinted, only maternally donated genes are expressed. Because complete moles contain only paternal genetic material, they cannot express this gene; do not produce p57^{KIP2}; and thus, do not pick up this immunostain. In contrast, this nuclear protein is strongly expressed in partial moles and in nonmolar pregnancies with hydropic change (Castrillon, 2001). As a result, the combined use of ploidy analysis and p57^{KIP2} immunostaining can be used to differentiate: (1) a complete mole (diploid/p57^{KIP2}-negative), (2) a partial mole (triploid/p57^{KIP2}-positive), and spontaneous

abortion with hydropic placental degeneration (diploid/p57^{KIP2}-positive) (Merchant, 2005).

Management

Maternal deaths from molar pregnancies are rare because of early diagnosis, timely evacuation, and vigilant postevacuation surveillance for GTN. Preoperative evaluation attempts to identify known potential complications such as preeclampsia, hyperthyroidism, anemia, electrolyte depletions from hyperemesis, and metastatic disease (Table 20-2) (Lurain, 2010). Most recommend chest x-ray, whereas computed tomography (CT) and magnetic resonance (MR) imaging are not routinely done unless the chest radiograph shows lung lesions or unless there is evidence of other extrauterine disease such as in the brain or liver.

Termination of Molar Pregnancy

Regardless of uterine size, molar evacuation by suction curettage is usually the preferred treatment. Preoperative cervical dilatation with an osmotic agent is recommended if the cervix is minimally dilated. Intraoperative bleeding can be greater with molar pregnancy than with a comparably sized uterus containing nonmolar products. Thus with large moles, adequate anesthesia, sufficient intravenous access, and blood-banking support is imperative. The cervix is mechanically dilated to allow insertion of a 10- to 14-mm suction curette. As evacuation is begun, oxytocin is infused to limit bleeding. Intraoperative sonography is recommended to

TABLE 20-2. Some Considerations for Management of Hydatidiform Mole

Preoperative
Laboratory
Hemogram; serum β -hCG, creatinine, and hepatic aminotransferase levels
TSH, free T ₄ levels
Type and Rh; group and screen or crossmatch
Chest radiograph
Consider hygroscopic dilators
Intraoperative
Large-bore intravenous catheter(s)
Regional or general anesthesia
Oxytocin (Pitocin): 20 units in 1000 mL RL for continuous infusion
One or more other uterotonic agents may be added as needed:
Methylergonovine (Methergine): 0.2 mg = 1 mL = 1 ampule IM every 2 hr prn
Carboprost tromethamine (PGF _{2α}) (Hemabate): 250 μ g = 1 mL = 1 ampule IM every 15–90 min prn
Misoprostol (PGE ₁) (Cytotec): 200 mg tablets for rectal administration, 800–1000 mg once
Karman cannula—size 10 or 12
Consider sonography machine
Postevacuation
Anti-D immune globulin (Rhogam) if Rh D-negative
Initiate effective contraception ^a
Review pathology report
Serum hCG levels: within 48 hours of evacuation, weekly until undetectable, then monthly for 6 months

^aIntrauterine devices are not suitable during surveillance.
GTN = gestational trophoblastic neoplasia; hCG = human chorionic gonadotropin; IM = intramuscular; PG = prostaglandin; RL = Ringer lactate; T₄ = thyroxine; TSH = thyroid-stimulating hormone.

help ensure that the uterine cavity has been emptied. When the myometrium has contracted, thorough but gentle curettage with a sharp large-loop Sims curette is performed. If bleeding continues despite uterine evacuation and oxytocin infusion, other uterotonics shown in Table 20-2 are given. In some cases, pelvic arterial embolization or hysterectomy may be necessary (Tse, 2007). Profuse hemorrhage and surgical methods that may be useful for its management are discussed in Chapter 41 (p. 818).

It is invariable that some degree of trophoblastic deportation into the pelvic venous system takes place during molar evacuation (Hankins, 1987). With large molar pregnancies, the volume of tissue may be sufficient to produce clinically apparent respiratory insufficiency, pulmonary edema, or even embolism. In our earlier experiences with very large moles, these and their chest x-ray manifestations clear rapidly without specific treatment. However, fatalities have been described (Delmis, 2000). Because of deportation, there is concern that trophoblastic tissue will thrive within the lung parenchyma to cause persistent disease or even overt malignancy. Fortunately, there is no evidence that this is a major problem.

Following curettage, anti-D immunoglobulin (Rhogam) is given to Rh D-negative women because fetal tissues with a partial mole may include red cells with D-antigen (Chap. 15, p. 311). Those with suspected complete mole are similarly treated because a definitive diagnosis of complete versus partial mole may not be confirmed until pathological evaluation of the evacuated products.

Following evacuation, the long-term prognosis for women with a hydatidiform mole is not improved with prophylactic chemotherapy (Goldstein, 1995). Moreover, chemotherapy toxicity—including death—may be significant, and thus it is not recommended routinely by the American College of Obstetricians and Gynecologists (2012).

Methods other than suction curettage may be considered for select cases. Hysterectomy with ovarian preservation may be preferable for women who have completed childbearing. Of women aged 40 and older, approximately a third will subsequently develop GTN, and hysterectomy markedly reduces this likelihood (Hanna, 2010). Theca-lutein cysts seen at the time of hysterectomy do not require removal, and they spontaneously regress following molar termination. Some recommend aspiration of larger cysts to minimize pain and torsion risk. In contrast, labor induction or hysterotomy is seldom used for molar evacuation in the United States. Both will likely increase blood loss and theoretically may increase the incidence of persistent trophoblastic disease (American College of Obstetricians and Gynecologists, 2012).

Postevacuation Surveillance

Close biochemical surveillance for persistent gestational neoplasia should follow hydatidiform mole evacuation. Concurrently, reliable contraception is imperative to avoid confusion caused by rising β -hCG levels from a new pregnancy. Most recommend either combination hormonal contraception or injectable medroxyprogesterone acetate. The latter is particularly useful if there is poor compliance. Intrauterine devices are not used until β -hCG levels are undetectable because of the risk of uterine perforation if there is an invasive mole. Finally, barrier and

other methods are not recommended because of their relatively high failure rates.

Biochemical surveillance is by serial measurements of serum β -hCG to detect persistent or renewed trophoblastic proliferation. The initial β -hCG level is obtained within 48 hours after evacuation. This serves as the baseline, which is compared with β -hCG quantification done thereafter every 1 to 2 weeks until levels progressively decline to become undetectable.

The median time for such resolution is 7 weeks for partial moles and 9 weeks for complete moles. Once β -hCG is undetectable, this is confirmed with monthly determinations for another 6 months. After this, surveillance is discontinued and pregnancy allowed. Because such intensive monitoring has a high noncompliance rate, a truncated approach has been studied, and it may be unnecessary to verify undetectable β -hCG levels for 6 months. Specifically, it was shown that no woman with a partial or complete mole whose serum β -hCG level became undetectable subsequently developed neoplasia (Lavie, 2005; Wolfberg, 2004). Importantly, during the time during which β -hCG levels are monitored, either increasing or persistently plateaued levels mandate evaluation for trophoblastic neoplasia. If the woman has not become pregnant, then these levels signify increasing trophoblastic proliferation that is most likely malignant.

There are a number of risk factors for developing trophoblastic neoplasia following molar evacuation. Most important, complete moles have a 15 to 20 percent incidence of malignant sequelae, compared with 1 to 5 percent following partial moles. Surprisingly, with much earlier recognition and evacuation of molar pregnancies, the risk for neoplasia has not been lowered (Schorge, 2000). Other risk factors are older age, β -hCG levels $> 100,000$ mIU/mL, uterine size that is large-for-gestational age, theca-lutein cysts > 6 cm, and slow decline in β -hCG levels (Berkowitz, 2009; Kang, 2012; Wolfberg, 2005). Although not routine, postevacuation uterine sonographic surveillance showing myometrial nodules or hypervascularity may be a predictor of subsequent neoplasia (Garavaglia, 2009).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This group includes invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These tumors almost always develop with or follow some form of recognized pregnancy. Half follow hydatidiform mole, a fourth follow miscarriage or tubal pregnancy, and another fourth develop after a preterm or term pregnancy (Goldstein, 2012). Although these four tumor types are histologically distinct, they are usually diagnosed solely by persistently elevated serum β -hCG levels because tissue is frequently not available for pathological study. Criteria for the diagnosis of postmolar gestational trophoblastic neoplasia are shown in Table 20-3.

Clinical Findings

These placental tumors are characterized clinically by their aggressive invasion into the myometrium and propensity to metastasize. The most common finding with gestational trophoblastic neoplasms is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or

TABLE 20-3. Criteria for Diagnosis of Gestational Trophoblastic Neoplasia

1. Plateau of serum β -hCG level (\pm 10 percent) for four measurements during a period of 3 weeks or longer—days 1, 7, 14, 21
2. Rise of serum β -hCG level > 10 percent during three weekly consecutive measurements or longer, during a period of 2 weeks or more—days 1, 7, 14
3. Serum β -hCG level remains detectable for 6 months or more
4. Histological criteria for choriocarcinoma

intermittent, with sudden and sometimes massive hemorrhage. Myometrial perforation from trophoblastic growth may cause intraperitoneal hemorrhage. In some women, lower genital tract metastases are evident, whereas in others there are only distant metastases with no trace of a uterine tumor.

■ Diagnosis, Staging, and Prognostic Scoring

Consideration for the possibility of gestational trophoblastic neoplasia is the most important factor in its recognition. Unusually persistent bleeding after any type of pregnancy should prompt measurement of serum β -hCG levels and consideration for diagnostic curettage. Uterine size is assessed along with careful examination for lower genital tract metastases, which usually appear as bluish vascular masses (Cagayan, 2010). Tissue diagnosis is unnecessary, thus biopsy is not required and may cause significant bleeding.

Once the diagnosis is verified, in addition to a baseline serum β -hCG level and hemogram, a search for local disease and metastases includes tests of liver and renal function, transvaginal sonography, chest CT scan or radiograph, and brain and abdominal/pelvic CT scan or MR imaging. Less commonly, positron-emission tomographic (PET) scanning and cerebrospinal fluid

β -hCG level determination are used to identify metastases (Lurain, 2011).

Gestational trophoblastic neoplasia is staged clinically using the system of the International Federation of Gynecology and Obstetrics (FIGO) (2009). This includes a modification of the World Health Organization (1983) prognostic index score, with which scores of 0 to 4 are given for each of the categories shown in Table 20-4. Women with WHO scores of 0 to 6 are considered to have low-risk disease, whereas those with a score \geq 7 are considered in the high-risk group.

■ Histological Classification

Again, it is stressed that the diagnosis of trophoblastic neoplasias is usually made by persistently elevated serum β -hCG levels without confirmation by pathological tissue study. Clinical staging is arrived at without regard for histological findings, even if available. Still, there are distinct histological types that are described next.

Invasive Mole

These are the most common trophoblastic neoplasms that follow hydatidiform moles, and almost all invasive moles arise

TABLE 20-4. International Federation of Gynecology and Obstetrics (FIGO) Staging and Diagnostic Scoring System for Gestational Trophoblastic Neoplasia

Anatomical Staging				
Stage I	Disease confined to the uterus			
Stage II	GTN extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)			
Stage III	GTN extends to the lungs, with or without known genital tract involvement			
Stage IV	All other metastatic sites			
Modified World Health Organization (WHO) Prognostic Scoring System ^a				
Scores ^b	0	1	2	4
Age (years)	< 40	≥ 40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval after index pregnancy (mo)	< 4	4–6	7–12	> 12
Pretreatment serum β-hCG (mIU/mL)	< 10 ³	10 ³ to 10 ⁴	10 ⁴ to 10 ⁵	≥ 10 ⁵
Largest tumor size (including uterus)	< 3 cm	3–4 cm	≥ 5 cm	—
Site of metastases	—	Spleen, kidney	GI	Liver, brain
Number of metastases	—	1–4	5–8	> 8
Previous failed chemotherapy drugs	—	—	1	≥ 2

^aAdapted by FIGO.

^bLow risk = WHO score of 0 to 6; high risk = WHO score of \geq 7.

from partial or complete moles (Sebire, 2005). Previously known as *chorioadenoma destruens*, invasive mole is characterized by extensive tissue invasion by trophoblast and whole villi. There is penetration deep into the myometrium, sometimes with involvement of the peritoneum, adjacent parametrium, or vaginal vault. Although locally aggressive, invasive moles are less prone to metastasize such as with choriocarcinoma.

Gestational Choriocarcinoma

This is the most common type of trophoblastic neoplasm to follow a term pregnancy or a miscarriage, and only a third of cases follow a molar gestation (Soper, 2006). Choriocarcinoma is composed of cells reminiscent of early cytotrophoblast and syncytiotrophoblast, however, it contains no villi. This rapidly growing tumor invades both myometrium and blood vessels to create hemorrhage and necrosis. Myometrial tumor may spread outward and become visible on the uterine surface as dark, irregular nodules. Metastases often develop early and are generally blood-borne (Fig. 20-5). The most common sites are the lungs and vagina, but tumor may be metastatic to the vulva, kidneys, liver, ovaries, brain, and bowel. Choriocarcinomas are commonly accompanied by ovarian theca-lutein cysts.

FIGURE 20-5 Metastatic choriocarcinoma. **A.** Chest radiograph demonstrates widespread metastatic lesions. **B.** Autopsy specimen with multiple hemorrhagic hepatic metastases. (Images contributed by Dr. Michael Conner.)

Placental Site Trophoblastic Tumor (PSST)

This uncommon tumor arises from implantation site-intermediate trophoblast. These tumors have associated serum β -hCG levels that may be only modestly elevated, but they produce variant forms of hCG, and identification of a high proportion of free β -hCG (> 30 percent) is considered diagnostic. Treatment of placental site trophoblastic tumor by hysterectomy is preferred because these locally invasive tumors are usually resistant to chemotherapy (Baergen, 2006). For higher-risk stage I and for later stages, adjuvant multidrug chemotherapy is also given (Schmid, 2009).

Epithelioid Trophoblastic Tumor

This rare tumor develops from chorionic-type intermediate trophoblast. Grossly, the tumor grows in a nodular fashion. Primary treatment is hysterectomy because this tumor is relatively resistant to chemotherapy. Approximately a fourth of women with this neoplasm will have metastatic disease, and they are given combination chemotherapy (Morgan, 2008).

Treatment

Women with gestational trophoblastic neoplasia are best managed by oncologists. Chemotherapy is usually the primary treatment, and repeat evacuation is not recommended by most because of risks for uterine perforation, bleeding, infection, or intrauterine adhesion formation. In a few, suction curettage may be necessary if there is bleeding or a substantial amount of retained molar tissue. Although controversial, some also consider a second uterine evacuation to be an initial therapeutic option in some cases of GTN following molar evacuation in an effort to avoid or minimize chemotherapy (Pezeshki, 2004; van Trommel, 2005). Moreover, in specific cases, hysterectomy may be primary or adjuvant treatment (Clark, 2010).

Single-agent chemotherapy protocols are usually sufficient for nonmetastatic or low-risk metastatic neoplasia (Horowitz, 2009). In their review of 108 women with low-risk disease, Abrão and colleagues (2008) reported that monotherapy protocols with either methotrexate or actinomycin D were equally effective compared with a regimen containing both. In general, methotrexate is less toxic than actinomycin D (Chan, 2006; Seckl, 2010). Regimens are repeated until serum β -hCG levels are undetectable.

Combination chemotherapy is given for high-risk disease, and reported cure rates approximate 90 percent (Lurain, 2010). A number of regimens have been used with success. One is *EMA-CO*, which includes *etoposide*, *methotrexate*, *actinomycin D*, *cyclophosphamide*, and *oncovin* (vincristine). Adjuvant surgical and radiotherapy may also be employed (Hanna, 2010).

With either low- or high-risk disease, once serum β -hCG levels are undetectable, serosurveillance is continued for 1 year. During this time, effective contraception is crucial to avoid any teratogenic effects of chemotherapy to the fetus as well as to mitigate confusion from rising β -hCG levels caused by superimposed pregnancy.

A small number of women during surveillance, despite no evidence of metastases, will be found to have very low β -hCG

levels that plateau. This phenomenon is referred to as quiescent hCG and presumably is caused by dormant trophoblast. Close observation without therapy is recommended, and 20 percent will eventually have recurrent active and progressive trophoblastic neoplasia (Khanlian, 2003).

SUBSEQUENT PREGNANCY

Women with prior gestational trophoblastic disease or successfully treated neoplasia usually do not have impaired fertility, and their pregnancy outcomes are usually normal (Tse, 2012). The primary concern in these women is their 2-percent risk for developing trophoblastic disease in a subsequent pregnancy (Garrett, 2008). Sonographic evaluation is recommended in early pregnancy, and subsequently if indicated. At delivery, the placenta or products of conception are sent for pathological evaluation, and a serum β -hCG level is measured 6 weeks postpartum.

PHASE 4 OF PARTURITION: THE PUERPERIUM 417

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION 417

PHASE 1: UTERINE QUIESCENCE AND CERVICAL COMPETENCE 419

PHASE 2: UTERINE ACTIVATION AND CERVICAL RIPENING 423

PHASE 3: UTERINE STIMULATION 426

The last few hours of human pregnancy are characterized by forceful and painful uterine contractions that effect cervical dilatation and cause the fetus to descend through the birth canal. There are extensive preparations in both the uterus and cervix long before this. During the first 36 to 38 weeks of normal gestation, the myometrium is in a preparatory yet unresponsive state. Concurrently, the cervix begins an early stage of remodeling—termed *softening*—yet maintains structural integrity. Following this prolonged uterine quiescence, there is a transitional phase during which myometrial unresponsiveness is suspended, and the cervix undergoes ripening, effacement, and loss of structural integrity.

The physiological processes that regulate parturition and the onset of labor continue to be defined. It is clear, however, that labor onset represents the culmination of a series of biochemical changes in the uterus and cervix. These result from endocrine

and paracrine signals emanating from both mother and fetus. Their relative contributions vary between species, and it is these differences that complicate elucidation of the exact factors that regulate human parturition. When parturition is abnormal, then preterm labor, dystocia, or postterm pregnancy may result. Of these, preterm labor remains the major contributor to neonatal mortality and morbidity in developed countries.

PHASES OF PARTURITION

The bringing forth of young—*parturition*—requires well-orchestrated transformations in both uterine and cervical function. As shown in [Figure 21-1](#), parturition can be arbitrarily divided into four overlapping phases that correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Casey, 1993, 1997; Challis, 2000; Word, 2007). These phases of parturition include: (1) a prelude to it, (2) the preparation for it, (3) the process itself, and (4) recovery. Importantly, the *phases of parturition* should not be confused with the *clinical stages of labor*, that is, the first, second, and third stages—which comprise the third phase of parturition ([Fig. 21-2](#)).

Phase 1 of Parturition: Uterine Quiescence and Cervical Softening

Uterine Quiescence

Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase normally comprises 95 percent of pregnancy and is characterized by uterine smooth muscle tranquility with maintenance of cervical structural integrity. The inherent propensity of the myometrium to contract is held in abeyance, and uterine muscle is rendered unresponsive to natural stimuli. Concurrently, the uterus must initiate extensive changes in its size and vascularity to accommodate the pregnancy and

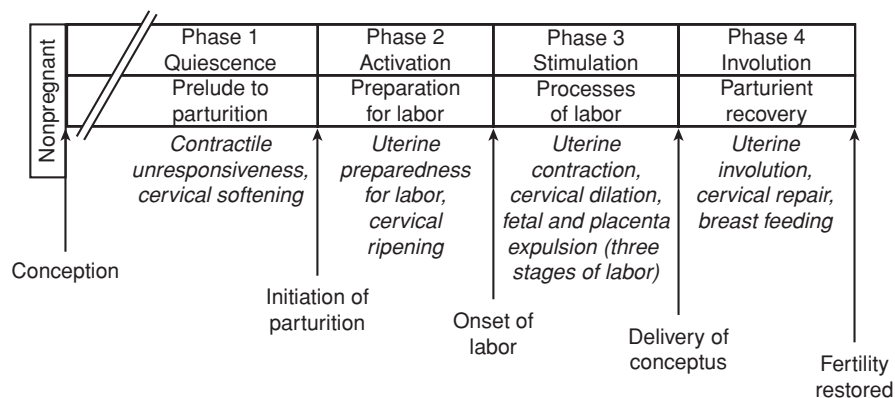

FIGURE 21-1 The phases of parturition.

prepare for uterine contractions. The myometrial unresponsiveness of phase 1 continues until near the end of pregnancy. Some low-intensity myometrial contractions are felt during the quiescent phase, but they do not normally cause cervical dilatation. Contractions of this type become more common toward the end of pregnancy, especially in multiparous women, and are referred to as *Braxton Hicks contractions* or *false labor* (Chap. 4, p. 47).

sible, and its consistency is similar to the lips of the oral cavity. Thus, the first stage of this remodeling—termed *softening*—is characterized by an increase in tissue compliance, yet the cervix remains firm and unyielding. Hegar (1895) first described palpable softening of the lower uterine segment at 4 to 6 weeks' gestation, and this sign was once used to diagnose pregnancy.

Clinically, the maintenance of cervical anatomical and structural integrity is essential for continuation of pregnancy to term. Preterm cervical dilatation, structural incompetence, or both may forecast delivery (Iams, 1996).

Cervical Softening

The cervix has multiple functions during pregnancy that include: (1) maintenance of barrier function to protect the reproductive tract from infection, (2) maintenance of cervical competence despite increasing gravitational forces, and (3) orchestration of extracellular matrix changes that allow progressive increases in tissue compliance.

In nonpregnant women, the cervix is closed and firm, and its consistency is similar to nasal cartilage. By the end of pregnancy, the cervix is easily distensible,

FIGURE 21-2 Composite of the average dilatation curve for labor in nulliparous women. The curve is based on analysis of data derived from a large, nearly consecutive series of women. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts: an acceleration phase, a linear phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

Structural Changes with Softening.

Cervical softening results from increased vascularity, stromal hypertrophy, glandular hypertrophy and hyperplasia, and slow, progressive compositional or structural changes of the extracellular matrix (House, 2009; Leppert, 1995; Mahendroo, 2012; Word, 2007). During matrix changes, collagen, the main structural protein in the cervix, undergoes conformational changes that alter tissue strength and flexibility. Specifically, collagen processing and the number or type of covalent cross-links between collagen triple helices are altered. These cross-links are normally required for stable collagen fibril formation (Canty, 2005). A reduction in cross-links between newly synthesized collagen monomers results from reduced expression and activity of the cross-link forming enzymes, lysyl hydroxylase and lysyl oxidase, beginning in early pregnancy (Akins, 2011; Drewes, 2007; Ozasa, 1981). Concurrently there is reduced expression of the matricellular proteins thrombospondin 2 and tenascin C. These proteins also influence collagen fibril structure and strength. Together, these early pregnancy changes contribute to the gradual increase in tissue compliance during pregnancy.

The clinical importance of these matrix changes is supported by the greater prevalence of cervical insufficiency in those with inherited defects in collagen and elastin synthesis or assembly (Anum, 2009; Hermanns-Lê, 2005; Paternoster, 1998; Rahman, 2003; Wang, 2006). Examples are Ehlers-Danlos and Marfan syndromes, discussed in Chapter 59 (p. 1181). Additionally, human cervical stromal cells express a transcription factor, microphthalmia-associated transcription factor (MiTF-Cx). During pregnancy, this factor maintains cervical competency by repressing the expression of genes involved in cervical dilation and parturition (Hari Kishore, 2012).

■ Phase 2 of Parturition: Preparation for Labor

To prepare for labor, the myometrial tranquility of phase 1 of parturition must be suspended—so-called *uterine awakening* or *activation*. This phase 2 is a progression of uterine changes during the last 6 to 8 weeks of pregnancy. Importantly, shifting events associated with phase 2 can cause either preterm or delayed labor.

Myometrial Changes

Phase 2 myometrial changes prepare it for labor contractions. This shift probably results from alterations in the expression of key proteins that control contractility. These *contraction-associated proteins (CAPs)* include the oxytocin receptor, prostaglandin F receptor, and connexin 43 (Smith, 2007). Thus, myometrial oxytocin receptors markedly increase along with increased numbers and surface areas of gap junction proteins such as connexin 43. Together, these lead to increased uterine irritability and responsiveness to *uterotonins*—agents that stimulate contractions.

Another critical change in phase 2 is formation of the lower uterine segment from the isthmus. With this development, the fetal head often descends to or even through the pelvic inlet—so-called *lightening*. The abdomen commonly undergoes a shape change, sometimes described by women as “the baby dropped.” It is also likely that the lower segment myometrium is unique from that in the upper uterine segment, resulting in distinct roles for each during labor. This is supported by baboon studies that demonstrate differential expression of prostaglandin receptors within myometrial regions. There are also human studies that report an expression gradient of oxytocin receptors, with greater expression in fundal myometrial cells (Fuchs, 1984; Havelock, 2005; Smith, 2001).

Cervical Ripening During Phase 2

Before contractions begin, the cervix must undergo more extensive remodeling. This eventually results in cervical yielding and dilatation upon initiation of forceful uterine contractions. Cervical modifications during this second phase principally involve connective tissue changes—so-called *cervical ripening*. The transition from the softening to the ripening phase begins weeks or days before onset of contractions. During this transformation, the total amount and composition of proteoglycans and glycosaminoglycans within the matrix are altered. Many of the processes that aid cervical remodeling are controlled by

the same hormones regulating uterine function. That said, the molecular events of each are varied because of differences in cellular composition and physiological requirements. The uterine corpus is predominantly smooth muscle, whereas the cervix is primarily connective tissue. Cellular components of the cervix include fibroblasts, epithelia, and few smooth muscle cells.

Endocervical Epithelia

During pregnancy, endocervical epithelial cells proliferate such that endocervical glands occupy a significant percentage of cervical mass. The endocervical canal is lined with mucus-secreting columnar and stratified squamous epithelia, which protect against microbial invasion. Mucosal epithelia function as sentinels for antigens by expressing Toll-like receptors that recognize pathogens. In addition, epithelia respond in ways that lead to bacterial and viral killing. For this, the epithelia express antimicrobial peptides and protease inhibitors and signal to underlying immune cells when a pathogenic challenge exceeds their protective capacity (Wira, 2005).

In mice, studies suggest that cervical epithelia may also aid cervical remodeling by regulating tissue hydration and maintenance of barrier function. Hydration may be regulated by expression of *aquaporins*—water channel proteins. Maintenance of barrier function and paracellular transport of ion and solutes is regulated by tight junction proteins, such as claudins 1 and 2 (Anderson, 2006; Timmons, 2007). In the human cervical and vaginal mucosal epithelia, junctional proteins are also reported to be expressed (Blaskewicz, 2011).

Cervical Connective Tissue

Collagen. The cervix is an extracellular matrix-rich tissue. Constituents of the matrix include type I, III, and IV collagen, glycosaminoglycans, matricellular proteins, proteoglycans, and elastin. Of these, collagen is largely responsible for structural disposition of the cervix. Collagen is the most abundant mammalian protein and has a complex biosynthesis pathway that includes at least six enzymes and chaperones to accomplish maturation. Each collagen molecule is composed of three alpha chains, which wind around each other to form procollagen. Multiple collagen triple-helical molecules are cross-linked to one another by the actions of lysyl oxidase to form fibrils. Collagen fibrils interact with small proteoglycans such as decorin or biglycan, as well as matricellular proteins such as thrombospondin 2. These interactions determine fibril size, packing, and organization (Fig. 21-3). This ensures that collagen fibrils are of uniform diameter and are packed together in a regular and highly organized pattern (Canty, 2005).

During cervical ripening, collagen fibril diameter is increased, and there is increased spacing between fibrils. These changes may result in part from accumulation of poorly cross-linked collagen and reduced expression of matricellular proteins. Dispersion of collagen fibrils leads to a loss of tissue integrity and increased tissue compliance. Matrix metalloproteases (MMPs) are proteases capable of degrading extracellular matrix proteins. Of these, collagenase members of the MMP family degrade collagen. Some studies support a role of MMPs in cervical ripening. But, others suggest that the biomechanical changes are not consistent solely with collagenase activation and

FIGURE 21-3 Fibrillar collagen synthesis and organization. Collagen fibrils are assembled into collagen fibers. Fibril size and packing are regulated in part by small proteoglycans such as decorin that bind collagen. Before cervical ripening, fibril size is uniform, and fibrils are well packed and organized. During cervical ripening, fibril size is less uniform, and spacing between collagen fibrils and fibers is increased and disorganized.

loss of collagen. For example, Buhmschi and colleagues (2004) performed tissue biomechanical studies in the rat and suggest that ripening correlates with changes in the three-dimensional structure of collagen rather than its degradation by collagenases. Moreover, mouse and human studies document no changes in collagen content between nonpregnancy and term pregnancy (Akins, 2011; Myers, 2008; Read, 2007).

Thus, it is likely that dynamic changes in collagen structure rather than collagen content may regulate remodeling. This point is well illustrated in specialized microscopy images of mouse and human cervical collagen (Zhang, 2012). In further support, polymorphisms or mutations in genes required for collagen assembly are associated with an increased incidence of cervical insufficiency (Anum, 2009; Paternoster, 1998; Rahman, 2003; Warren, 2007).

Glycosaminoglycans (GAGs). These are high-molecular-weight polysaccharides that complex with proteins to form proteoglycans. One glycosaminoglycan is hyaluronan (HA), a carbohydrate polymer whose synthesis is carried out by hyaluronan synthase isoenzymes. Expression of these enzymes is increased in the cervix during ripening (Akgul, 2012; Osmers, 1993; Straach, 2005). The functions of hyaluronans are dependent on size, and the breakdown of large- to small-molecular-weight molecules is carried out by a family of hyaluronidase enzymes. Hyaluronidase genes are expressed in both the mouse and human cervix, and increased hyaluronidase activity is reported in the mouse cervix at term (Akgul, 2012). Large-molecular-weight HA predominates in the mouse cervix during ripening and has a dynamic role to increase viscoelasticity and matrix disorganization. Low-molecular-weight HA has proinflammatory properties, and studies in mice and women reveal increased concentrations during labor and in the puerperium

(Akgul, 2012; Ruscheinsky, 2008). The importance of regulated changes in HA size during cervical ripening and dilatation is supported by a study reporting hyaluronidase administration to the cervix for ripening in term pregnant women (Spallicci, 2007). Activation of intracellular signaling cascades and other biological functions requires interactions with cell-associated HA-binding proteins such as *versican* (Ruscheinsky, 2008).

Proteoglycans. These glycoproteins are composed of a protein core and GAG chains. Changes in the amount of core protein or in the number, length, or degree of sulfation of GAG chains can influence proteoglycan function. Although not well-defined, changes in proteoglycan composition are thought to accompany cervical ripening. At least three small leucine-rich proteoglycans are

expressed in the cervix—decorin, biglycan, and fibromodulin (Westergren-Thorsson, 1998). In other connective tissues, decorin and other family members interact with collagen and influence the packing and order of collagen fibrils (Ameys, 2002). Collagen fibrils are rearranged in the skin of decorin-deficient mice and result in collagen fibers that are weakened, shortened, and disorganized (see Fig. 21-3). In addition to the cervix, these proteoglycans are expressed in the fetal membranes and uterus. Changes in expression levels may regulate fetal membrane tensile strength and uterine function (Meiner, 2007; Wu, 2012).

Inflammatory Changes. The marked changes within the extracellular matrix during cervical ripening in phase 2 are accompanied by stromal invasion with inflammatory cells. This has led to a model in which cervical ripening is considered an inflammatory process. As such, cervical chemoattractants attract inflammatory cells, which in turn release proteases that may aid degradation of collagen and other matrix components. In phase 3 or 4 of parturition, there is increased cervical expression of chemokines and collagenase/protease activity. It was assumed that processes regulating phases 3 and 4 of dilation and postpartum recovery of the cervix were similar to those in phase 2 of cervical ripening (Bokström, 1997; Osman, 2003; Sennström, 2000; Young, 2002). This has been challenged by observations from both human and animal studies. Sakamoto and associates (2004, 2005) found no correlation between the degree of clinical cervical ripening and the tissue concentrations of cervical neutrophil-chemoattractant interleukin 8 (IL-8). Microarray studies comparing gene expression patterns at term before and after cervical ripening report little increase in expression of proinflammatory genes. In contrast, there is a robust increase in proinflammatory and immunosuppressive genes in the cervix after delivery compared with during cervical ripening (Bollapragada, 2009; Hassan, 2006, 2009).

In mouse models, monocyte migration, but not activation, takes place before labor (Timmons, 2006, 2007, 2009). Mice deficient in the chemokine receptor CCR2, important in monocyte homing to tissues, have normally timed labor. This further supports the suggestion that labor is not initiated by an inflammatory response (Menzies, 2012). Furthermore, tissue depletion of neutrophils before birth has no effect on the timing or success of parturition. Finally, activation of neutrophils, proinflammatory M1 macrophages, and alternatively of activated M2 macrophages is increased within 2 hours after birth. This suggests a role for inflammatory cells in postpartum cervical remodeling and repair.

Induction and Prevention of Cervical Ripening

There are no therapies to prevent premature cervical ripening. Cervical cerclage is used to circumvent cervical insufficiency, although success appears limited (Owen, 2012). In contrast, treatment to promote cervical ripening for labor induction includes direct application of prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$). Prostaglandins likely modify extracellular matrix structure to aid ripening. Although the role of prostaglandins in the normal physiology of cervical ripening remains unclear, this property is useful clinically to assist labor induction (Chap. 26, p. 526). In some nonhuman species, the cascades of events that allow cervical ripening are induced by decreasing serum progesterone concentrations. And in humans, administration of progesterone antagonists causes cervical ripening. As discussed later, humans may have developed unique mechanisms to localize decreases in progesterone action in the cervix and myometrium.

Phase 3 of Parturition: Labor

This phase is synonymous with active labor, which is customarily divided into three stages. These compose the commonly used labor graph shown in Figure 21-2. The clinical stages of labor may be summarized as follows. The first stage begins when spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about cervical thinning, or *effacement*. This labor stage ends when the cervix is fully dilated—about 10 cm—to allow passage of the term-sized fetus. The first stage of labor, therefore, is the *stage of cervical effacement and dilatation*.

The second stage begins when cervical dilatation is complete and ends with delivery. Thus, the second stage of labor is the *stage of fetal expulsion*. Last, the third stage begins immediately after delivery of the fetus and ends with the delivery of the placenta. Thus, the third stage of labor is the *stage of placental separation and expulsion*.

First Stage of Labor: Clinical Onset of Labor

In some women, forceful uterine contractions that effect delivery begin suddenly. In others, labor initiation is heralded by spontaneous release of a small amount of blood-tinged mucus from the vagina. This extrusion of the mucus plug that had previously filled the cervical canal during pregnancy is referred to as “show” or “bloody show.” There is very little blood with the mucous plug, and its passage indicates that labor is already in progress or likely will ensue in hours to days.

Uterine Labor Contractions

Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. The cause of this is not known definitely, but several possibilities have been suggested: (1) hypoxia of the contracted myometrium—such as that with angina pectoris; (2) compression of nerve ganglia in the cervix and lower uterus by contracted interlocking muscle bundles; (3) cervical stretching during dilatation; and (4) stretching of the peritoneum overlying the fundus.

Of these, compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with local anesthetic usually produces appreciable pain relief with contractions (Chap. 25, p. 509). Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockade from epidural analgesia does not diminish their frequency or intensity. In other examples, myometrial contractions in paraplegic women and in women after bilateral lumbar sympathectomy are normal but painless.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon has been referred to as the *Ferguson reflex* (Ferguson, 1941). Its exact mechanism is not clear, and release of oxytocin has been suggested but not proven. Manipulation of the cervix and “stripping” the fetal membranes is associated with an increase in blood levels of prostaglandin $F_{2\alpha}$ metabolite (PGFM).

The interval between contractions diminishes gradually from approximately 10 minutes at the onset of first-stage labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential for fetal welfare. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In active-phase labor, the duration of each contraction ranges from 30 to 90 seconds, averaging about 1 minute. There is appreciable variability in contraction intensity during normal labor. Specifically, amniotic fluid pressures generated by contractions during spontaneous labor average 40 mm Hg, but vary from 20 to 60 mm Hg (Chap. 24, p. 498).

Distinct Lower and Upper Uterine Segments. During active labor, the anatomical uterine divisions that were initiated in phase 2 of parturition become increasingly evident (Figs. 21-4 and 21-5). By abdominal palpation, even before membrane rupture, the two segments can sometimes be differentiated. The upper segment is firm during contractions, whereas the lower segment is softer, distended, and more passive. This mechanism is imperative because if the entire myometrium, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would be markedly decreased. Thus, the upper segment contracts, retracts, and expels the fetus. In response to these contractions, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass.

The myometrium of the upper segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length. The upper active uterine segment

FIGURE 21-4 Sequence of development of the segments and rings in the uterus at term and in labor. Note comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower uterine segment is derived from the isthmus, and the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. Anat. I.O. = anatomical internal os; E.O. = external os; Hist. I.O. = histological internal os; Ph. R.R. = physiological retraction ring.

contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in expulsion of the fetus. Concurrently, the uterine musculature is kept in firm contact with the uterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers, the upper active segment becomes progressively thickened throughout first- and second-stage labor (see Fig. 21-4). This process continues and results in a tremendously thickened upper uterine segment immediately after delivery.

Clinically, it is important to understand that the phenomenon of upper segment retraction is contingent on a decrease in

the volume of its contents. For this to happen, particularly early in labor when the entire uterus is virtually a closed sac with only minimal cervical dilatation, the musculature of the lower segment must stretch. This permits an increasing portion of the uterine contents to occupy the lower segment. The upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment mirrors the same gradual progression of retraction. Recall that after each contraction of the upper segment, the muscles do not return to their previous length, but tension remains essentially the same. By comparison, in the lower segment, successive lengthening of the fibers with labor is accompanied by thinning, normally to only a few millimeters in the thinnest part. As a result of the lower segment thinning and concomitant upper segment thickening, a boundary between the two is marked by a ridge on the inner uterine surface—the *physiological retraction ring*. When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is prominent and forms a *pathological retraction ring*. This abnormal condition is also known as the *Bandl ring*, which is discussed further and illustrated in Chapter 23 (p. 470).

FIGURE 21-5 The uterus at the time of vaginal delivery. The active upper segment retracts around the presenting part as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

Changes in Uterine Shape During Labor. Each contraction produces an elongation of the ovoid uterine shape with a concomitant decrease in horizontal diameter. This change in shape has important effects on the labor process. First, there is increased *fetal axis pressure*, that is, the decreased horizontal diameter serves to straighten the fetal vertebral column. This presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust farther downward. The lengthening of the ovoid shape has been estimated at 5 and 10 cm. Second, with lengthening of the uterus, the longitudinal muscle fibers are drawn taut. As a result, the lower segment and cervix are the only parts of the uterus that are flexible, and these are pulled upward and around the lower pole of the fetus.

Ancillary Forces in Labor

After the cervix is dilated fully, the most important force in fetal expulsion is that produced by maternal intraabdominal

pressure. Contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed is referred to as *pushing*. The force is similar to that with defecation, but the intensity usually is much greater. The importance of intraabdominal pressure is shown by the prolonged descent during labor in paraplegic women and in those with a dense epidural block. And, although increased intraabdominal pressure is necessary to complete second-stage labor, pushing accomplishes little in the first stage. It exhausts the mother, and its associated increased intrauterine pressures may be harmful to the fetus.

Cervical Changes

As the result of contraction forces, two fundamental changes—effacement and dilatation—occur in the already-ripened cervix. For an average-sized fetal head to pass through the cervix, its canal must dilate to a diameter of approximately 10 cm. At this time, the cervix is said to be completely or fully dilated. Although there may be no fetal descent during cervical effacement, most commonly the presenting fetal part descends somewhat as the cervix dilates. During second-stage labor in nulliparas, the presenting part typically descends slowly and steadily. In multiparas, however, particularly those of high parity, descent may be rapid.

Cervical effacement is “obliteration” or “taking up” of the cervix. It is manifest clinically by shortening of the cervical

FIGURE 21-6 Schematic showing effacement and dilatation.

A. Before labor, the primigravid cervix is long and undilated in contrast to that of the multipara, which has dilatation of the internal and external os. **B.** As effacement begins, the multiparous cervix shows dilatation and funneling of the internal os. This is less apparent in the primigravid cervix. **C.** As complete effacement is achieved in the primigravid cervix, dilation is minimal. The reverse is true in the multipara.

FIGURE 21-7 Hydrostatic action of membranes in effecting cervical effacement and dilatation. With labor progression, note the changing relations of the internal and external os in **(A)**, **(B)**, and **(C)**. Although not shown in this diagram, with membrane rupture, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly.

canal from a length of approximately 2 cm to a mere circular orifice with almost paper-thin edges. The muscular fibers at the level of the internal cervical os are pulled upward, or “taken up,” into the lower uterine segment. The condition of the external os remains temporarily unchanged (Fig. 21-6).

Effacement may be compared to a funneling process in which the whole length of a narrow cylinder is converted into a very obtuse, flaring funnel with a small circular opening. Because of increased myometrial activity during uterine preparedness for labor, appreciable effacement of a softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucous plug as the cervical canal is shortened.

Because the lower segment and cervix have lesser resistance during a contraction, a centrifugal pull is exerted on the cervix and creates *cervical dilatation* (Fig. 21-7). As uterine contractions cause pressure on the membranes, the hydrostatic action of the amniotic sac in turn dilates the cervical canal like a wedge. In the absence of intact membranes, the pressure of the presenting fetal part against the cervix and lower uterine segment is similarly effective. Early rupture of the membranes does not retard cervical dilatation so long as the presenting fetal part is positioned to exert pressure against the cervix and lower segment. The process of cervical effacement and dilatation causes formation of the *forebag* of amniotic fluid. This is the leading portion of fluid and amniotic sac located in front of the presenting part.

Referring back to Figure 21-2, recall that cervical dilatation is divided into latent and active phases. The active phase is subdivided further into the acceleration phase, the phase of maximum slope, and the deceleration phase (Friedman, 1978). The duration of the latent phase is more variable and sensitive to changes by extraneous factors. For example, sedation may prolong the latent phase, and myometrial stimulation shortens it. The latent phase duration has little bearing on the subsequent course of labor, whereas the characteristics of the accelerated phase are usually predictive of labor outcome. Completion of cervical dilatation during the active phase is accomplished by cervical retraction about the presenting part. The first stage ends when cervical dilatation is complete. Once the second stage commences, only progressive descent of the presenting part will foretell further progress.

Second Stage of Labor: Fetal Descent

In many nulliparas, engagement of the head is accomplished before labor begins. That said, the head may not descend further until late in labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of labor duration. *Station* describes descent of the fetal biparietal diameter in relation to a

line drawn between maternal ischial spines (Chap. 22, p. 449). Active descent usually takes place after dilatation has progressed for some time (Fig. 21-8). In nulliparas, increased rates of descent are observed ordinarily during cervical dilatation phase of maximum slope. At this time, the speed of descent is also maximal and is maintained until the presenting part reaches the perineal floor (Friedman, 1978).

Pelvic Floor Changes During Labor

The birth canal is supported and is functionally closed by several layers of tissues that together form the pelvic floor. These anatomical structures are shown in detail in Chapter 2 (p. 22). The most important are the levator ani muscle and the fibromuscular connective tissue covering its upper and lower surfaces. There are marked changes in the biomechanical properties of these structures and of the vaginal wall during parturition. These result from altered extracellular matrix structure or composition (Lowder, 2007; Rahn, 2008). The levator ani consists of the pubovisceral, puborectalis, and iliococcygeus muscles, which close the lower end of the pelvic cavity as a diaphragm. Thereby, a concave upper and a convex lower surface are presented. The posterior and lateral portions of the pelvic floor, which are not spanned by the levator ani, are occupied bilaterally by the piriformis and coccygeus muscles.

The levator ani muscle varies in thickness from 3 to 5 mm, although its margins encircling the rectum and vagina are somewhat thicker. During pregnancy, the levator ani usually undergoes hypertrophy, forming a thick band that extends backward from the pubis and encircles the vagina about 2 cm above the plane of the hymen. On contraction, the levator ani draws both the rectum and the vagina forward and upward in the direction of the symphysis pubis and thereby acts to close the vagina.

FIGURE 21-8 Labor course divided on the basis of expected evolution of the dilatation and descent curves into three functional divisions. The preparatory division includes the latent and acceleration phases. The dilatational division is the phase of maximum slope of dilatation. The pelvic division encompasses both the deceleration phase and the second stage, which is concurrent with the phase of maximum slope of fetal descent. (Redrawn from Friedman, 1978.)

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve to dilate the upper vagina. The most marked change consists of stretching of the levator ani muscle fibers. This is accompanied by thinning of the central portion of the perineum, which becomes transformed from a wedge-shaped, 5-cm-thick tissue mass to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges.

Third Stage of Labor: Delivery of Placenta and Membranes

This stage begins immediately after fetal delivery and involves separation and expulsion of the placenta and membranes. As the neonate is born, the uterus spontaneously contracts around its diminishing contents. Normally, by the time the newborn is completely delivered, the uterine cavity is nearly obliterated. The organ consists of an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 21-9). For the placenta to accommodate itself to this reduced area, it increases in thickness, but because of limited placental elasticity, it is forced to buckle. The resulting tension

FIGURE 21-9 Diminution in size of the placental site after birth of the infant. **A.** Spatial relations before birth. **B.** Placental spatial relations after birth.

FIGURE 21-10 Postpartum, membranes are thrown up into folds as the uterine cavity decreases in size. (Photograph contributed by Dr. Kelley S. Carrick.)

pulls the weakest layer—decidua spongiosa—from that site. Thus, placental separation follows the disproportion created between the relatively unchanged placental size and the reduced size of the implantation site.

Cleavage of the placenta is aided greatly by the loose structure of the spongy decidua, which may be likened to the row of perforations between postage stamps. As separation proceeds, a hematoma forms between the separating placenta/decidua and the decidua that remains attached to the myometrium. The hematoma is usually the result rather than the cause of the separation, because in some cases bleeding is negligible.

Fetal Membrane Separation and Placental Extrusion.

The great decrease in uterine cavity surface area simultaneously throws the fetal membranes—the amniochorion and the parietal decidua—into innumerable folds (Fig. 21-10). Membranes usually remain in situ until placental separation is nearly completed. These are then peeled off the uterine wall, partly by further contraction of the myometrium and partly by traction that is exerted by the separated placenta.

After the placenta has separated, it may be expelled by increased abdominal pressure. Completion of the third stage is also accomplished by alternately compressing and elevating the fundus, while exerting minimal traction on the umbilical cord (Fig. 27-12, p. 546). The retroplacental hematoma either follows the placenta or is found within the inverted sac formed by the membranes. In this process, known as the *Schultze mechanism* of placental expulsion, blood from the placental site pours into the membrane sac and does not escape externally until after extrusion of the placenta. In the other form of placental extrusion, known as the *Duncan mechanism*, the placenta separates first at the periphery and blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends sideways, and its maternal surface appears first.

Phase 4 of Parturition: The Puerperium

Immediately and for about an hour or so after delivery, the myometrium remains in a state of rigid and persistent contraction and retraction. This directly compresses large uterine vessels and allows thrombosis of their lumens to prevent hemorrhage (Fig. 2-11, p. 27). This is typically augmented by uterotonics (Chap. 27, p. 547).

Uterine involution and cervical repair, both remodeling processes that restore these organs to the nonpregnant state, follow in a timely fashion. These protect the reproductive tract from invasion by commensal microorganisms and restore endometrial responsiveness to normal hormonal cyclicity.

During the early puerperium, there is onset of lactogenesis and milk let-down in mammary glands, as described in Chapter 36 (p. 672). Reinstitution of ovulation signals preparation for the next pregnancy. This generally occurs within 4 to 6 weeks after birth, but it is dependent on the duration of breast feeding and lactation-induced, prolactin-mediated anovulation and amenorrhea.

PHYSIOLOGICAL AND BIOCHEMICAL PROCESSES REGULATING PARTURITION

There are two general contemporaneous theorems concerning labor initiation. Viewed simplistically, the first is the *functional loss of pregnancy maintenance factors*, whereas the second focuses on *synthesis of factors that induce parturition*. Some investigators also speculate that the mature fetus is the source of the initial signal for parturition commencement. Others suggest that one or more uterotonins, produced in increased amounts, or an increased population of myometrial uterotonic receptors is the proximate cause. Indeed, an obligatory role for one or more uterotonins is included in most parturition theories, as either a primary or a secondary phenomenon in the final events of childbirth. Both rely on careful regulation of smooth muscle contraction.

Myometrial Action

Anatomical and Physiological Considerations

There are unique characteristics of smooth muscle, including myometrium, compared with those of skeletal muscle that may confer advantages for uterine contraction efficiency and fetal delivery. First, the degree of smooth-muscle cell shortening with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in multiple directions. In contrast, the contraction force generated by skeletal muscle is always aligned with the axis of the muscle fibers. Third, smooth muscle is not organized in the same manner as skeletal muscle. In myometrium, the thick and thin filaments are found in long, random bundles throughout the cells. This plexiform arrangement aids greater shortening and force-generating capacity. Last, greater multidirectional force generation in the uterine fundus compared with that of the lower uterine segment permits versatility in expulsive force directionality. These forces thus can be brought to bear irrespective of the fetal lie or presentation.

Regulation of Myometrial Contraction and Relaxation

Myometrial contraction is controlled by transcription of key genes, which produce proteins that repress or enhance cellular contractility. These proteins function to: (1) enhance the interactions between the actin and myosin proteins that cause muscle contraction, (2) increase excitability of individual myometrial cells, and (3) promote intracellular cross talk that allows development of synchronous contractions.

Actin-Myosin Interactions. The interaction of myosin and actin is essential to muscle contraction. This interaction requires that actin be converted from a globular to a filamentous form. Moreover, actin must be attached to the cytoskeleton at focal points in the cell membrane to allow development of tension (Fig. 21-11). Actin must partner with myosin, which is composed of multiple light and heavy chains. The interaction of myosin and actin activates adenosine triphosphatase (ATPase), hydrolyzes adenosine triphosphate, and generates force. This interaction is brought about by enzymatic phosphorylation of the 20-kDa light chain of myosin (Stull, 1988, 1998). This is catalyzed by the enzyme *myosin light-chain kinase*, which is activated by calcium. Calcium binds to *calmodulin*, a calcium-binding regulatory protein, which in turn binds to and activates myosin light-chain kinase.

Intracellular Calcium. Agents that promote contraction act on myometrial cells to increase intracellular cytosolic calcium concentration— $[Ca^{2+}]_i$. Or, they allow an influx of extracellular calcium through ligand- or voltage-regulated calcium channels (see Fig. 21-11). For example, prostaglandin $F_{2\alpha}$ and oxytocin bind their respective receptors during labor to open ligand-activated calcium channels. Activation of these receptors also releases calcium from the sarcoplasmic reticulum to cause decreased electronegativity within the cell. Voltage-gated ion channels open, additional calcium ions move into the cell, and cellular depolarization follows. The increase in $[Ca^{2+}]_i$ is often transient, but contractions can be prolonged through the inhibition of myosin phosphatase activity (Woodcock, 2004).

Conditions that decrease $[Ca^{2+}]_i$ and increase intracellular concentrations of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) ordinarily promote uterine relaxation. Corticotropin-releasing hormone is one of several factors reported to regulate $[Ca^{2+}]_i$ and subsequently modulate expression of the large-conductance potassium channels (BKCa) in the human myometrium (Xu, 2011; You, 2012). Genetic studies in humans and transgenic overexpression in mice reveal that small-conductance calcium-activated K^+ isoform 3 (SK3) channels may also be important in maintenance of uterine relaxation (Day, 2011; Rada, 2012). SK3 channel expression declines at the end of term pregnancy as contractility is increased and overexpression of SK3 in transgenic mice dampens uterine contraction force to prevent delivery. Yet another potential mechanism for maintenance of relaxation shown in Figure 21-11 is the promotion of actin in a globular form rather than in fibrils required for contraction (Macphee, 2000; Yu, 1998).

FIGURE 21-11 Uterine myocyte relaxation and contraction. **A.** Uterine relaxation is maintained by factors that increase myocyte cyclic adenosine monophosphate (cAMP). This activates protein kinase A (PKA) to promote phosphodiesterase activity with dephosphorylation of myosin light-chain kinase (MLCK). There are also processes that serve to maintain actin in a globular form, and thus to prevent fibril formation necessary for contractions. **B.** Uterine contractions result from reversal of these sequences. Actin now assumes a fibrillar form, and calcium enters the cell to combine with calmodulin to form complexes. These complexes activate MLCK to bring about phosphorylation of the myosin light chains. This generates ATPase activity to cause sliding of myosin over the actin fibrils, which is a uterine contractor. AC = adenyl cyclase; Ca^{++} = calcium; DAG = diacylglycerol; Gs and $\text{G}\alpha$ = G-receptor proteins; IP_3 = inositol triphosphate; LC20 = light chain 20; PIP_3 = phosphatidylinositol 3,4,5-triphosphate; PLC = phospholipase C; R-PKA = inactive protein kinase. (Redrawn from Smith, 2007.)

In addition to myocyte contractility, myocyte excitability is also regulated by changes in the electrochemical potential gradient across the plasma membrane. Before labor, myocytes maintain a relatively high interior electronegativity. This state is maintained by the combined actions of the ATPase-driven sodium-potassium pump and the large conductance voltage- and Ca^{2+} -sensitive K channel—*maxi-K channel* (Parkington, 2001). During uterine quiescence, the maxi-K channel is open and allows potassium to leave the cell to maintain interior electronegativity. At the time of labor, changes in electronegativity lead to depolarization and contraction (Brainard, 2005; Chanrachakul, 2003). And, as parturition progresses, there is increased synchronization of electrical uterine activity.

Myometrial Gap Junctions. Cellular signals that control myometrial contraction and relaxation can be effectively transferred between cells through intercellular junctional channels. Communication is established between myocytes by gap junctions, which aid the passage of electrical or ionic coupling currents as well as metabolite coupling. The transmembrane channels that make up the gap junctions consist of two protein

“hemi-channels” (Sáez, 2005). These *connexons* are each composed of six *connexin* subunit proteins (Fig. 21-12). These pairs of connexons establish a conduit between coupled cells for the exchange of small molecules that can be nutrients, waste, metabolites, second messengers, or ions.

Optimal numbers of gap junctions are believed to be important for electrical myometrial synchrony. Four described in the uterus are connexins 26, 40, 43, and 45. Connexin 43 junctions are scarce in the nonpregnant uterus, and they increase in size and abundance during human parturition (Chow, 1994). Also, mouse models deficient in connexin 43-enriched gap junctions exhibit delayed parturition, further supporting their role (Döring, 2006; Tong, 2009).

Cell Surface Receptors. There are various cell surface receptors that can directly regulate myocyte contractile state. Three major classes are G-protein-linked, ion channel-linked, and enzyme-linked. Multiple examples of each have been identified in human myometrium. These further appear to be modified during the phases of parturition. Most G-protein-coupled receptors are associated with adenyl cyclase activation. Examples are the CRHR1 α and the LH

FIGURE 21-12 The protein subunits of gap junction channels are called connexins. Six connexins form a hemichannel (connexon), and two connexons (one from each cell) form a gap junction channel. Connexons and gap junction channels can be formed from one or more connexin proteins. The composition of the gap junction channel is important for their selectivity with regard to passage of molecules and communication between cells.

receptors (Fig. 21-13). Other G-protein-coupled myometrial receptors, however, are associated with G-protein-mediated activation of phospholipase C. Ligands for the G-protein-coupled receptors include numerous neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration via *endocrine* or *autocrine* mechanisms (Fig. 21-14).

Cervical Dilatation During Labor

There is a large influx of leukocytes into the cervical stroma with cervical dilatation (Sakamoto, 2004, 2005). Cervical tissue levels of leukocyte chemoattractants such as IL-8 are increased just after delivery, as are IL-8 receptor levels. Identification of genes upregulated just after vaginal delivery further suggests that dilatation and early stages of postpartum repair are aided by inflammatory responses, apoptosis, and activation of proteases that degrade extracellular matrix components (Hassan, 2006; Havelock, 2005). The composition of glycosaminoglycans, proteoglycans, and poorly formed collagen fibrils that were necessary during ripening and dilatation must be rapidly removed to allow reorganization and recovery of cervical structure. In the days that follow

parturition, recovery of cervical structure involves processes that resolve inflammation, promote tissue repair, and regenerate dense cervical connective tissue with structural integrity and mechanical strength.

Phase 1: Uterine Quiescence and Cervical Competence

Myometrial quiescence is so remarkable and successful that it probably is induced by multiple independent and cooperative biomolecular processes. Individually, some of these processes may be redundant to ensure pregnancy continuance. It is likely that all manners of molecular systems—neural, endocrine, paracrine, and autocrine—are called on to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary “fail-safe” system that protects the uterus against agents that could perturb the tranquility of phase 1 also must be in place (see Fig. 21-14).

As shown in Figure 21-15, phase 1 of human parturition and its quiescence are likely the result of many factors that include: (1) actions of estrogen and progesterone via intracellular receptors, (2) myometrial cell plasma membrane receptor-mediated increases in cAMP, (3) generation of cGMP, and (4) other systems, including modification of myometrial-cell ion channels.

Progesterone and Estrogen Contributions

In many species, the role of the sex steroid hormones is clear—progesterone inhibits and estrogen promotes the events leading to parturition. In humans, however, it seems most likely that both estrogen and progesterone are components of a broader-based molecular system that implements and maintains uterine quiescence. In many species, the removal of progesterone, that is, *progesterone withdrawal*, directly precedes progression of phase 1 into phase 2 of parturition. In addition, providing progesterone to some species will delay parturition via a decrease in myometrial activity and continued cervical competency (Challis, 1994). Studies in these species have led to a better understanding of why the progesterone-replete myometrium of phase 1 is relatively noncontractile.

Plasma levels of estrogen and progesterone in normal pregnancy are enormous and in great excess of the affinity constants for their receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of their concentrations could modulate physiological processes during pregnancy. The teleological evidence, however, for an increased progesterone-to-estrogen ratio in the maintenance of pregnancy and a decline in the progesterone-to-estrogen ratio for parturition is overwhelming. In all species studied to date, including humans, administration of the progesterone-receptor antagonists *mifepristone* (RU-486) or *onapristone* will promote some or all key features of parturition. These include cervical ripening, increased cervical distensibility, and increased uterine sensitivity to uterotonins (Bygdeman, 1994; Chwalisz, 1994a; Wolf, 1993).

The exact role of estrogen in regulating human uterine activity and cervical competency is less well understood. That said, it appears that estrogen can act to promote progesterone

FIGURE 21-13 G-protein-coupled receptor signal transduction pathways. **A.** Receptors coupled to heterotrimeric guanine-triphosphate (GTP)-binding proteins (G proteins) are integral transmembrane proteins that transduce extracellular signals to the cell interior. G-protein-coupled receptors exhibit a common structural motif consisting of seven membrane-spanning regions. **B.** Receptor occupation promotes interaction between the receptor and the G protein on the interior surface of the membrane. This induces an exchange of guanine diphosphate (GDP) for GTP on the G protein α subunit and dissociation of the α subunit from the $\beta\gamma$ heterodimer. Depending on its isoform, the GTP- α subunit complex mediates intracellular signaling either indirectly by acting on effector molecules such as adenyl cyclase (AC) or phospholipase C (PLC), or directly by regulating ion channel or kinase function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP₃ = inositol triphosphate.

FIGURE 21-14 Theoretical fail-safe system involving endocrine, paracrine, and autocrine mechanisms for the maintenance of phase 1 of parturition, uterine quiescence. CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PGE₂ = prostaglandin E₂; PGI₂ = prostaglandin I₂; PGDH = 15-hydroxyprostaglandin dehydrogenase.

responsiveness and, in doing so, promote uterine quiescence. The estrogen receptor, acting via the estrogen-response element of the progesterone-receptor gene, induces progesterone-receptor synthesis, which allows increased progesterone-mediated function.

Myometrial Cell-to-Cell Communication. Progesterone maintains uterine quiescence by various mechanisms that cause decreased expression of the contraction-associated proteins (CAPs) (p. 410). Progesterone can promote expression of the inhibitory transcription factor ZEB1—zinc finger E-box binding homeobox protein 1—which can inhibit expression of the CAP genes, connexin 43, and oxytocin receptor (Renthal, 2010). As another mechanism, progesterone bound to the progesterone receptor (PR) can recruit coregulatory factors. These include PSF—polypyrimidine tract binding protein-associated splicing factor—and Sin3A/HDACs—yeast switch-dependent3 homologue A/histone deacetylase corepressor complex—which inhibit expression of the gene encoding the gap junctional protein connexin 43 in rat and human myocytes (Xie, 2012).

At the end of pregnancy, increased stretch along with increased estrogen dominance results in a decline in PSF and Sin/HDAC levels, thus abrogating the suppression of connexin 43 expression by progesterone. Additionally, with loss of progesterone function at term, ZEB1 levels decline due to increased production of small regulatory RNAs termed microRNAs. This releases inhibition of connexin 43 and oxytocin receptor levels to promote increased uterine contractility (Renthal, 2010; Williams, 2012b).

G-Protein-Coupled Receptors

A number of G-protein-coupled receptors that normally are associated with $G\alpha_s$ -mediated activation of adenylyl cyclase and increased levels of cAMP are present in myometrium. These receptors together with appropriate ligands may act in concert with sex steroid hormones as part of a fail-safe system to maintain uterine quiescence (Price, 2000; Sanborn, 1998).

Beta-Adrenoreceptors. These receptors are prototypical examples of cAMP signaling causing myometrium relaxation. Agents binding to these receptors have been used for tocolysis with preterm labor and include ritodrine and terbutaline (Chap. 42, p. 852). β -Adrenergic receptors mediate $G\alpha_s$ -stimulated increases in adenylyl cyclase, increased levels of cAMP, and myometrial cell relaxation. The rate-limiting factor is likely the number of receptors expressed and the level of adenylyl cyclase expression.

Luteinizing Hormone (LH) and Human Chorionic Gonadotropin (hCG) Receptors

These hormones share the same receptor, and this G-protein-coupled receptor has been demonstrated in myometrial smooth muscle and blood vessels (Lei, 1992; Ziecik, 1992). Levels of myometrial LH-hCG receptors during pregnancy are greater before than during labor (Zuo, 1994). Chorionic gonadotropin acts to activate adenylyl cyclase by way of a plasma membrane receptor- G_{α_s} -linked system. This decreases contraction frequency and force and decreases the number of tissue-specific myometrial cell gap junctions (Ambrus, 1994; Eta, 1994). Thus, high circulating levels of hCG may be one mechanism causing uterine quiescence.

Relaxin. This peptide hormone consists of an A and B chain and is structurally similar to the insulin family of proteins (Bogic, 1995; Weiss, 1995). Relaxin mediates lengthening of the pubic ligament, cervical softening, vaginal relaxation, and inhibition of myometrial contractions. There are two separate human relaxin genes, designated *H1* and *H2*. The *H1* gene is primarily expressed in the decidua, trophoblast, and prostate, whereas the *H2* gene is primarily expressed in the corpus luteum.

Relaxin in plasma of pregnant women is believed to originate exclusively from corpus luteum secretion. Plasma levels peak at approximately 1 ng/mL between 8 and 12 weeks' gestation. Thereafter, they decline to lower levels that persist until term. Its plasma membrane receptor—*relaxin family peptide receptor 1 (RXFP1)*—mediates activation of adenylyl cyclase. Relaxin inhibits contractions of nonpregnant myometrial strips, but not those of uterine tissue taken from pregnant women. It also effects cervical remodeling through cell proliferation and

modulation of extracellular matrix components such as collagen and hyaluronan (Park, 2005; Soh, 2012).

Corticotropin-Releasing Hormone (CRH). This hormone is synthesized in the placenta and hypothalamus. As discussed later, CRH plasma levels increase dramatically during the final 6 to 8 weeks of normal pregnancy and have been implicated in the mechanisms controlling the timing of human parturition (Smith, 2007; Wadhwa, 1998). CRH appears to promote myometrial quiescence during most of pregnancy and aids myometrial contractions with onset of parturition. Recent studies suggest that these opposing actions are achieved by differential actions of CRH via its receptor CRHR1. In the term nonlaboring myometrium, the interaction of CRH with its CRHR1 receptor results in activation of the Gs-adenylate cyclase-cAMP signaling pathway. This results in inhibition of inositol triphosphate (IP_3) production and a stabilization of $[Ca^{2+}]_i$ (You, 2012). In term laboring myometrium, $[Ca^{2+}]_i$ is increased by CRH activation of G proteins Gq and Gi and leads to stimulation of IP_3 production and increased contractility. Another aspect of CRH regulation is union of CRH to its binding protein, which can limit bioavailability. CRH-binding protein levels are high during pregnancy and are reported to decline at the time of labor.

Prostaglandins. These interact with a family of eight different G-protein-coupled receptors, several of which are expressed in myometrium (Myatt, 2004). Prostaglandins usually are considered as uterotonins. However, their effects are diverse, and some act as smooth muscle relaxants.

The major synthetic pathways involved in prostaglandin biosynthesis are shown in Figure 21-16. Prostaglandins are produced using plasma membrane-derived arachidonic acid, which usually is released by the action of the phospholipases A₂ or C. Arachidonic acid can then act as substrate for both type 1 and type 2 prostaglandin H synthase (PGHS-1 and -2), which are also called cyclooxygenase-1 and -2 (COX-1 and -2). Both PGHS isoforms convert arachidonic acid to the unstable endoperoxide prostaglandin G₂ and then to prostaglandin H₂. These enzymes are the target of many nonsteroidal antiinflammatory drugs (NSAIDs). Indeed, the tocolytic actions of specific NSAIDs, as discussed in Chapter 42 (p. 852), were considered promising until they were shown to have adverse fetal effects (Loudon, 2003; Olson, 2003, 2007).

Through prostaglandin isomerases, prostaglandin H₂ is converted to active prostaglandins, including PGE₂, PGF_{2α}, and PGI₂. Isomerase expression is tissue-specific and thereby controls the relative production of various prostaglandins. Another important control point for prostaglandin activity is its metabolism, which most often is through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). Expression of this enzyme can be regulated in the uterus, which is important because of its ability to rapidly inactivate prostaglandins.

The effect of prostaglandins on tissue targets is complicated in that there are a number of G-protein-coupled prostaglandin receptors (Coleman, 1994). This family of receptors is classified according to the binding specificity of a given receptor to a

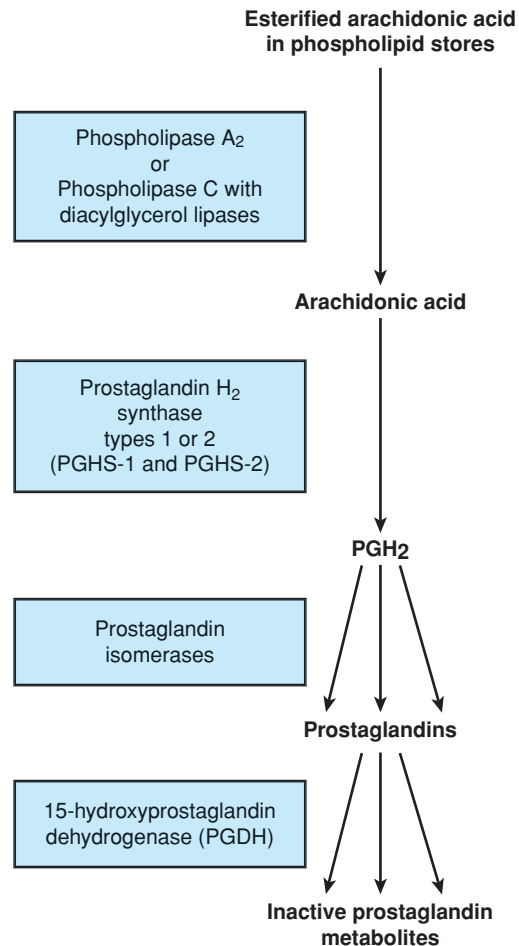

FIGURE 21-16 Overview of the prostaglandin biosynthetic pathway.

particular prostaglandin. Both PGE₂ and PGI₂ could potentially act to maintain uterine quiescence by increasing cAMP signaling, yet PGE₂ can promote uterine contractility through binding to prostaglandin E receptors 1 and 3 (EP₁ and EP₃). Also, PGE₂, PGD₂, and PGI₂ have been shown to cause vascular smooth muscle relaxation and vasodilatation in many circumstances. Thus, either the generation of specific prostaglandins or the relative expression of the various prostaglandin receptors may determine myometrial responses to prostaglandins (Lyall, 2002; Olson, 2003, 2007; Smith, 2001; Smith, 1998).

In addition to gestational changes, other studies show that there may be regional changes in the upper and lower uterine segments. COX-2 expression is spatially regulated in the myometrium and cervix in pregnancy and labor, with an increasing concentration gradient from the fundus to the cervix (Havelock, 2005). Thus, it is entirely possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to regional fundal myometrial contractions after parturition initiation (Myatt, 2004).

Atrial and Brain Natriuretic Peptides and Cyclic Guanosine Monophosphate (cGMP)

Activation of guanylyl cyclase increases intracellular cGMP levels, which promotes smooth muscle relaxation (Word, 1993). Intracellular cGMP levels are increased in the pregnant

myometrium and can be stimulated by atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP) receptors, and nitric oxide (Telfer, 2001). All of these factors and their receptors are expressed in the pregnant uterus. However, it remains unclear if these factors and intracellular cGMP play a role in uterine quiescence in normal pregnancy physiology (Itoh, 1994; Yallampalli, 1994a,b).

Accelerated Uterotonin Degradation

In addition to pregnancy-induced compounds that promote myometrial cell refractoriness, there are striking increases in the activity of enzymes that degrade or inactivate endogenously produced uterotonins. Some of these and their degradative enzymes include: PGDH and prostaglandins; enkephalinase and endothelins; oxytocinase and oxytocin; diamine oxidase and histamine; catechol *O*-methyltransferase and catecholamines; angiotensinases and angiotensin-II; and platelet-activating factor (PAF) acetylhydrolase and PAF. Activities of several of these enzymes are increased by progesterone, and many decrease late in gestation (Bates, 1979; Casey, 1980; Germain, 1994).

Phase 2: Uterine Activation and Cervical Ripening

Classic Progesterone Withdrawal and Parturition

Key factors in uterine activation are depicted in Figure 21-15. In species that exhibit progesterone withdrawal, parturition progression to labor can be blocked by administering progesterone to the mother. However, there are conflicting reports as to whether progesterone administration in pregnant women can delay the timely onset of parturition or prevent preterm labor. The possibility that progesterone-containing injections or vaginal suppositories may be used to prevent preterm labor has been studied in a number of randomized trials conducted during the past 15 years. These are discussed in Chapter 42 (p. 844), but in general, their use has marginal clinical benefits in preventing recurrent preterm birth and its associated perinatal morbidity.

Progesterone Receptor Antagonists and Human Parturition

When the steroidal antiprogesterin mifepristone (RU-486) is administered during the latter phase of the ovarian cycle, it induces menstruation prematurely. It is also an effective abortifacient during early pregnancy (Chap. 18, p. 368). Mifepristone is a classic steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor in women later in pregnancy, mifepristone appears to have some effect on cervical ripening and on increasing myometrial sensitivity to uterotonins (Berkane, 2005; Chwalisz, 1994a,b). These data suggest that humans have a mechanism for progesterone inactivation, whereby the myometrium and cervix become refractory to the inhibitory actions of progesterone.

Functional Progesterone Withdrawal in Human Parturition

As an alternative to classic progesterone withdrawal resulting from decreased secretion, research has focused on mechanisms that inhibit progesterone action in human pregnancy.

Functional progesterone withdrawal or antagonism is possibly mediated through several mechanisms: (1) changes in the relative expression of the nuclear progesterone-receptor isoforms, PR-A, PR-B, and PR-C; (2) changes in the relative expression of membrane-bound progesterone receptors; (3) posttranslational modifications of the progesterone receptor; (4) alterations in PR activity through changes in the expression of coactivators or corepressors that directly influence receptor function; (5) local inactivation of progesterone by steroid-metabolizing enzymes or synthesis of a natural antagonist; and (6) microRNA regulation of progesterone-metabolizing enzymes and transcription factors that modulate uterine quiescence.

There is evidence that progesterone-receptor activity is decreased late in gestation. A series of studies have shown that the relative ratio of PR-A to PR-B within the myometrium, decidua, and chorion shifts late in gestation (Madsen, 2004; Mesiano, 2002; Pieber, 2001). Specifically, increased PR-A levels during parturition depress the antiinflammatory actions of PR-B and thereby promote proinflammatory gene expression at term (Tan, 2012). Moreover, these activities have been shown to be specific for the upper and lower uterine segments (Condon, 2003, 2006). Similarly, studies of cervical stroma suggest changes in receptor isoform concentrations (Stjernholm-Vladic, 2004). In addition, membrane PR isoforms are also expressed in the myometrium and placenta. However, it remains to be determined if they play a role to promote the transition from myometrial quiescence to activation (Chapman, 2006; Karteris, 2006; Zachariades, 2012). There is evidence in rodent models that local action of enzymes such as steroid 5 α -reductase type 1 or 20 α -hydroxysteroid dehydrogenase (20 α -HSD) catabolize progesterone to metabolites that have a weak affinity for the progesterone receptor (Mahendroo, 1999; Piekorz, 2005). In the human cervix, decreased activity of 17 β -hydroxysteroid dehydrogenase type 2 at term results in a net increase in estrogen and decline in progesterone levels (Andersson, 2008). Recent studies provide new insights into the regulatory role of small noncoding RNAs (microRNAs) in regulating expression of the steroid-metabolizing enzyme 20 α -HSD (Williams, 2012a). Increased expression of microRNA200a in the term myometrium blunts the expression of STAT5b, an inhibitor of 20 α -HSD. Reduced STAT5b function allows increased 20 α -HSD levels that result in increased progesterone metabolism and reduced progesterone function.

Taken together, all of these observations support the concept that multiple pathways exist for a functional progesterone withdrawal that includes changes in PR isoform and receptor coactivator levels, microRNA regulation, and increased local hormone metabolism to less active products.

Oxytocin Receptors

Because of its longstanding application for labor induction, it seemed logical that oxytocin must play a central role in spontaneous human labor. But this venerable hormone may have only a minor supporting role. Currently, it still is controversial whether oxytocin plays a role in the early phases of uterine activation or whether its sole function is in the expulsive phase

of labor. Most studies of regulation of myometrial oxytocin-receptor synthesis have been performed in rodents. Disruption of the oxytocin receptor gene in the mouse does not affect parturition. This suggests that, at least in this species, multiple systems likely ensure that parturition occurs. There is little doubt, however, that there is an increase in myometrial oxytocin receptors during phase 2 of parturition. Moreover, their activation results in increased phospholipase C activity and subsequent increases in cytosolic calcium levels and uterine contractility.

Progesterone and estradiol appear to be the primary regulators of oxytocin receptor expression. Estradiol treatment in vivo or in myometrial explants increases myometrial oxytocin receptor concentrations. This action, however, is prevented by simultaneous treatment with progesterone (Fuchs, 1983). Progesterone also may act within the myometrial cell to increase oxytocin-receptor degradation and inhibit oxytocin activation of its receptor at the cell surface (Bogacki, 2002). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through the inhibition of myometrial oxytocin response.

The increase in oxytocin receptor levels in nonhuman species appears to be mainly regulated either directly or indirectly by estradiol. Treatment of several species with estrogen leads to increased uterine oxytocin receptor levels (Blanks, 2003; Challis, 1994). Moreover, the level of oxytocin receptor mRNA in human myometrium at term is greater than that found in preterm myometrium (Wathes, 1999). Thus, increased receptors at term may be attributable to increased gene transcription. An estrogen response element, however, is not present in the oxytocin receptor gene, suggesting that the stimulatory effects of estrogen may be indirect.

Human studies suggest that inflammatory-related rapid-response genes may regulate oxytocin receptors (Bethin, 2003; Kimura, 1999; Massrieh, 2006). These receptors also are present in human endometrium and in decidua at term and stimulate prostaglandin production. In addition, these receptors are found in the myometrium and at lower levels in amniochorion-decidual tissues (Benedetto, 1990; Wathes, 1999).

Relaxin

Although relaxin may contribute to uterine quiescence, it also has roles in phase 2 of parturition. These include remodeling of the extracellular matrix of the uterus, cervix, vagina, breast, and pubic symphysis as well as promoting cell proliferation and inhibiting apoptosis. Its actions on cell proliferation and apoptosis are mediated through the G-protein-coupled receptor, RXFP1, whereas some but not all actions of relaxin on matrix remodeling are mediated through this receptor (Samuel, 2009; Yao, 2008). The precise mechanisms for modulation of matrix turnover have not been fully elucidated. However, relaxin appears to mediate glycosaminoglycan and proteoglycan synthesis and degrade matrix macromolecules such as collagen by induction of matrix metalloproteases. Relaxin promotes growth of the cervix, vagina, and pubic symphysis and is necessary for breast remodeling for lactation. Consistent with its proposed roles, mice deficient in relaxin or the RXFP1 receptor have protracted labor; show reduced growth of the cervix, vagina, and symphysis; and

are unable to nurse because of incomplete nipple development (Feng, 2005; Park, 2005; Rosa, 2012; Soh, 2012; Yao, 2008).

Fetal Contributions to Initiation of Parturition

It is intellectually intriguing to envision that the mature human fetus provides the signal to initiate parturition. Teleologically, this seems most logical because such a signal could be transmitted in several ways to suspend uterine quiescence. The fetus may provide a signal through a blood-borne agent that acts on the placenta. Research is ongoing to better understand the fetal signals that contribute to parturition initiation (Mendelson, 2009). Although signals may arise from the fetus, the uterus and cervix likely first must be prepared for labor before a uterotonin produced by or one whose release is stimulated by the fetus can be optimally effective (Casey, 1994).

Uterine Stretch and Parturition

There is now considerable evidence that fetal growth is an important component in uterine activation in phase 1 of parturition. In association with fetal growth, significant increases in myometrial tensile stress and amniotic fluid pressure follow (Fisk, 1992). With uterine activation, stretch is required for induction of specific contraction-associated proteins (CAPs). Specifically, stretch increases expression of the gap junction protein—connexin 43 and of oxytocin receptors. Gastrin-releasing peptide, a stimulatory agonist for smooth muscle, is increased by stretch in the myometrium (Tattersall, 2012). Others have hypothesized that stretch plays an integrated role with fetal-maternal endocrine cascades of uterine activation (Lyll, 2002; Ou, 1997, 1998).

Clinical support for a role of stretch comes from the observation that multifetal pregnancies are at a much greater risk for preterm labor than singletons. And preterm labor is also significantly more common in pregnancies complicated by hydramnios. Although the mechanisms causing preterm birth in these two examples are debated, a role for uterine stretch must be considered.

Cell signaling systems used by stretch to regulate the myometrial cell continue to be defined. This process—*mechano-transduction*—may include activation of cell-surface receptors or ion channels, transmission of signals through extracellular matrix, or release of autocrine molecules that act directly on myometrium (Shynlova, 2009; Young, 2011). For example, the extracellular matrix protein fibronectin and its cell-surface receptor, alpha 5 integrin receptor, are induced in the rodent by stretch (Shynlova, 2007). This interaction may aid force transduction during labor contraction by anchoring hypertrophied myocytes to the uterine extracellular matrix.

Fetal Endocrine Cascades Leading to Parturition

The ability of the fetus to provide endocrine signals that initiate parturition has been demonstrated in several species. Liggins and associates (1967, 1973) demonstrated that the fetus provides the signal for the timely onset of parturition in sheep. This signal was shown to come from the fetal hypothalamic-pituitary-adrenal axis (Whittle, 2001).

FIGURE 21-17 The placental-fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The latter stimulates production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. ACTH = adrenocorticotropic hormone.

Defining the exact mechanisms regulating human parturition has proven more difficult, and all evidence suggests that it is not regulated in the exact manner seen in the sheep. Even so, activation of the human fetal hypothalamic-pituitary-adrenal-placental axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered to prompt many cases of preterm labor (Challis, 2000, 2001). As in the sheep, steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually transform myometrium from a quiescent to contractile state. A key component in the human may be the unique ability of the placenta to produce large amounts of CRH, as shown in [Figure 21-17](#).

Placental Corticotropin-Releasing Hormone Production.

A CRH hormone identical to maternal and fetal hypothalamic CRH is synthesized by the placenta in relatively large amounts (Grino, 1987; Saijonmaa, 1988). One important difference is that, unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol has been shown to *stimulate* placental CRH production. This is by activation of the transcription factor, nuclear factor kappa B (NF- κ B) (Jones, 1989; Marinoni, 1998; Thomson, 2013). This ability makes it possible to create a feed-forward endocrine cascade that does not end until delivery.

Maternal plasma CRH levels are low in the first trimester and rise from midgestation to term. In the last 12 weeks, CRH plasma levels rise exponentially, peaking during labor and then falling precipitously after delivery (Frim, 1988; Sasaki, 1987). Amniotic fluid CRH levels similarly increase in late gestation. CRH is the only trophic hormone-releasing factor to have a specific serum binding protein. During most of pregnancy, it appears that CRH-binding protein (CRH-BP) binds most maternal circulating CRH, and this inactivates it (Lowry, 1993). During later pregnancy, however, CRH-BP levels in

both maternal plasma and amniotic fluid decline, leading to markedly increased levels of bioavailable CRH (Perkins, 1995; Petraglia, 1997).

In pregnancies in which the fetus can be considered to be “stressed” from various complications, concentrations of CRH in fetal plasma, amniotic fluid, and maternal plasma are increased compared with those seen in normal gestation (Berkowitz, 1996; Goland, 1993; McGrath, 2002; Perkins, 1995). The placenta is likely the source for this increased CRH concentration (Torricelli, 2011). For example, placental CRH content was fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins, 1995). Such increases in placental CRH production during normal gestation and the excessive secretion of placental CRH in complicated pregnancies may play a role in fetal adrenal cortisol synthesis (Murphy, 1982). They also may result in the supranormal levels of umbilical cord blood cortisol noted in stressed neonates (Falkenberg, 1999; Goland, 1994).

Corticotropin-Releasing Hormones and Parturition Timing

Placental CRH has been proposed to play several roles in parturition regulation. Placental CRH may enhance fetal cortisol production to provide positive feedback so that the placenta produces more CRH. Late in pregnancy—phase 2 or 3 of parturition—modification in the CRH receptor favors a switch from cAMP formation to increased myometrial cell calcium levels via protein kinase C activation (You, 2012). Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue. And, CRH augments the contraction-inducing potency of a given dose of oxytocin in human myometrial strips (Quarero, 1991, 1992). CRH acts to increase myometrial contractile force in response to PGF_{2 α} (Benedetto, 1994). Finally, CRH has been shown to stimulate fetal adrenal C₁₉-steroid synthesis, thereby increasing substrate for placental aromatization. Increased production of estrogens would shift the estrogen-to-progesterone ratio and promote the expression of a series of myometrial contractile proteins.

Some have proposed that the rising level of CRH at the end of gestation reflects a *fetal-placental clock* (McLean, 1995). CRH levels vary greatly among women, and it appears that the rate of increase in maternal CRH levels is a more accurate predictor of pregnancy outcome than is a single measurement (Leung, 2001; McGrath, 2002). In this regard, the placenta and fetus, through endocrinological events, influence the timing of parturition at the end of normal gestation.

Fetal Lung Surfactant and Parturition

Surfactant protein A (SP-A) produced by the fetal lung is required for lung maturation. Its levels are increased in amniotic fluid at term in mice. Studies in the mouse suggest that the increasing SP-A concentrations in amniotic fluid activate fluid macrophages to migrate into the myometrium and induce NF- κ B (Condon, 2004). This factor activates inflammatory response genes in the myometrium, which in

turn promote uterine contractility. This model supports the supposition that fetal signals play a role in parturition initiation. SP-A is expressed by the human amnion and decidua, is present in the amniotic fluid, and prompts signaling pathways in human myometrial cells (Garcia-Verdugo, 2008; Lee, 2010; Snegovskikh, 2011). The exact mechanisms by which SP-A activates myometrial contractility in women, however, remains to be clarified (Leong, 2008). SP-A selectively inhibits prostaglandin $F_{2\alpha}$ in the term decidua, and amniotic fluid concentration of SP-A declines at term (Chaiworapongsa, 2008).

Fetal Anomalies and Delayed Parturition

There is fragmentary evidence that pregnancies with markedly diminished estrogen production may be associated with prolonged gestation. These “natural experiments” include fetal anencephaly with adrenal hypoplasia and those with inherited placental sulfatase deficiency. The broad range of gestational length seen with these disorders calls into question the exact role of estrogen in human parturition initiation.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine into amniotic fluid—renal agenesis, or into lung secretions—pulmonary hypoplasia, do not prolong human pregnancy. Thus, a fetal signal through the paracrine arm of the fetal-maternal communication system does not appear to be mandated for parturition initiation.

Some brain anomalies of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. More than a century ago, Rea (1898) observed an association between fetal anencephaly and prolonged human gestation. Malpas (1933) extended these observations and described a pregnancy with an anencephalic fetus that was prolonged to 374 days—53 weeks. He concluded that the association between anencephaly and prolonged gestation was attributable to anomalous fetal brain-pituitary-adrenal function. The adrenal glands of the anencephalic fetus are very small and, at term, may be only 5 to 10 percent as large as those of a normal fetus. This is caused by developmental failure of the fetal zone that normally accounts for most of fetal adrenal mass and production of C_{19} -steroid hormones (Chap. 5, p. 108). Such pregnancies are associated with delayed labor and suggest that the fetal adrenal glands are important for the timely onset of parturition (Anderson, 1973).

Phase 3: Uterine Stimulation

This parturition phase is synonymous with uterine contractions that bring about progressive cervical dilatation and delivery. Current data favor the *uterotonin theory of labor initiation*. Increased uterotonin production would follow once phase 1 is suspended and uterine phase 2 processes are implemented. A number of uterotonins may be important to the success of phase 3, that is, active labor (see Fig. 21-15). Just as multiple processes likely contribute to myometrial unresponsiveness of phase 1 of parturition, other processes may contribute jointly to a system that ensures labor success.

Uterotonins that are candidates for labor induction include oxytocin, prostaglandins, serotonin, histamine, PAF,

angiotensin II, and many others. All have been shown to stimulate smooth muscle contraction through G-protein coupling.

Oxytocin and Phase 3 of Parturition

Late in pregnancy, during phase 2 of parturition, there is a 50-fold or more increase in the number of myometrial oxytocin receptors (Fuchs, 1982; Kimura, 1996). This increase coincides with an increase in uterine contractile responsiveness to oxytocin. Moreover, prolonged gestation is associated with a delay in the increase of these receptors (Fuchs, 1984).

Oxytocin—literally, *quick birth*—was the first uterotonin to be implicated in parturition initiation. This nanopeptide is synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The prohormone is transported with its carrier protein, *neurophysin*, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. The prohormone is converted enzymatically to oxytocin during transport (Gainer, 1988; Leake, 1990).

Role of Oxytocin in Phases 3 and 4 of Parturition. Because of successful labor induction with oxytocin, it was logically suspected in parturition initiation. First, in addition to its effectiveness in inducing labor at term, oxytocin is a potent uterotonin and occurs naturally in humans. Subsequent observations provide additional support for this theory: (1) the number of oxytocin receptors strikingly increases in myometrial and decidual tissues near the end of gestation; (2) oxytocin acts on decidual tissue to promote prostaglandin release; and (3) oxytocin is synthesized directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar, 1993; Zingg, 1995).

Although little evidence suggests a role for oxytocin in phase 2 of parturition, abundant data support its important role during second-stage labor and in the puerperium—phase 4 of parturition. Specifically, there are increased maternal serum oxytocin levels: (1) during second-stage labor, which is the end of phase 3 of parturition; (2) in the early puerperium; and (3) during breast feeding (Nissen, 1995). Immediately after delivery of the fetus, placenta, and membranes, which completes parturition phase 3, firm and persistent uterine contractions and myometrial retraction are essential to prevent postpartum hemorrhage. Oxytocin likely causes persistent contractions.

Oxytocin infusion in women promotes increased levels of mRNAs from myometrial genes that encode proteins essential for uterine involution. These include interstitial collagenase, monocyte chemoattractant protein-1, interleukin-8, and urokinase plasminogen activator receptor. Therefore, oxytocin action at the end of labor may be involved in uterine involution.

Prostaglandins and Phase 3 of Parturition

Although their role in parturition phase 2 of noncomplicated pregnancies is less well defined, a critical role for prostaglandins in phase 3 of parturition is clear (MacDonald, 1993). First, levels of prostaglandins—or their metabolites—in amniotic fluid, maternal plasma, and maternal urine are increased during labor (Fig. 21-18). Second, treatment of pregnant women with

FIGURE 21-18 Mean (\pm SD) concentrations of prostaglandin $F_{2\alpha}$ (PGF_{2α}) and prostaglandin E_2 (PGE₂) in amniotic fluid at term before labor and in the upper and forebag compartments during labor at all stages of cervical dilatation. (Data from MacDonald, 1993.)

prostaglandins, by any of several administration routes, causes abortion or labor at all gestational stages. Moreover, administration of prostaglandin H synthase type 2 (PGHS-2) inhibitors to pregnant women will delay spontaneous labor onset and sometimes arrest preterm labor (Loudon, 2003). Last, prostaglandin treatment of myometrial tissue in vitro sometimes causes contraction, dependent on the prostanoïd tested and the physiological status of the tissue treated.

Uterine Events Regulating Prostaglandin Production.

During labor, prostaglandin production within the myometrium and decidua is an efficient mechanism of activating contractions. For example, prostaglandin synthesis is high and unchanging in the decidua during phase 2 and 3 of parturition. Moreover, the receptor level for PGF_{2α} is increased in the decidua at term, and this increase most likely is the regulatory step in prostaglandin action in the uterus. The myometrium synthesizes PGHS-2 with labor onset, but most prostaglandins likely come from the decidua.

The fetal membranes and placenta also produce prostaglandins. Primarily PGE₂, but also PGF_{2α}, are detected in amniotic fluid at all gestational stages. As the fetus grows, prostaglandins levels in the amniotic fluid increase gradually. Their major increases in concentration within amniotic fluid, however, are demonstrable after labor begins (see Fig. 21-18). These higher levels likely result as the cervix dilates and exposes decidual tissue (Fig. 21-19). These increased levels in the forebag compared with those in the upper compartment are believed to follow an inflammatory response that signals the events leading to active labor. Together, the increases in cytokines and prostaglandins further degrade the extracellular matrix, thus weakening fetal membranes.

Findings of Kemp and coworkers (2002) and Kelly (2002) support a possibility that inflammatory mediators aid cervical

FIGURE 21-19 Sagittal view of the exposed forebag and attached decidual fragments after cervical dilatation during labor. (Redrawn from MacDonald, 1996.)

dilatation and alterations to the lower uterine segment. It can be envisioned that they, along with the increased prostaglandin levels measured in vaginal fluid during labor, add to the relatively rapid cervical changes that are characteristic of parturition.

Endothelin-1

The endothelins are a family of 21-amino acid peptides that powerfully induce myometrial contraction (Word, 1990). The endothelin A receptor is preferentially expressed in smooth muscle and effects an increase in intracellular calcium. Endothelin-1 is produced in myometrium of term gestations and is able to induce synthesis of other contractile mediators such as prostaglandins and inflammatory mediators (Momohara, 2004; Sutcliffe, 2009). The requirement of endothelin-1 in normal parturition physiology remains to be established. However, there is evidence of pathologies associated with aberrant endothelin-1 expression, such as premature birth and uterine leiomyomas (Tanfin, 2011, 2012).

Angiotensin II

There are two G-protein-linked angiotensin II receptors expressed in the uterus—AT1 and AT2. In nonpregnant women, the AT2 receptor is predominant, but the AT1 receptor is preferentially expressed in pregnant women (Cox, 1993). Angiotensin II binding to the plasma-membrane receptor evokes contraction. During pregnancy, the vascular smooth muscle that expresses the AT2 receptor is refractory to the pressor effects of infused angiotensin II (Chap. 4, p. 61). In myometrium near term, however, angiotensin II may be another component of the uterotonic system of parturition phase 3 (Anton, 2009).

Contribution of Intrauterine Tissues to Parturition

Although they have a potential role in parturition initiation, the amnion, chorion laeve, and decidua parietalis more likely have an alternative role. The membranes and decidua make up an important tissue shell around the fetus that serves as a physical, immunological, and metabolic shield to protect against untimely initiation of parturition. Late in gestation, however, the fetal membranes may indeed act to prepare for labor.

Amnion

Virtually all of the tensile strength—resistance to tearing and rupture—of the fetal membranes is provided by the amnion (Chap. 5, p. 98). This avascular tissue is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells. It also constitutes a selective filter to prevent fetal particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from amniotic fluid constituents that could worsen decidual or myometrial function or could promote adverse events such as amniotic-fluid embolism (Chap. 41, p. 812).

Several bioactive peptides and prostaglandins that cause myometrial relaxation or contraction are synthesized in amnion (Fig. 21-20). Late in pregnancy, amniotic prostaglandin biosynthesis is increased, and phospholipase A_2 and PGHS-2 show increased activity (Johnson, 2002). Accordingly, many hypothesize that prostaglandins regulate events leading to parturition. It is likely that amnion is the major source for amniotic fluid prostaglandins, and their role in activation of cascades that promote membrane rupture is clear. The influence of amnion-derived prostaglandins on uterine quiescence and activation, however, is less clear. This is because prostaglandin transport from the amnion through the chorion to access maternal tissues is limited by expression of the inactivating enzyme, prostaglandin dehydrogenase.

Chorion Laeve

This tissue layer also is primarily protective and provides immunological acceptance. The chorion laeve is also enriched with enzymes

that inactivate uterotonins. Enzymes include prostaglandin dehydrogenase (PGDH), oxytocinase, and enkephalinase (Cheung, 1990; Germain, 1994). As noted, PGDH inactivates amnion-derived prostaglandins. With chorionic rupture, this barrier would be lost, and prostaglandins could readily influence adjacent decidua and myometrium.

There is also evidence that PGDH levels found in the chorion decline during labor. This would allow increased prostaglandin-stimulated matrix metalloproteinase activity associated with membrane rupture. It would further allow prostaglandin entry into the maternal compartment to promote myometrial contractility (Patel, 1999; Van Meir, 1996; Wu, 2000). It is likely that progesterone maintains chorion PGDH expression, whereas cortisol decreases its expression. Thus, PGDH levels would decrease late in gestation as fetal cortisol production increases and as part of progesterone withdrawal.

Decidua

A metabolic contribution of decidual activation to parturition initiation is an appealing possibility for both anatomical and functional reasons. The generation of decidual uterotonins that act in a paracrine manner on contiguous myometrium is intuitive. In addition, decidua expresses steroid metabolizing enzymes such as 20α -HSD and steroid 5α R1 that may regulate local progesterone withdrawal. Decidual activation is characterized by increased proinflammatory cells and increased expression of proinflammatory cytokines, prostaglandins, and uterotonins such as oxytocin receptors and connexin 43.

Cytokines produced in the decidua can either increase uterotonin production—principally prostaglandins. Or they can act directly on myometrium to cause contraction. Examples are tumor necrosis factor- α (TNF- α) and interleukins 1, 6, 8, and 12. These molecules also can act as chemokines that recruit to the myometrium neutrophils and eosinophils, which further increase contractions and labor (Keelan, 2003).

There is uncertainty whether prostaglandin concentration or output from the decidua increases with term labor onset. Olson and Ammann (2007) suggest that the major regulation

FIGURE 21-20 The amnion synthesizes prostaglandins, and late in pregnancy, synthesis is increased by increased phospholipase A_2 and prostaglandin H synthase, type 2 (PGHS-2) activity. During pregnancy, the transport of prostaglandins from the amnion to maternal tissues is limited by expression of the inactivating enzymes, prostaglandin dehydrogenase (PGDH), in the chorion. During labor, PGDH levels decline, and amnion-derived prostaglandins can influence membrane rupture and uterine contractility. The role of decidual activation in parturition is unclear but may involve local progesterone metabolism and increased prostaglandin receptor concentrations, thus enhancing uterine prostaglandin actions and cytokine production. (Adapted from Smith, 2007.)

of decidual prostaglandin action is not their synthesis but rather increased $\text{PGF}_{2\alpha}$ receptor expression.

Summary: Regulation of Phase 3 and 4 of Parturition

It is likely that multiple and possibly redundant processes contribute to the success of the three active labor phases once phase 1 of parturition is suspended and phase 2 is initiated. Phase 3 is highlighted by increased activation of G-protein-coupled receptors that inhibit cAMP formation, increase intracellular calcium stores, and promote interaction of actin and myosin and subsequent force generation. Simultaneously, cervical proteoglycan composition and collagen structure are altered to a form that promotes tissue distensibility and increased compliance. The net result is initiation of coordinated myometrial contractions of sufficient amplitude and frequency to dilate the prepared cervix and push the fetus through the birth canal. Multiple regulatory ligands orchestrate these processes and vary from endocrine hormones such as oxytocin to locally produced prostaglandins.

In phase 4 of parturition, a complicated series of repair processes are initiated to resolve inflammatory responses and remove glycosaminoglycans, proteoglycans, and structurally compromised collagen. Simultaneously, matrix and cellular components required for complete uterine involution are synthesized, and the dense connective tissue and structural integrity of the cervix is reformed.

LABOR MANAGEMENT PROTOCOLS	452

Labor is the process that leads to childbirth. It begins with the onset of regular uterine contractions and ends with delivery of the newborn and expulsion of the placenta. The term *labor* in the obstetrical context takes on several connotations from the English language. It is undoubtedly true that pregnancy and birth are physiological processes, and as such, labor and delivery should be considered to be normal for most women (Lawrence, 2012). This understanding of normal labor and delivery as a physiological process has come under some scrutiny in the past decade because pelvic floor disorders have been observed to be more prevalent among women who have delivered at least one child (Handa, 2011; Nygaard, 2008). Determining which aspects of childbirth contribute most to this risk has become an area of intense investigation and discussed further in Chapter 30 (p. 588).

MECHANISMS OF LABOR

At the onset of labor, the position of the fetus with respect to the birth canal is critical to the route of delivery and thus should be determined in early labor. Important relationships include fetal lie, presentation, attitude, and position.

Fetal Lie

The relation of the fetal long axis to that of the mother is termed *fetal lie* and is either *longitudinal* or *transverse*. Occasionally, the fetal and the maternal axes may cross at a 45-degree angle, forming an *oblique lie*. This lie is unstable and becomes longitudinal or transverse during labor. A longitudinal lie is present in more than 99 percent of labors at term. Predisposing factors for transverse fetal position include multiparity, placenta previa, hydramnios, and uterine anomalies (Chap. 23, p. 468).

Fetal Presentation

The *presenting part* is that portion of the fetal body that is either foremost within the birth canal or in closest proximity to it. It typically can be felt through the cervix on vaginal examination. Accordingly, in longitudinal lies, the presenting part is either the fetal head or breech, creating *cephalic* and *breech presentations*, respectively. When the fetus lies with the long axis transversely, the *shoulder* is the presenting part. Table 22-1 describes the incidences of the various fetal presentations.

Cephalic Presentation

Such presentations are classified according to the relationship between the head and body of the fetus (Fig. 22-1). Ordinarily, the head is flexed sharply so that the chin is in contact with the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation*. Much

TABLE 22-1. Fetal Presentation in 68,097 Singleton Pregnancies at Parkland Hospital

Presentation	Percent	Incidence
Cephalic	96.8	—
Breech	2.7	1:36
Transverse lie	0.3	1:335
Compound	0.1	1:1000
Face	0.05	1:2000
Brow	0.01	1:10,000

less commonly, the fetal neck may be sharply extended so that the occiput and back come in contact, and the face is foremost in the birth canal—*face presentation* (Fig. 23-6, p. 466). The fetal head may assume a position between these extremes, partially flexed in some cases, with the anterior (large) fontanel, or bregma, presenting—*sinciput presentation*—or partially extended in other cases, to have a *brow presentation* (Fig. 23-8, p. 468). These latter two presentations are usually transient. As labor progresses, sinciput and brow presentations almost always convert into vertex or face presentations by neck flexion or extension, respectively. Failure to do so can lead to dystocia, as discussed in Chapter 23 (p. 455).

The term fetus usually presents with the vertex, most logically because the uterus is piriform or pear shaped. Although the fetal head at term is slightly larger than the breech, the entire *podalic pole* of the fetus—that is, the breech and its flexed extremities—is bulkier and more mobile than the cephalic pole. The *cephalic pole* is composed of the fetal head only. Until approximately 32 weeks, the amniotic cavity is large compared with the fetal mass, and the fetus is not crowded by the uterine walls. Subsequently, however, the ratio of amniotic fluid volume decreases relative to the increasing fetal mass. As a result, the uterine walls are apposed more closely to the fetal parts.

If presenting by the breech, the fetus often changes polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. As discussed in Chapter 28 (p. 559), the incidence of breech presentation decreases with gestational age. It approximates 25 percent at 28 weeks, 17 percent at 30 weeks,

11 percent at 32 weeks, and then decreases to approximately 3 percent at term. The high incidence of breech presentation in hydrocephalic fetuses is in accord with this theory, as the larger fetal cephalic pole requires more room than its podalic pole.

Breech Presentation

When the fetus presents as a breech, the three general configurations are *frank*, *complete*, and *footling presentations* and are described in Chapter 28 (p. 559). Breech presentation may result from circumstances that prevent normal version from taking place. One example is a septum that protrudes into the uterine cavity (Chap. 3, p. 42). A peculiarity of fetal attitude, particularly extension of the vertebral column as seen in frank breeches, also may prevent the fetus from turning. If the placenta is implanted in the lower uterine segment, it may distort normal intrauterine anatomy and result in a breech presentation.

Fetal Attitude or Posture

In the later months of pregnancy, the fetus assumes a characteristic posture described as attitude or habitus as shown in Figure 22-1. As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity. The fetus becomes folded or bent upon itself in such a manner that the back becomes markedly convex; the head is sharply flexed so that the chin is almost in contact with the chest; the thighs are flexed over the abdomen; and the legs are bent at the knees. In all cephalic presentations, the arms are usually crossed over the thorax or become parallel to the sides. The umbilical cord lies in the space between them and the lower extremities. This characteristic posture results from the mode of fetal growth and its accommodation to the uterine cavity.

Abnormal exceptions to this attitude occur as the fetal head becomes progressively more extended from the vertex to the face presentation (see Fig. 22-1). This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column.

Fetal Position

Position refers to the relationship of an arbitrarily chosen portion of the fetal presenting part to the right or left side of the birth canal. Accordingly, with each presentation there may be two positions—right or left. The fetal occiput, chin (mentum), and sacrum are the determining points in vertex, face, and breech presentations, respectively (Figs. 22-2 to 22-6). Because the presenting part may be in either the left or right position, there are left and right occipital, left and right mental, and left and right sacral presentations. These are abbreviated as LO and RO, LM and RM, and LS and RS, respectively.

FIGURE 22-1 Longitudinal lie. Cephalic presentation. Differences in attitude of the fetal body in (A) vertex, (B) sinciput, (C) brow, and (D) face presentations. Note changes in fetal attitude in relation to fetal vertex as the fetal head becomes less flexed.

FIGURE 22-5 Longitudinal lie. Face presentation. Left and right mentum anterior and right mentum posterior positions.

Varieties of Presentations and Positions

For still more accurate orientation, the relationship of a given portion of the presenting part to the anterior, transverse, or posterior portion of the maternal pelvis is considered. Because the presenting part in right or left positions may be directed anteriorly (A), transversely (T), or posteriorly (P), there are six varieties of each of the three presentations as shown in Figures 22-2 to 22-6. Thus, in an occiput presentation, the presentation, position, and variety may be abbreviated in clockwise fashion as:

Approximately two thirds of all vertex presentations are in the left occiput position, and one third in the right.

In shoulder presentations, the acromion (scapula) is the portion of the fetus arbitrarily chosen for orientation with the maternal pelvis. One example of the terminology sometimes employed for this purpose is illustrated in Figure 22-7. The acromion or back of the fetus may be directed either posteriorly or anteriorly and superiorly or inferiorly. Because it is impossible to differentiate exactly the several varieties of shoulder presentation by clinical examination and because such specific differentiation serves no practical purpose, it is customary to refer to all transverse lies simply as *shoulder presentations*. Another term used is *transverse lie*, with *back up* or *back down*, which is clinically important when deciding incision type for cesarean delivery (Chap. 23, p. 468).

Diagnosis of Fetal Presentation and Position

Several methods can be used to diagnose fetal presentation and position. These include abdominal palpation, vaginal examination, auscultation, and, in certain doubtful cases, sonography. Rarely, plain radiographs, computed tomography, or magnetic resonance imaging may be used.

Abdominal Palpation—Leopold Maneuvers

Abdominal examination can be conducted systematically employing the four maneuvers described by Leopold in 1894 and shown in Figure 22-8. The mother lies supine and comfortably positioned with her abdomen bared. These maneuvers may be difficult if not impossible to perform and interpret if the patient is obese, if there is excessive amniotic fluid, or if the placenta is anteriorly implanted.

The first maneuver permits identification of which fetal pole—that is, cephalic or podalic—occupies the uterine fun-

FIGURE 22-7 Transverse lie. Right acromiodorsoposterior (RADP). The shoulder of the fetus is to the mother's right, and the back is posterior.

dus. The breech gives the sensation of a large, nodular mass, whereas the head feels hard and round and is more mobile and ballotable.

Performed after determination of fetal lie, the second maneuver is accomplished as the palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt—the back. On the other, numerous small, irregular, mobile parts are felt—the fetal extremities. By noting whether the back is directed anteriorly, transversely, or posteriorly, fetal orientation can be determined.

The third maneuver is performed by grasping with the thumb and fingers of one hand the lower portion of the maternal abdomen just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver. If the presenting part is deeply engaged, however, the findings from this maneuver are simply indicative that the lower fetal pole is in the pelvis, and details are then defined by the fourth maneuver.

To perform the fourth maneuver, the examiner faces the mother's feet and, with the tips of the first three fingers of each hand, exerts deep pressure in the direction of the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder may be differentiated readily by the third maneuver.

FIGURE 22-8 Leopold maneuvers (A–D) performed in a fetus with a longitudinal lie in the left occiput anterior position (LOA).

Abdominal palpation can be performed throughout the latter months of pregnancy and during and between the contractions of labor. With experience, it is possible to estimate the size of the fetus. According to Lydon-Rochelle and colleagues (1993), experienced clinicians accurately identify fetal malpresentation using Leopold maneuvers with a high sensitivity—88 percent, specificity—94 percent, positive-predictive value—74 percent, and negative-predictive value—97 percent.

Vaginal Examination

Before labor, the diagnosis of fetal presentation and position by vaginal examination is often inconclusive because the presenting part must be palpated through a closed cervix and lower uterine segment. With the onset of labor and after cervical dilatation, vertex presentations and their positions are recognized by palpation of the various fetal sutures and fontanelles. Face and breech presentations are identified by palpation of facial features and fetal sacrum, respectively.

In attempting to determine presentation and position by vaginal examination, it is advisable to pursue a definite routine, comprising four movements. First, the examiner inserts two fingers into the vagina and the presenting part is found. Differentiation of vertex, face, and breech is then accomplished readily. Second, if the vertex is presenting, the fingers are directed posteriorly and then swept forward over the fetal head toward the maternal symphysis (Fig. 22-9). During this movement, the fingers necessarily cross the sagittal suture and its linear course is delineated. Next, the positions of the two fontanelles are ascertained. For this, fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified. Then, with a sweeping motion, the fingers pass along the suture to the other end of the head until the other fontanel is felt and differentiated (Fig. 22-10). Last, the station, or extent to which the presenting part has descended into the pelvis, can also be established at this time (p. 449). Using these maneuvers, the various sutures and fontanelles are located readily (Fig. 7-11, p. 139).

Sonography and Radiography

Sonographic techniques can aid fetal position identification, especially in obese women or in women with rigid abdominal walls.

Zahalka and associates (2005) compared digital examinations with transvaginal and transabdominal sonography for fetal head position determination during second-stage labor and reported that transvaginal sonography was superior.

Occiput Anterior Presentation

In most cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. The fetus enters the pelvis in the *left occiput transverse* (LOT) position in 40 percent of labors and in the *right occiput transverse* (ROT) position in 20 percent (Caldwell, 1934). In *occiput anterior positions*—LOA or ROA—the head either enters the pelvis with the occiput rotated 45 degrees anteriorly from the transverse position, or this rotation occurs subsequently. The mechanism of labor in all these presentations is usually similar.

The positional changes of the presenting part required to navigate the pelvic canal constitute the *mechanisms of labor*.

FIGURE 22-9 Locating the sagittal suture by vaginal examination.

The *cardinal movements of labor* are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion (Fig. 22-11). During labor, these movements not only are sequential but also show great temporal overlap. For example, as part of engagement, there is both flexion and descent of the head. It is impossible for the movements to be completed unless the presenting part descends simultaneously. Concomitantly, uterine contractions effect important modifications in fetal attitude, or habitus, especially after the head has descended into the pelvis. These changes consist principally of fetal straightening, with loss of dorsal convexity and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.

Engagement

The mechanism by which the biparietal diameter—the greatest transverse diameter in an occiput presentation—passes through the pelvic inlet is designated *engagement*. The fetal head may engage during the last few weeks of pregnancy or not until after labor commencement. In many multiparous and some nulliparous women, the fetal head is freely movable above the

pelvic inlet at labor onset. In this circumstance, the head is sometimes referred to as “floating.” A normal-sized head usually does not engage with its sagittal suture directed anteroposteriorly. Instead, the fetal head usually enters the pelvic inlet either transversely or obliquely. Segel and coworkers (2012) analyzed labor in 5341 nulliparous women and found that fetal head engagement before labor onset did not affect vaginal delivery rates in either spontaneous or induced labor.

Asynclitism. The fetal head tends to accommodate to the transverse axis of the pelvic inlet, whereas the sagittal suture, while remaining parallel to that axis, may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected either posteriorly toward the promontory or anteriorly toward the symphysis (Fig. 22-12). Such lateral deflection to a more anterior or posterior position in the pelvis is called *asynclitism*. If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism*. If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism*. With extreme posterior asynclitism, the posterior ear may be easily palpated.

Moderate degrees of asynclitism are the rule in normal labor. However, if severe, the condition is a common reason for cephalopelvic disproportion even with an otherwise normal-sized pelvis. Successive shifting from posterior to anterior asynclitism aids descent.

Descent

This movement is the first requisite for birth of the newborn. In nulliparas, engagement may take place before the onset of labor, and further descent may not follow until the onset of the second stage. In multiparas, descent usually begins with engagement. Descent is brought about by one or more of four forces: (1) pressure of the amniotic fluid, (2) direct pressure of the fundus upon the breech with contractions, (3) bearing-down efforts of maternal abdominal muscles, and (4) extension and straightening of the fetal body.

Flexion

As soon as the descending head meets resistance, whether from the cervix, pelvic walls, or pelvic floor, it normally flexes. With this movement, the chin is brought into more intimate contact with the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter is substituted for the longer occipitofrontal diameter (Figs. 22-13 and 22-14).

FIGURE 22-10 Differentiating the fontanelles by vaginal examination.

FIGURE 22-12 Synclitism and asynclitism.

FIGURE 22-13 Lever action produces flexion of the head. Conversion from occipitofrontal to suboccipitobregmatic diameter typically reduces the anteroposterior diameter from nearly 12 to 9.5 cm.

FIGURE 22-14 Four degrees of head flexion. The solid line represents the occipitofrontal diameter, whereas the broken line connects the center of the anterior fontanel with the posterior fontanel. **A.** Flexion poor. **B.** Flexion moderate. **C.** Flexion advanced. **D.** Flexion complete. Note that with complete flexion, the chin is on the chest. The suboccipitobregmatic diameter, the shortest anteroposterior diameter of the fetal head, is passing through the pelvic inlet.

FIGURE 22-15 Mechanism of labor for the left occiput transverse position, lateral view. **A.** Engagement. **B.** After engagement, further descent. **C.** Descent and initial internal rotation. **D.** Rotation and extension.

Internal Rotation

This movement consists of a turning of the head in such a manner that the occiput gradually moves toward the symphysis pubis anteriorly from its original position or, less commonly, posteriorly toward the hollow of the sacrum (Figs. 22-15 to 22-17). Internal rotation is essential for completion of labor, except when the fetus is unusually small.

Calkins (1939) studied more than 5000 women in labor to ascertain the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about another fourth, internal rotation is completed shortly after the head reaches the pelvic floor; and in the remaining 5 percent, rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions in multiparas. In nulliparas, rotation usually occurs during the next three to five contractions.

Extension

After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the perineal tissues. When the head presses on the pelvic floor, however, two forces come

into play. The first force, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see Fig. 22-16).

FIGURE 22-16 Mechanism of labor for left occiput anterior position.

FIGURE 22-17 Mechanism of labor for right occiput posterior position showing anterior rotation.

With progressive distention of the perineum and vaginal opening, an increasingly larger portion of the occiput gradually appears. The head is born as the occiput, bregma, forehead, nose, mouth, and finally the chin pass successively over the anterior margin of the perineum (see Fig. 22-17). Immediately after its delivery, the head drops downward so that the chin lies over the maternal anus.

External Rotation

The delivered head next undergoes *restitution* (see Fig. 22-11). If the occiput was originally directed toward the left, it rotates toward the left ischial tuberosity. If it was originally directed toward the right, the occiput rotates to the right. Restitution of the head to the oblique position is followed by external rotation completion to the transverse position. This movement corresponds to rotation of the fetal body and serves to bring its bisacromial diameter into relation with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior. This movement apparently is brought about by the same pelvic factors that produced internal rotation of the head.

Expulsion

Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the

perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes.

Occiput Posterior Presentation

In approximately 20 percent of labors, the fetus enters the pelvis in an *occiput posterior* (OP) position (Caldwell, 1934). The right occiput posterior (ROP) is slightly more common than the left (LOP). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis. They also are more commonly seen in association with anterior placentation (Gardberg, 1994a).

In most occiput posterior presentations, the mechanism of labor is identical to that observed in the transverse and anterior varieties, except that the occiput has to internally rotate to the symphysis pubis through 135 degrees, instead of 90 and 45 degrees, respectively (see Fig. 22-17).

Effective contractions, adequate head flexion, and average fetal size together permit most posteriorly positioned occiputs to rotate promptly as soon as they reach the pelvic floor, and labor is not lengthened appreciably. In perhaps 5 to 10 percent of cases, however, rotation may be incomplete or may not take place at all, especially if the fetus is large (Gardberg, 1994b). Poor contractions, faulty head flexion, or epidural

analgesia, which diminishes abdominal muscular pushing and relaxes pelvic floor muscles, may predispose to incomplete rotation. If rotation is incomplete, transverse arrest may result. If no rotation toward the symphysis takes place, the occiput may remain in the direct occiput posterior position, a condition known as *persistent occiput posterior*. Both persistent occiput posterior and transverse arrest represent deviations from the normal mechanisms of labor and are considered further in Chapter 23.

Fetal Head Shape Changes

Caput Succedaneum

In vertex presentations, labor forces alter fetal head shape. In prolonged labors before complete cervical dilatation, the portion of the fetal scalp immediately over the cervical os becomes edematous (Fig. 33-1, p. 647). This swelling, known as the *caput succedaneum*, is shown in [Figures 22-18](#) and [22-19](#). It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent differentiation of the various sutures and fontanelles. More commonly, the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position by noting the location of the caput succedaneum.

Molding

In addition to soft tissue changes, the bony fetal head shape is also altered by external compressive forces and is referred to as *molding* (see Fig. 22-19). Possibly related to Braxton

FIGURE 22-19 Considerable molding of the head and caput succedaneum formation in a recently delivered newborn.

Hicks contractions, some molding develops before labor. Most studies indicate that there is seldom overlapping of the parietal bones. A “locking” mechanism at the coronal and lambdoidal connections actually prevents such overlapping (Carlan, 1991). Molding results in a shortened suboccipitobregmatic diameter and a lengthened mentovertical diameter. These changes are of greatest importance in women with contracted pelves or asynclitic presentations. In these circumstances, the degree to which the head is capable of molding may make the difference between spontaneous vaginal delivery and an operative delivery. Some older literature cited severe head molding as a cause for possible cerebral trauma. Because of the multitude of associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to link molding to any alleged fetal or neonatal neurological sequelae. Most cases of molding resolve within the week following delivery, although persistent cases have been described (Graham, 2006).

FIGURE 22-18 Formation of caput succedaneum and head molding.

CHARACTERISTICS OF NORMAL LABOR

The greatest impediment to understanding normal labor is recognizing its start. The strict definition of labor—*uterine contractions that bring about demonstrable effacement and dilatation of the cervix*—does not easily aid the clinician in determining when labor has actually begun, because this diagnosis is confirmed only retrospectively. Several methods may be used to define its start. One defines onset as the clock time when painful contractions become regular. Unfortunately, uterine activity that causes discomfort, but that does not represent true labor, may develop at any time during pregnancy. False labor often stops spontaneously, or it may proceed rapidly into effective contractions.

A second method defines the onset of labor as beginning at the time of admission to the labor unit. In the United States, admission for labor is frequently based on the extent of cervical dilatation accompanied by painful contractions. If a woman has intact membranes, then a cervical dilatation of 3 to 4 cm or greater is presumed to be a reasonably reliable threshold for the diagnosis of labor. In this case, labor onset commences

FIGURE 22-20 Average labor curves for women with singleton term pregnancies presenting in spontaneous labor with vaginal delivery for nulliparas for 1959–1966 compared with 2002–2008. (From Zhang, 2002.)

with the time of admission. This presumptive method obviates many of the uncertainties in diagnosing labor during earlier stages of cervical dilatation. Laughon and colleagues (2012) compared the duration of spontaneous labor at term in nulliparas delivered in the United States between 1959 and 1966 to that of those delivered from 2002 to 2008. As shown in [Figure 22-20](#), the length of labor increased by approximately 2 hours during those 50 years.

First Stage of Labor

Assuming that the diagnosis has been confirmed, what then are the expectations for the progress of normal labor? A scientific approach was begun by Friedman (1954), who described a characteristic sigmoid pattern for labor by graphing cervical dilatation against time. This graphical approach, based on statistical observations, changed labor management. Friedman developed the concept of three functional labor divisions to describe the physiological objectives of each division as shown in [Figure 22-21](#). First, during the *preparatory division*, although the cervix dilates little, its connective tissue components change considerably (Chap. 21, p. 410). Sedation and conduction analgesia are capable of arresting this labor division. The *dilatational division*, during which dilatation proceeds at its most rapid rate, is unaffected by sedation. Last, the *pelvic division* commences with the deceleration phase of cervical dilatation. The classic labor mechanisms that involve the cardinal fetal movements of the cephalic presentation take place principally during this pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

As shown in [Figure 22-21](#), the pattern of cervical dilatation during the preparatory and dilatational divisions of normal labor is a sigmoid curve. Two phases of cervical dilatation are defined. The *latent phase* corresponds to the preparatory division, and the *active phase* to the dilatational division. And as shown in [Figure 22-22](#), Friedman subdivided the active phase into the *acceleration phase*, the *phase of maximum slope*, and the *deceleration phase*.

FIGURE 22-21 Labor course divided functionally on the basis of dilatation and descent curves into: (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, occupying the phase of maximum slope; and (3) a pelvic division, encompassing both deceleration phase and second stage concurrent with the phase of maximum slope of descent. (Redrawn from Friedman, 1978.)

Latent Phase

The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. The latent phase for most women ends once dilatation of 3 to 5 cm is achieved. This threshold may be clinically useful, for it defines dilatation limits beyond which active labor can be expected.

This concept of a latent phase has great significance in understanding normal human labor, because labor is considerably longer when a latent phase is included. To better illustrate

FIGURE 22-22 Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. In the active phase, there are three identifiable component parts that include an acceleration phase, a phase of maximum slope, and a deceleration phase. (Redrawn from Friedman, 1978.)

FIGURE 22-23 Progress of labor in primigravid women from the time of admission. When the starting point on the abscissa begins with admission to the hospital, a latent phase is not observed.

this, [Figure 22-23](#) shows eight labor curves from nulliparas in whom labor was diagnosed beginning with their admission, rather than with the onset of regular contractions. When labor is defined similarly, there is remarkable similarity of individual labor curves.

Prolonged Latent Phase. Friedman and Sachtleben (1963) defined this by a latent phase exceeding 20 hours in the nullipara and 14 hours in the multipara. These times corresponded to the 95th percentiles. Factors that affected latent phase duration include excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. In those who had been administered heavy sedation, 85 percent of women eventually entered active labor. In another 10 percent, uterine contractions ceased, suggesting that they had false labor. The remaining 5 percent experienced persistence of an abnormal latent phase and required oxytocin stimulation. Amniotomy was discouraged because of the 10-percent incidence of false labor. Sokol and associates (1977) reported a 3- to 4- percent incidence of prolonged latent phase, regardless of parity. Friedman (1972) reported that latent phase prolongation did not adversely influence fetal or maternal morbidity or mortality rates. However, Chelmow and coworkers (1993) disputed the long-held belief that prolongation of the latent phase is benign.

Active Labor

The progress of labor in nulliparas has particular significance because these curves all reveal a rapid change in the slope of cervical dilatation rates between 3 and 5 cm (see [Fig. 22-23](#)). *Thus, cervical dilatation of 3 to 5 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor.* Similarly, these curves provide useful guideposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was 4.9 hours. But the standard deviation of 3.4 hours is large, hence, the active phase was reported to have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilatation ranged from a minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat faster in active-phase labor, with a *minimum* normal rate of 1.5 cm/hr. His analysis of active-phase labor concomitantly describes rates of fetal descent and cervical dilatation (see [Fig. 22-21](#)). Descent begins in the later stage of active dilatation, commencing at 7 to 8 cm in nulliparas and becoming most rapid after 8 cm.

Active-Phase Abnormalities. These have been reported to occur in 25 percent of nulliparous and 15 percent of multiparous labors (Sokol, 1977). Friedman (1972) subdivided active-phase problems into *protraction* and *arrest disorders*. Protraction is defined as a *slow rate* of cervical dilatation or descent, which for nulliparas was < 1.2 cm dilatation per hour or < 1 cm descent per hour. For multiparas, protraction was defined as < 1.5 cm dilatation per hour or < 2 cm descent per hour. Friedman defined arrest as a *complete cessation* of dilatation or descent. *Arrest of dilatation* was defined as 2 hours with no cervical change, and *arrest of descent* as 1 hour without fetal descent. The prognosis for protraction and arrest disorders differs considerably. Friedman found that approximately 30 percent of women with protraction disorders had cephalopelvic disproportion (CPD). This compared with a 45-percent CPD rate for women in whom an arrest disorder developed. Abnormal labor patterns, diagnostic criteria, and treatment methods are summarized in Chapter 23 (p. 456).

Hendricks and colleagues (1970) challenged Friedman's conclusions about the course of normal human labor. Their principal differences included: (1) absence of a latent phase, (2) no deceleration phase, (3) brevity of labor, and (4) dilatation at similar rates for nulliparas and multiparas after 4 cm. They disputed the concept of a latent phase because they observed that the cervix dilated and effaced slowly during the 4 weeks preceding labor. They contended that the *latent phase* actually progressed over several weeks. They also reported that labor was relatively rapid. Specifically, the average time from admission to complete dilatation was 4.8 hours for nulliparas and 3.2 hours for multiparas.

There have been other reports in which investigators have reassessed the Friedman labor curves. Zhang and associates (2010) studied electronic labor records from 62,415 parturients with spontaneous labor at term and vaginal birth. They found that normal labor may take more than 6 hours to progress from 4 to 5 cm and more than 3 hours to progress from 5 to 6 cm dilation. Thereafter, labor accelerated much faster in multiparas. In a study performed at Parkland Hospital, epidural analgesia was found to lengthen the active phase of the Friedman labor curve by 1 hour (Alexander, 2002). This increase was the result of a slight but significant decrease in the rate of cervical dilatation—1.4 cm/hr in women given epidural analgesia compared with 1.6 cm/hr in those without such analgesia. There are now several reports that maternal obesity

lengthens the first stages of labor by 30 to 60 minutes (Chin, 2012; Kominiarek, 2011). Finally, Adams and coworkers (2012) found that maternal fear increased labor by approximately 45 minutes.

Second Stage of Labor

This stage begins with complete cervical dilatation and ends with fetal delivery. The median duration is approximately 50 minutes for nulliparas and about 20 minutes for multiparas, but it is highly variable (Kilpatrick, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilatation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis, with a large fetus, or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may become abnormally long. Robinson and colleagues (2011) found that increasing maternal body mass index did not interfere with the second stage of labor. Abnormalities of this labor stage are described in Chapter 23 (p. 456).

Duration of Labor

Our understanding of the normal duration of labor may be clouded by the many clinical variables that affect conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labor was approximately 9 hours in nulliparous women without regional analgesia, and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparous women were a mean of 6 hours with a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilatation of 5 cm or less. Parity—nulliparous versus multiparous—and cervical dilatation at admission were significant determinants of the length of spontaneous labor. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human labor is relatively short. Zhang and associates (2009a,b) described similar findings in their study of 126,887 deliveries from 12 United States institutions.

Summary of Normal Labor

Labor is characterized by brevity and considerable biological variation. Active labor can be reliably diagnosed when cervical dilatation is 3 cm or more in the presence of uterine contractions. Once this cervical dilatation threshold is reached, normal progression to delivery can be expected, depending on parity, in the ensuing 4 to 6 hours. Anticipated progress during a 1- to 2-hour second stage is monitored to ensure fetal safety. Finally, most women in spontaneous labor, regardless

TABLE 22-2. Recommended Nurse/Patient Ratios for Labor and Delivery

Ratio	Clinical Setting
1:2	Patients in labor
1:1	Patients in second-stage labor
1:1	Patients with medical/obstetrical complications
1:2	Oxytocin induction/augmentation
1:1	During epidural analgesia initiation
1:1	Circulation for cesarean delivery

of parity, if left unaided, will deliver within approximately 10 hours after admission for spontaneous labor. Insufficient uterine activity is a common and correctable cause of abnormal labor progress. *Therefore, when the length of otherwise normal labor exceeds the expected norm, interventions other than cesarean delivery—for example, oxytocin administration—must be first considered.*

MANAGEMENT OF NORMAL LABOR

The ideal management of labor and delivery requires two potentially opposing viewpoints on the part of clinicians. First, birthing should be recognized as a normal physiological process that most women experience without complications. Second, intrapartum complications, often arising quickly and unexpectedly, should be anticipated. Thus, clinicians must simultaneously make every woman and her supporters feel comfortable, yet ensure safety for the mother and newborn should complications suddenly develop. Principles such as these are the basis for a recent “*Call to Action*” by seven national organizations intended to emphasize quality patient care in labor and delivery (Lawrence, 2012). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements. Shown in Table 22-2 are the recommended nurse-to-patient ratios recommended for labor and delivery. Shown in Table 22-3 are the recommended room dimensions for these functions.

TABLE 22-3. Recommended Minimum Room Dimensions for Labor and Delivery

Function	Net Floor Space (square feet)
LDR	340
Intensive care	200
Vaginal delivery	340
Cesarean delivery	440

LDR = labor, delivery, and recovery.
Data from American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012.

Admission Procedures

Pregnant women should be urged to report early in labor rather than to procrastinate until delivery is imminent for fear that they might be experiencing false labor. Early admittance to the labor and delivery unit is important, especially if during antepartum care the woman, her fetus, or both have been identified as being at risk.

Identification of Labor

Although the differentiation between false and true labor is difficult at times, the diagnosis usually can be clarified by contraction frequency and intensity and by cervical dilatation. In those instances when a diagnosis of labor cannot be established with certainty, observation for a longer period is often wise.

Pates and associates (2007) studied the commonly used recommendations given to pregnant women that, in the absence of ruptured membranes or bleeding, uterine contractions 5 minutes apart for 1 hour—that is, ≥ 12 contractions in 1 hour—may signify labor onset. Among 768 women studied at Parkland Hospital, active labor defined as cervical dilatation ≥ 4 cm was diagnosed within 24 hours in three fourths of women with ≥ 12 contractions per hour. Bailit and coworkers (2005) compared labor outcomes of 6121 women who presented in active labor defined as uterine contractions plus cervical dilatation ≥ 4 cm with those of 2697 women who presented in the latent phase. Women admitted during latent-phase labor had more active-phase arrest, more frequent need for oxytocin labor stimulation, and higher rates of chorioamnionitis. It was concluded that physician interventions in women presenting in the latent phase may have been the cause of subsequent labor abnormalities.

Emergency Medical Treatment and Labor Act—EMTALA

Congress enacted EMTALA in 1986 to ensure public access to emergency services regardless of the ability to pay. All Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions and presenting to the emergency department for evaluation.

The definition of an emergency condition makes specific reference to a pregnant woman who is having contractions. Labor is defined as “the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor.” A woman in true labor is considered “unstable” for interhospital transfer purposes until the newborn and placenta are delivered. An unstable woman may, however, be transferred at the direction of the patient or by a physician who certifies that the benefits of treatment at another facility outweigh the transfer risks. Physicians and hospitals violating these federal requirements are subject to civil penalties up to \$50,000 and termination from the Medicare program.

Electronic Fetal Heart Rate Monitoring

As discussed in Chapter 24 (p. 473), electronic fetal heart rate monitoring is routinely used for high-risk pregnancies commencing at admission. Some investigators recommend monitoring women with low-risk pregnancies upon admission as a test of fetal well-being—the so-called *fetal admission test*. If no fetal heart rate abnormalities are detected, continuous electronic monitoring is replaced by intermittent assessment for the remainder of labor. We are of the view that electronic fetal heart rate monitoring is reasonable in the preadmission evaluation of women, including those who subsequently are discharged. At Parkland Hospital, external electronic monitoring is performed for at least 1 hour before discharging the woman who was ascertained to have false labor.

Home Births

A major emphasis of obstetrical care during the 20th century was the movement to birthing in hospitals rather than in homes. In 2006, 98.9 percent of births in the United States took place in hospitals (Martin, 2011). Of the other 1.1 percent, 67.2 percent were in homes, and 27.6 percent were in birthing centers. Between 2004 and 2008, more than half of all states had an increase in home births (MacDorman, 2011). As discussed in Chapter 1 (p. 11) most studies suggest increased risks with home deliveries (Berghella, 2008; Cheng, 2013; de Jonge, 2013; Grunebaum, 2013). Indeed, Chervenak and colleagues (2013) have questioned the ethics of physicians voluntarily involved in home births.

Initial Evaluation

Maternal blood pressure, temperature, pulse, and respiratory rate are recorded. The pregnancy record is promptly reviewed to identify complications. Problems identified or anticipated during prenatal care should be displayed prominently in the pregnancy record. Most often, *unless there has been bleeding in excess of bloody show*, a vaginal examination is performed. The gloved index and second fingers are then introduced into the vagina while avoiding the anal region (Fig. 22-24). The number of vaginal examinations correlates with infection-related morbidity, especially in cases of early membrane rupture.

Ruptured Membranes

The woman should be instructed during the antepartum period to be aware of fluid leakage from the vagina and to report such an event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the possibility of umbilical cord prolapse and compression is greatly increased. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed after membrane rupture, intrauterine infection is more likely as the time interval increases (Herbst, 2007).

Upon sterile speculum examination, ruptured membranes are diagnosed if amniotic fluid pools in the posterior fornix or clear fluid flows from the cervical canal. Although several

FIGURE 22-24 To perform vaginal examination, the labia have been separated with one hand, and the first and second fingers of the other hand are carefully inserted into the introitus.

diagnostic tests for the detection of ruptured membranes have been recommended, none is completely reliable. If the diagnosis remains uncertain, another method involves pH determination of vaginal fluid. The pH of vaginal secretions normally ranges from 4.5 to 5.5, whereas that of amniotic fluid is usually 7.0 to 7.5. The use of the indicator *nitrazine* to identify ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction between these paper strips and vaginal fluids is interpreted by comparison with a standard color chart. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may occur with coexistent blood, semen, or bacterial vaginosis, whereas false-negative tests may result with scant fluid.

Other tests include arborization or ferning of vaginal fluid, which suggests amniotic rather than cervical fluid. Amniotic fluid crystallizes to form a fernlike pattern due to its relative concentrations of sodium chloride, proteins, and carbohydrates (Fig. 4-2, p. 49). Detection of alpha-fetoprotein in the vaginal vault has been used to identify amniotic fluid (Yamada, 1998). Although rarely required, identification may also follow injection of indigo carmine into the amniotic sac via abdominal amniocentesis.

Cervical Assessment

The degree of *cervical effacement* usually is expressed in terms of the length of the cervical canal compared with that of an uneffaced cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as

thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical dilatation is determined by estimating the average diameter of the cervical opening by sweeping the examining finger from the margin of the cervical opening on one side to that on the opposite side. The diameter traversed is estimated in centimeters. The cervix is said to be dilated fully when the diameter measures 10 cm, because the presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

The *position* of the cervix is determined by the relationship of the cervical os to the fetal head and is categorized as posterior, mid-position, or anterior. Along with position, the *consistency* of cervix is determined to be soft, firm, or intermediate between these two.

The level—or *station*—of the presenting fetal part in the birth canal is described in relationship to the ischial spines, which are halfway between the pelvic inlet and the pelvic outlet. When the lowermost portion of the presenting fetal part is at the level of the spines, it is designated as being at zero (0) station. In the past, the long axis of the birth canal above and below the ischial spines was arbitrarily divided into thirds by some and into fifths (approximately 1 cm) by other groups. In 1989, the American College of Obstetricians and Gynecologists adopted the classification of station that divides the pelvis above and below the spines into fifths. Each fifth represents 1 cm above or below the spines. Thus, as the presenting fetal part descends from the inlet *toward* the ischial spines, the designation is −5, −4, −3, −2, −1, then 0 station. Below the spines, as the presenting fetal part descends, it passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at 0 station or below, most often the fetal head has engaged—thus, the biparietal plane has passed through the pelvic inlet. *If the head is unusually molded or if there is an extensive caput formation or both, engagement might not have taken place although the head appears to be at 0 station.*

In a study done at five teaching centers in Denver, residents, nurses, and faculty were surveyed to determine what definitions were being used to describe fetal station (Carollo, 2004). Four different definitions were in use. Disturbingly, these investigators found that few caregivers were aware that others were using different definitions of station! Dupuis and colleagues (2005) tested the reliability of clinical estimations of station using the position of the leading part in centimeters above or below the spines as recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012). A birth simulator was used in which station could be precisely measured and compared with the vaginal examination done by clinicians. They reported that the clinical examiners were incorrect a third of the time.

These five characteristics: cervical dilatation, effacement, consistency, position, and fetal station are assessed when tabulating the Bishop score. This score is commonly used to predict labor induction outcome and is discussed in Chapter 26 (p. 526).

Laboratory Studies

When a woman is admitted in labor, most often the hematocrit or hemoglobin concentration should be rechecked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a standard collection tube with anticoagulant. From this, a heparinized capillary tube is filled to spin in a microhematocrit centrifuge in the labor and delivery unit. This provides a hematocrit value within 3 minutes. The initial collection tube is also sent to the hematology laboratory for evaluation. Another labeled tube of blood is allowed to clot and sent to the blood bank for blood type and antibody screen, if needed. A final sample is collected for syphilis and human immunodeficiency virus (HIV) serology. We obtain a urine specimen for protein determination in hypertensive women only (Chap. 40, p. 729). In some labor units, however, a clean-catch voided specimen is examined in all women for protein and glucose.

Women who have had no prenatal care should be considered to be at risk for syphilis, hepatitis B, and HIV (Chap. 65, p. 1265). In those with no prior prenatal care, these laboratory studies, as well as a blood type and antibody screen, should be performed (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Some states, for example, Texas, require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units, even if these were done during prenatal care.

Management of the First Stage of Labor

As soon as possible after admittance, the remainder of a general examination is completed. Whether a pregnancy is normal can best be determined when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor can then be established based on the needs of the fetus and the mother. Because there are marked individual variations in labor lengths, precise statements as to its anticipated duration are unwise.

Intrapartum Fetal Monitoring

This is discussed in detail in Chapter 24. Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2012) recommend that during first-stage labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during the second stage. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during second-stage labor. For women with pregnancies at risk, fetal heart auscultation is performed at least every 15 minutes during first-stage labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Uterine Contractions

Although usually assessed by electronic monitoring as also discussed in Chapter 24, contractions can be both quantitatively

and qualitatively evaluated manually. With the palm of the hand resting lightly on the uterus, the time of contraction onset is determined. Its intensity is gauged from the degree of firmness the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus during a “firm” contraction. The time at which the contraction disappears is noted next. This sequence is repeated to evaluate the frequency, duration, and intensity of uterine contractions.

Maternal Vital Signs

Temperature, pulse, and blood pressure are evaluated at least every 4 hours. If membranes have been ruptured for many hours before labor onset or if there is a borderline temperature elevation, the temperature is checked hourly. Moreover, with prolonged membrane rupture, defined as greater than 18 hours, antimicrobial administration for prevention of group B streptococcal infections is recommended. This is discussed in Chapter 64 (p. 1249).

Subsequent Cervical Examinations

During the first stage of labor, the need for subsequent vaginal examinations to monitor cervical change and presenting part position will vary considerably. When the membranes rupture, an examination to exclude cord prolapse should be performed expeditiously if the fetal head was not definitely engaged at the previous examination. The fetal heart rate should also be checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals to evaluate labor progress.

Oral Intake

Food should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are not absorbed. Instead, they may be vomited and aspirated (Chap. 25, p. 519). According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2007), sips of clear liquids, occasional ice chips, and lip moisturizers are permitted.

Intravenous Fluids

Although it has become customary in many hospitals to establish an intravenous infusion system routinely early in labor, there is seldom any real need for this in the normal pregnant woman, at least until analgesia is administered. An intravenous infusion system is advantageous during the immediate puerperium to administer oxytocin prophylactically and at times therapeutically when uterine atony persists. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis. Shrivastava and associates (2009) noted shorter labors in nulliparas delivering vaginally who were provided an intravenous normal saline with dextrose solution compared with those given saline solution only. Garite and coworkers (2000) randomly assigned 195 women in

labor to receive either 125 or 250 mL/hr of lactated Ringer or isotonic sodium chloride solution. The mean volume of total intravenous fluid was 2008 mL in the 125 mL/hr group and 2487 mL in the 250 mL/hr group. Labor lasted > 12 hours in significantly more (26 versus 13 percent) of the women given a 125 mL/hr infusion compared with those given 250 mL/hr—26 versus 13 percent, respectively.

Maternal Position

The normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. In bed, the laboring woman should be allowed to assume the position she finds most comfortable—this will be lateral recumbency most of the time. She must not be restricted to lying supine because of resultant aortocaval compression and its potential to lower uterine perfusion (Chap. 4, p. 60). Bloom and colleagues (1998) conducted a randomized trial of walking during labor in more than 1000 women with low-risk pregnancies. They found that walking neither enhanced nor impaired active labor and that it was not harmful. Lawrence and associates (2009) reached similar findings in their Cochrane database review.

Analgesia

This is discussed in detail in Chapter 25. In general, pain relief should depend on the needs and desires of the woman. The American College of Obstetricians and Gynecologists (2009) has specified optimal goals for anesthesia care in obstetrics.

Amniotomy

If the membranes are intact, there is a great temptation, even during normal labor, to perform amniotomy. The presumed benefits are more rapid labor, earlier detection of meconium-stained amniotic fluid, and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity for monitoring. The advantages and disadvantages of amniotomy are discussed in Chapter 26 (p. 531). Importantly, the fetal head must be well applied to the cervix and not be dislodged from the pelvis during the procedure to avert umbilical cord prolapse.

Urinary Bladder Function

Distention of the bladder should be avoided because it can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. During each abdominal examination, the suprapubic region should be inspected and palpated to detect distention. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. At times, those who may be unable to void on a bedpan may be able to ambulate with assistance to a toilet and successfully void. If the bladder is distended and voiding is not possible, catheterization is indicated. Carley and coworkers (2002) found that 51 of 11,332 vaginal deliveries (1 in 200) were complicated by urinary retention. Most women resumed normal voiding before discharge from the hospital. Musselwhite and associates (2007) reported retention in 4.7 percent of women who had labor epidural

analgesia. Risk factors for retention were primiparity, oxytocin-induced or -augmented labor, perineal lacerations, operative vaginal delivery, catheterization during labor, and labor duration > 10 hours.

Management of the Second Stage of Labor

With full cervical dilatation, which signifies the onset of the second stage, a woman typically begins to bear down. With descent of the presenting part, she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may now last 1 minute and recur at an interval no longer than 1½ minute. As discussed on page 447, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, although the interval can be highly variable. Monitoring of the fetal heart rate is discussed on page 450, and interpretation of second-stage electronic fetal heart rate patterns is discussed in Chapter 24 (p. 487).

Expulsive Efforts

In most cases, bearing down is reflexive and spontaneous during second-stage labor. Occasionally, a woman may not employ her expulsive forces to good advantage and coaching is desirable. Her legs should be half-flexed so that she can push with them against the mattress. When the next uterine contraction begins, she is instructed to exert downward pressure as though she were straining at stool. A woman is not encouraged to push beyond the completion of each contraction. Instead, she and her fetus should be allowed to rest and recover. During this period of actively bearing down, the fetal heart rate auscultated immediately after the contraction is likely to be slow but should recover to normal range before the next expulsive effort.

Several positions during the second stage have been recommended to augment pushing efforts. Eason and colleagues (2000) performed an extensive review of various positions and their effect on the incidence of perineal trauma. They found that the supported upright position had no advantages over the recumbent one. Upright positions include sitting, kneeling, squatting, or resting with the back at a 30-degree elevation. Conversely, in their systematic review, Berghella and coworkers (2008) reported good-quality data that supported the upright position. Fetal and obstetrical outcomes appear to be unaffected whether pushing is coached or uncoached during second-stage labor (Bloom, 2006; Tuuli, 2012). The maternal effects of coached pushing were reported by Schaffer and colleagues (2005), who performed urodynamic testing in primigravida 3 months following delivery. Women coached to push during second-stage labor had decreased bladder capacity and decreased first urge to void compared with women encouraged to push or rest as desired. The long-term effects of this practice are yet to be defined.

As the head descends through the pelvis, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery, which is described in Chapter 27 (p. 537).

LABOR MANAGEMENT PROTOCOLS

An orderly and systematic approach to labor management results in reproducible maternal and perinatal outcomes. This was proven by Althabe and coworkers (2008), who randomized implementation of evidence-based care in 19 hospitals in Argentina and Uruguay. Several labor management protocols are subsequently presented. These include those from the National Maternity Hospital in Dublin, the World Health Organization, and from Parkland Hospital.

Active Management of Labor

More than 30 years ago, O'Driscoll and associates (1984) pioneered the concept that a disciplined, standardized labor management protocol reduced the number of cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor*. Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States. With this protocol, labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody “show,” or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilatation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours and high-dose oxytocin infusion, described in Chapter 26 (p. 530), is started unless dilatation of at least 1 cm/hr is documented. Women are constantly attended by midwives. If membranes rupture before admission, oxytocin is begun for no progress at the 1-hour mark.

López-Zeno and colleagues (1992) prospectively compared such active management with their “traditional” approach to labor management at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was significantly lower with active versus traditional management—10.5 versus 14.1 percent, respectively. Subsequent studies did not show this. Wei and associates (2009) in a Cochrane database review found a modest reduction in cesarean delivery rates when active management of labor was compared with standard care. Frigoletto and coworkers (1995) reported another randomized trial with 1934 nulliparous women at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. These observations have since been reported by many others (Brown, 2008).

World Health Organization Partograph

A *partograph* was designed by the World Health Organization (WHO) for use in developing countries (Dujardin, 1992). According to Orji (2008), the partograph is similar for nulliparas and multiparas. Labor is divided into a latent phase, which should last no longer than 8 hours, and an active phase. The

active phase starts at 3 cm dilatation, and progress should be no slower than 1 cm/hr. A 4-hour wait is recommended before intervention when the active phase is slow. Labor is graphed, and analysis includes use of alert and action lines. Lavender and colleagues (2006) randomized 3000 nulliparous women to labor interventions at 2 hours versus 4 hours as recommended by WHO. Their cesarean delivery rate was unaffected, and they concluded that interventions such as amniotomy and oxytocin were needlessly increased using the 2-hour time interval. After their Cochrane Database review, Lavender and associates (2008) do not recommend use of the partograph for standard labor management.

Parkland Hospital Labor Management Protocol

Women are admitted if active labor—defined as cervical dilatation of 3 to 4 cm or more in the presence of uterine contractions—is diagnosed or if ruptured membranes are confirmed. Management guidelines summarized in Figure 22-25 stipulate that a pelvic examination be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within approximately 2 hours of admission. Amniotomy is then performed, and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilatation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in Chapter 26 (p. 530). The goal is uterine activity of 200 to 250 Montevideo units for 2 to 4 hours before dystocia can be diagnosed.

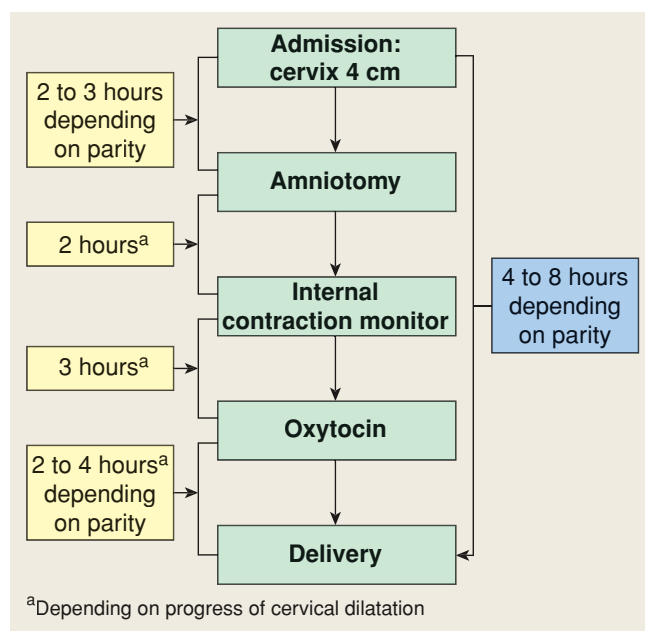

FIGURE 22-25 Schematic of labor management protocol in use at Parkland Hospital. The total admission-to-delivery times are shorter than the potential sum of the intervention intervals because not every woman requires every intervention.

Dilatation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. This can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in more than 20,000 women with uncomplicated pregnancies. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn.

COMPLICATIONS WITH DYSTOCIA	470

DYSTOCIA

There are several labor abnormalities that may interfere with the orderly progression to spontaneous delivery. Generally, these are referred to as *dystocia*. Dystocia literally means *difficult labor* and is characterized by abnormally slow labor progress. It arises from four distinct abnormalities that may exist singly or in combination. First, expulsive forces may be abnormal. For example, uterine contractions may be insufficiently strong or inappropriately coordinated to efface and dilate the cervix—uterine dysfunction. Also, there may be inadequate voluntary maternal muscle effort during second-stage labor. Second, fetal abnormalities of presentation, position, or development may slow labor. Also, abnormalities of the maternal bony pelvis may create a contracted pelvis. And last, soft tissue abnormalities of the reproductive tract may form an obstacle to fetal descent.

More simply, these abnormalities can be mechanistically simplified into three categories that include abnormalities of the *powers*—uterine contractility and maternal expulsive effort; the *passenger*—the fetus; and the *passage*—the pelvis. Common clinical findings in women with these labor abnormalities are summarized in [Table 23-1](#).

Dystocia Descriptors

Abnormalities that are shown in Table 23-1 often interact in concert to produce dysfunctional labor. Commonly used expressions today such as *cephalopelvic disproportion* and *failure to progress* are used to describe ineffective labors. Of these, *cephalopelvic disproportion* is a term that came into use before the 20th century to describe obstructed labor resulting from disparity between the fetal head size and maternal pelvis. But the term originated at a time when the main indication for cesarean delivery was overt pelvic contracture due to rickets (Olah, 1994). Such absolute disproportion is now rare, and most cases result from malposition of the fetal head within the pelvis (asynclitism) or from ineffective uterine contractions. True disproportion is a tenuous diagnosis because two thirds or more of women

TABLE 23-1. Common Clinical Findings in Women with Ineffective Labor

Inadequate cervical dilation or fetal descent:
Protracted labor—slow progress
Arrested labor—no progress
Inadequate expulsive effort—ineffective pushing
Fetopelvic disproportion:
Excessive fetal size
Inadequate pelvic capacity
Malpresentation or position of the fetus
Ruptured membranes without labor

TABLE 23-2. Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment

Labor Pattern	Diagnostic Criteria		Preferred Treatment	Exceptional Treatment
	Nulliparas	Multiparas		
Prolongation Disorder				
Prolonged latent phase	> 20 hr	> 14 hr	Bed rest	Oxytocin or cesarean delivery for urgent problems
Protraction Disorders				
Protracted active-phase dilatation	< 1.2 cm/hr	1.5 cm/hr	Expectant and support	Cesarean delivery for CPD
Protracted descent	< 1 cm/hr	< 2 cm/hr		
Arrest Disorders				
Prolonged deceleration phase	> 3 hr	> 1 hr	Evaluate for CPD: CPD: cesarean No CPD: oxytocin	Rest if exhausted Cesarean delivery
Secondary arrest of dilatation	> 2 hr	> 2 hr		
Arrest of descent	> 1 hr	> 1 hr		
Failure of descent	No descent in deceleration phase or second stage			

CPD = cephalopelvic disproportion.
Modified from Cohen, 1983.

undergoing cesarean delivery for this reason subsequently deliver even larger newborns vaginally. A second phrase, *failure to progress* in either spontaneous or stimulated labor, has become an increasingly popular description of ineffectual labor. This term reflects lack of progressive cervical dilatation or lack of fetal descent. Neither of these two expressions is specific. Terms presented in Table 23-2 and their diagnostic criteria more precisely describe abnormal labor.

Mechanisms of Dystocia

Dystocia as described by Williams (1903) in the first edition of this text is still true today. Figure 23-1 demonstrates the mechanical process of labor and potential obstacles. The cervix and lower uterus are shown at the end of pregnancy and at the end of labor. At the end of pregnancy, the fetal head, to traverse

the birth canal, must encounter a relatively thick lower uterine segment and undilated cervix. The uterine fundus muscle is less developed and presumably less powerful. Uterine contractions, cervical resistance, and the forward pressure exerted by the leading fetal part are the factors influencing the progress of first-stage labor.

As also shown in Figure 23-1B, after complete cervical dilatation, the mechanical relationship between the fetal head size and position and the pelvic capacity, namely *fetopelvic proportion*, becomes clearer as the fetus descends. Because of this, abnormalities in fetopelvic proportions become more apparent once the second stage is reached.

Uterine muscle malfunction can result from uterine overdistention or obstructed labor or both. Thus, *ineffective labor* is generally accepted as a possible warning sign of *fetopelvic disproportion*.

FIGURE 23-1 Diagrams of the birth canal. **A.** At the end of pregnancy. **B.** During the second-stage of labor, showing formation of the birth canal. C.R. = contraction ring; Int. = internal; Ext = external. (Adapted from Williams, 1903.)

Although artificial separation of labor abnormalities into pure *uterine dysfunction* and *fetopelvic disproportion* simplifies classification, it is an incomplete characterization because these two abnormalities are so closely interlinked. Indeed, according to the American College of Obstetricians and Gynecologists (2013), the bony pelvis rarely limits vaginal delivery. In the absence of objective means of precisely distinguishing these two causes of labor failure, clinicians must rely on a *trial of labor* to determine if labor can be successful in effecting vaginal delivery.

Revised Dystocia Diagnosis

In 2009, the total cesarean delivery rate for all births in the United States reached a record high of 32.9 percent (Martin, 2011). This was the 13th consecutive year in which the cesarean rate increased, and it represented a nearly 60-percent increase compared with 20.7 percent in 1996. The 2010 rate of 32.8 percent could suggest that this long trend of increasing cesarean rates may now be moderating (Martin, 2012). Given that many repeat cesarean deliveries are performed after primary operations for dystocia, it is estimated that 60 percent of all cesarean deliveries in the United States are ultimately attributable to the diagnosis of abnormal labor (American College of Obstetricians and Gynecologists, 2013).

To address this increasing cesarean delivery rate, a workshop was convened by the National Institute of Child Health and Human Development (NICHD) and the American College of Obstetricians and Gynecologists (Spong, 2012). The workshop recommended new definitions for arrest of labor progress to prevent unnecessary first cesarean deliveries. Specifically, it concluded that “adequate time for normal latent and active phases of the first stage and for the second stage should be allowed as long as the maternal and fetal conditions permit. The adequate time for each of these stages appears to be longer than traditionally estimated.” The implication of this viewpoint is that changing the diagnostic criteria of abnormal labor will reduce the excessive cesarean birth rate. Shown in Table 23-3 is a synopsis of some of these workshop recommendations for revised labor management criteria. According to the workshop, these definitions “vary somewhat from published criteria and are recommended in recognition of more recent findings regarding labor progress that challenge our long-held practices based on the Friedman curve.”

These proposed new criteria listed in Table 23-3 for normal, and therefore also abnormal labor, were heavily dependent on

TABLE 23-4. Duration of Active Phase Labor: Comparison in Contemporary Reports^a

Investigator	Oxytocin (%)	Epidural (%)	Active Phase, 4–10 cm Dilation
Zhang (2010) ^b	47	84	6 hr
Graseck (2012)	0	70	5 hr
Alexander (2002)	44	100	7.4 hr

^aIncludes nulliparous women at term with spontaneous labor and cervical dilatation 4 cm.

^b*Safe Labor Consortium.*

results of the NICHD-sponsored *Safe Labor Consortium* and on an NICHD-sponsored report on second-stage labor duration (Rouse, 2009; Zhang, 2010). Shown in Table 23-4 is a comparison of active labor phase duration in the *Safe Labor Consortium* compared with other contemporary reports. It is important to note that almost half of the *Consortium* cohort received oxytocin and 84 percent had received epidural analgesia—both factors associated with longer active-phase labor. Indeed, cases using oxytocin and epidural analgesia in the studies of Graseck (2012) and Alexander (2002) had similar active-labor phase durations to those from the *Consortium*. Importantly, all these reports were based on contemporary obstetrical practices.

The *Safe Labor Consortium* report by Zhang and associates (2010) was a multicenter retrospective study using abstracted 2002 to 2008 data from electronic medical records in 19 hospitals across the United States. One purpose of this study was to analyze labor patterns and develop contemporary criteria for labor progress in nulliparas. Shown in Figure 23-2 is a synopsis of the study cohort, which formed the basis of the proposed new criteria for labor progress. Importantly, all women with cesarean delivery were excluded as were all of those with compromised newborn infants. Because of these major exclusions, the pattern of labor now defined as normal is problematic given that only women who achieved vaginal birth with a *normal* infant outcome were included. It is also problematic to conclude that these revised labor criteria will reduce the cesarean rate when the overall rate in the *Safe Labor Consortium* was 30.5 percent using the newly proposed first-stage labor intervals. The authors of a report from the Maternal Fetal Medicine Units Network of the NICHD analyzed labor management practices

TABLE 23-3. Evidence for Adequate and Arrested Labor

Arrest of labor: “. . . the diagnosis of arrest of labor should not be made until adequate time has elapsed.”

Adequate labor: “. . . includes greater than 6 cm dilation with membrane rupture and 4 or more hours of adequate contractions (e.g., greater than 200 Montevideo units) or 6 hours or more if contractions inadequate with no cervical change. . . .”

Second-stage labor: “. . . no progress for more than 4 hours in nulliparous women with an epidural, more than 3 hours in nulliparous women without an epidural. . . .”

“No cesarean before these time limits . . . in the presence of reassuring maternal and fetal status.”

From Spong, 2012.

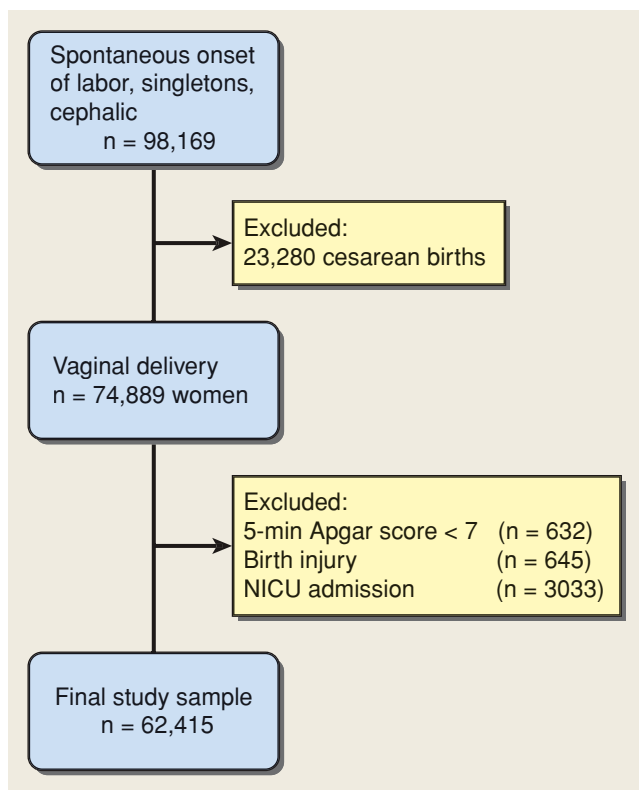

FIGURE 23-2 Study cohort for the analysis of spontaneous labor in the *Safe Labor Consortium*. NICU = neonatal intensive care unit. (Data from Zhang, 2010.)

in 8546 women undergoing primary cesarean delivery for dystocia in a wide cross section of hospitals in the United States (Alexander, 2003). Approximately 92 percent of the cesareans for dystocia were performed in the active phase of labor defined as ≥ 4 cm cervical dilatation. The median admission to delivery interval was 17 hours, and the median cervical dilation was 6 cm before the dystocia diagnosis in women in active-phase labor. Oxytocin was used in 90 percent of women diagnosed with dystocia. It was concluded that bona-fide efforts were being made in contemporary practice to achieve active labor before diagnosing dystocia leading to cesarean delivery.

The report by Rouse and colleagues (2009) on second-stage labor was a secondary analysis of 4126 nulliparous women who reached the second stage during a randomized trial to study fetal pulse oximetry. Of the 360 women—9 percent—whose second stage was > 3 hours, 95 percent had received epidural analgesia. A third of these 360 women—3.5 percent of the whole cohort—had a second stage > 4 hours. The results of this study were interpreted as support for extending the duration of the second stage in nulliparas to beyond the current recommended 3 hours when epidural analgesia is used (American College of Obstetricians and Gynecologists, 2013). The investigators concluded that a fetus born after a > 3 -hour second stage had a higher—albeit still low—neonatal intensive care unit (NICU) admission rate and a low risk for brachial plexus injury (Rouse, 2009).

These latter results are in contrast to those associated with prolonged second-stage labors at Parkland Hospital (Bleich, 2012). This study included 21,991 women of whom 7 percent had a second-stage labor > 3 hours. Most of the 2 percent of

women reaching 4 hours in the second stage had been given epidural analgesia and were awaiting cesarean delivery that was decided on at the 3-hour time point. Typically, oxytocin had been discontinued, and they also had reassuring fetal heart rate tracings that permitted temporization awaiting operative space. Thus, such prolonged second stages were *unintentional* in that further efforts to effect vaginal delivery were not made. Despite these caveats, virtually every adverse infant outcome analyzed increased significantly when the second stage exceeded 3 hours in women with labor epidural analgesia (Table 23-5).

We conclude that at this time, an improved definition of the adequacy of a trial of labor before diagnosing dystocia remains an elusive goal. The newly proposed criteria for first-stage labor are already in use in contemporary practice, and thus they are unlikely to have much impact on the cesarean delivery rate for abnormal labor. Importantly, the purported safety of the proposed new criteria for second-stage labor management should be viewed with caution until more published experiences accrue.

ABNORMALITIES OF THE EXPULSIVE FORCES

Cervical dilatation and propulsion and expulsion of the fetus are brought about by contractions of the uterus, which are reinforced during the second stage by voluntary or involuntary muscular action of the abdominal wall—“pushing.” The diagnosis of uterine dysfunction in the latent phase is difficult and sometimes can be made only in retrospect (Chap. 22, p. 446). Women who are not yet in active labor commonly are erroneously treated for uterine dysfunction.

Beginning in the 1960s, there have been at least three significant advances in the treatment of uterine dysfunction. First is the realization that undue labor prolongation may contribute to maternal and perinatal morbidity and mortality rates. Second, dilute intravenous infusion of oxytocin is used for treatment of certain types of uterine dysfunction. Last, cesarean delivery is selected rather than difficult midforceps delivery when oxytocin fails or its use is inappropriate.

Types of Uterine Dysfunction

Reynolds and coworkers (1948) emphasized that uterine contractions of normal labor are characterized by a gradient of myometrial activity. These forces are greatest and last longest at the fundus—considered *fundal dominance*—and they diminish toward the cervix. Caldeyro-Barcia and colleagues (1950) from Montevideo, Uruguay, inserted small balloons into the myometrium at various levels (Chap. 24, p. 498). They reported that in addition to a gradient of activity, there was a time differential in the onset of the contractions in the fundus, mid-zone, and lower uterine segments. Larks (1960) described the stimulus as starting in one cornu and then several milliseconds later in the other. The excitation waves then join and sweep over the fundus and down the uterus. Normal spontaneous contractions often exert pressures approximating 60 mm Hg (Hendricks, 1959). Even so, the Montevideo group ascertained that the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg.

TABLE 23-5. Neonatal Outcomes in Relation to Second-Stage Labor Duration

Outcome	Second-Stage Duration			p value
	< 3 hours n = 20,502	3–4 hours n = 1062	≥ 4 hours n = 427	
Birthweight ≥ 4000 g	962 (5)	150 (14) ^a	71 (17) ^a	< 0.001
Apgar scores ≤ 3 at 5 minutes	14 (0.1)	3 (0.3) ^a	2 (0.5) ^a	0.002
Umbilical artery blood pH < 7.0	75 (0.4)	8 (0.8) ^a	4 (1) ^d	0.024
Resuscitation at delivery	120 (0.6)	18 (2) ^a	13 (3) ^a	< 0.001
Admission to intensive care	150 (0.7)	22 (2) ^a	8 (2) ^a	< 0.001
Seizures ^b	23 (0.1)	18 (1.7) ^a	13 (3) ^a	< 0.001
Sepsis ^c	32 (0.2)	7 (0.7) ^a	0	< 0.001
Erb palsy	67 (0.3)	15 (1.4) ^a	2 (0.5)	< 0.001
Neonatal death	3 (0.02)	0	0	0.897

All data shown as n (%).

^aSignificantly different compared to < 3 hours.

^bSeizure within the first 24 hours of life.

^cSepsis defined as positive blood culture.

^dSignificant compared to < 3 hours after adjustment for age, race, body mass index, and epidural analgesia.

Data from Bleich, 2012.

From these observations, it is possible to define two types of uterine dysfunction. In the more common *hypotonic uterine dysfunction*, there is no basal hypertonus and uterine contractions have a normal gradient pattern (synchronous), but pressure during a contraction is insufficient to dilate the cervix. In the second type, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction*, either basal tone is elevated appreciably or the pressure gradient is distorted. Gradient distortion may result from more forceful contraction of the uterine midsegment than the fundus or from complete asynchrony of the impulses originating in each cornu or a combination of these two.

■ Active-Phase Disorders

Labor abnormalities are divided into either a slower-than-normal progress—*protraction disorder*—or a complete cessation of progress—*arrest disorder*. A woman must be in the active phase of labor with cervical dilatation to at least 3 to 4 cm to be diagnosed with either of these. Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilatation for 2 hours or more, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as less than 180 Montevideo units, calculated as shown in Figure 23-3, were diagnosed in 80 percent of women with active-phase arrest.

Protraction disorders are less well described, and the time necessary before diagnosing slow progress is undefined. The World Health Organization (1994) has proposed a labor management *partograph* in which protraction is defined as less than 1 cm/hr cervical dilatation for a minimum of 4 hours. Criteria for the diagnosis of protraction and arrest disorders have been recommended by the American College of Obstetricians and Gynecologists (2013). These criteria were adapted from those of Cohen and Friedman (1983), shown in Table 23-2.

Hauth and coworkers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo units, and 40 percent achieve at least 300 Montevideo units. These results suggest that there are certain minimums of uterine activity that should be achieved before performing cesarean delivery for dystocia. Accordingly, the American College of Obstetricians and Gynecologists (2013) has suggested that before the diagnosis of first-stage labor arrest is made, specific criteria should be met. First, the latent phase has been completed, and the cervix is dilated 4 cm or more. Also, a uterine contraction pattern of 200 Montevideo units or more in a 10-minute period has been present for 2 hours without cervical change. Rouse and associates (1999) have challenged the “2-hour rule” on the grounds that a longer time, that is, at least 4 hours, is necessary before concluding that the active phase of labor has failed. We agree.

■ Second-Stage Disorders

As discussed in Chapter 21 (p. 415), fetal descent largely follows complete dilatation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal. Accordingly, disproportion of the fetus and pelvis frequently becomes apparent during second-stage labor.

Until recently, there have been largely unquestioned second-stage rules that limited its duration. These rules were established in American obstetrics by the beginning of the 20th century. They stemmed from concerns about maternal and fetal health, likely regarding infection, and led to difficult forceps operations. The second stage in nulliparas was limited to 2 hours and extended to 3 hours when regional analgesia was used. For multiparas, 1 hour was the limit, extended to 2 hours with regional analgesia.

FIGURE 23-3 Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions, producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.

Cohen (1977) investigated the fetal effects of second-stage labor length at Beth Israel Hospital. He included 4403 term nulliparas in whom electronic fetal heart rate monitoring was performed. The neonatal mortality rate was not increased in women whose second-stage labor exceeded 2 hours. Epidural analgesia was used commonly, and this likely accounted for the large number of pregnancies with a prolonged second stage. These data influenced decisions to permit an additional hour for the second stage when regional analgesia is used.

Menticoglou and coworkers (1995a,b) challenged the prevailing dictums on second-stage duration. These arose because of grave neonatal injuries associated with forceps rotations to shorten second-stage labor. As a result, they allowed a longer second stage to decrease the operative vaginal delivery rate. Between 1988 and 1992, second-stage labor exceeded 2 hours in a fourth of 6041 nulliparas at term. Labor epidural analgesia was used in 55 percent. The length of the second stage, even in those lasting up to 6 hours or more, was not related to neonatal outcome. These results were attributed to careful use of electronic monitoring and scalp pH measurements. These investigators concluded that there is no compelling reason to intervene with a possibly difficult forceps or vacuum extraction because a certain number of hours have elapsed. They observed, however, that after 3 hours in the second stage, delivery by cesarean or other operative method increased progressively. By 5 hours, the prospects for spontaneous delivery in the subsequent hour are only 10 to 15 percent.

Adverse maternal outcomes, however, are increased with prolonged second-stage labor. Myles and Santolaya (2003) analyzed both the maternal and neonatal consequences of this in 7818 women in Chicago between 1996 and 1999. Adverse maternal outcomes in relation to the duration of second-stage labor were increased as shown in Table 23-6. Neonatal mortal-

ity and morbidity rates were not related to the length of the second stage.

Relationship between First- and Second-Stage Labor Duration

It is possible that prolonged first-stage labor presages that with the second stage. Nelson and associates (2013) studied the relationships between the lengths of the first and second stages of labor in 12,523 nulliparous women at term delivered at Parkland Hospital. The length of the second stage significantly increased concomitantly with increasing length of the first stage. The 95th percentile was 15.6 and 2.9 hours for the first and second stages, respectively. Women with first stages lasting longer than 15.6 hr (> 95th percentile) had a 16.3 percent rate of a second-stage labor lasting 3 hr (95th percentile) compared with a 4.5-percent rate in women with first-stages labors lasting less than the 95th percentile.

TABLE 23-6. Clinical Outcomes in Relation to the Duration of Second-Stage Labor			
Clinical Outcome (%)	Duration of Second Stage		
	< 2 hr n = 6529	2-4 hr n = 384	> 4 hr n = 148
Cesarean delivery	1.2	9.2	34.5
Instrumented delivery	3.4	16.0	35.1
Perineal trauma	3.6	13.4	26.7
Postpartum hemorrhage	2.3	5.0	9.1
Chorioamnionitis	2.3	8.9	14.2

Maternal Pushing Efforts

With full cervical dilatation, most women cannot resist the urge to “bear down” or “push” each time the uterus contracts (Chap. 22, p. 451). The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. Bloom and colleagues (2006) studied effects of actively coaching expulsive efforts. They reported that although the second stage was slightly shorter in coached women, there were no other maternal advantages.

At times, force created by abdominal musculature is compromised sufficiently to slow or even prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia may reduce the reflex urge to push and may impair the ability to contract abdominal muscles sufficiently. In other instances, the inherent urge to push is overridden by the intense pain created by bearing down. Two approaches to second-stage pushing in women with epidural analgesia have yielded contradictory results. The first advocates pushing forcefully with contractions after complete dilation, regardless of the urge to push. With the second, analgesia infusion is stopped and pushing begun only after the woman regains the sensory urge to bear down. Fraser and coworkers (2000) found that delayed pushing reduced difficult operative deliveries, whereas Manyonda and associates (1990) reported the opposite. Hansen and colleagues (2002) randomly assigned 252 women with epidural analgesia to one of the two approaches. There were no adverse maternal or neonatal outcomes linked to delayed pushing despite significantly prolonging second-stage labor. Plunkett and coworkers (2003), in a similar study, confirmed these findings.

Fetal Station at Onset of Labor

Descent of the leading edge of the presenting part to the level of the ischial spines (0 station) is defined as engagement. Friedman and Sachtleben (1965, 1976) reported a significant association between higher station at the onset of labor and subsequent dystocia. Handa and Laros (1993) found that fetal station at the time of arrested labor was also a risk factor for dystocia. Roshanfekr and associates (1999) analyzed fetal station in 803 nulliparous women at term in active labor. At admission, the third with the fetal head at or below 0 station had a 5-percent cesarean delivery rate. This is compared with a 14-percent rate for those with higher stations. The prognosis for dystocia, however, was not related to incrementally higher fetal head stations above the pelvic midplane (0 station). Importantly, 86 percent of nulliparous women without fetal head engagement at diagnosis of active labor delivered vaginally. These observations apply especially for parous women because the head typically descends later in labor.

Reported Causes of Uterine Dysfunction

Epidural Analgesia

Various labor factors have been implicated as causes of uterine dysfunction. Of these, epidural analgesia can slow labor (Sharma, 2000). As shown in Table 23-7, epidural analgesia has been associated with lengthening of both first- and second-stage labor and with slowing of the rate of fetal descent. This is documented further in Chapter 25 (p. 515).

TABLE 23-7. Effect of Epidural Analgesia on the Progress of Labor in 199 Nulliparous Women Delivered Spontaneously at Parkland Hospital

Factor ^a	Epidural Analgesia	Meperidine Analgesia	p value
Cervical dilatation at analgesia	4.1 cm	4.2 cm	NS
Active phase	7.9 hr	6.3 hr	.005
Second stage	60 min	48 min	.03
Fetal descent	4.2 cm/hr	7.9 cm/hr	.003

^aMean values are listed.

NS = not stated.

Data from Alexander, 1998.

Chorioamnionitis

Because of the association of prolonged labor with maternal intrapartum infection, some clinicians have suggested that infection itself contributes to abnormal uterine activity. Satin and coworkers (1992) studied the effects of chorioamnionitis on oxytocin stimulation in 266 pregnancies. Infection diagnosed late in labor was found to be a marker of cesarean delivery performed for dystocia, whereas this was not a marker in women diagnosed as having chorioamnionitis early in labor. Specifically, 40 percent of women developing chorioamnionitis after requiring oxytocin for dysfunctional labor later required cesarean delivery for dystocia. It is likely that uterine infection in this clinical setting is a consequence of dysfunctional, prolonged labor rather than a cause of dystocia.

Maternal Position During Labor

Advocacy for recumbency or ambulation during labor has vacillated. Proponents of walking report it to shorten labor, decrease rates of oxytocin augmentation, decrease the need for analgesia, and lower the frequency of operative vaginal delivery (Flynn, 1978; Read, 1981). But other observations do not support this. According to Miller (1983), the uterus contracts more frequently but with less intensity with the mother lying on her back rather than on her side. Conversely, contraction frequency and intensity have been reported to increase with sitting or standing. Lupe and Gross (1986) concluded, however, that there is no conclusive evidence that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. They tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson, 1986; Williams, 1980).

Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation did not affect labor duration. Ambulation did not reduce the need for analgesia, nor was it harmful to the perinate. Because of these observations, we give women without complications the

option to select either recumbency or supervised ambulation during labor. This policy is in agreement with the American College of Obstetricians and Gynecologists (2013), which has concluded that ambulation in labor is not harmful, and mobility may result in greater comfort.

Birthing Position in Second-Stage Labor

Considerable interest has been shown in alternative second-stage labor birth positions and their effect on labor. Gupta and Hofmeyr (2004) in their Cochrane database review compared upright positions with supine or lithotomy positions. Upright positions included sitting in a “birthing chair,” kneeling, squatting, or resting with the back at a 30-degree elevation. With these positions, they found a 4-minute shorter interval to delivery, less pain, and a lower incidence both of nonreassuring fetal heart rate patterns and of operative vaginal delivery. There was, however, an increased rate of blood loss > 500 mL with the upright positions. Berghella and colleagues (2008) hypothesized that parity, less intense aortocaval compression, improved fetal alignment, and larger pelvic outlet diameters might explain these findings. In an earlier study, Russell (1969) described a 20- to 30-percent increase in the area of the pelvic outlet with squatting compared with that in the supine position. Finally, Babayer and associates (1998) cautioned that prolonged sitting or squatting during the second stage may cause common fibular nerve neuropathy.

Water Immersion

A birthing tub or bath has been advocated as a means of relaxation that may contribute to more efficient labor. Cluett and coworkers (2004) randomly assigned 99 laboring women at term in first-stage labor identified to have dystocia to immersion in a birthing pool or to oxytocin augmentation. Water immersion lowered the rate of epidural analgesia use but did not alter the rate of operative delivery. More infants of women in the immersion group were admitted to the NICU. These findings were similar to their subsequent Cochrane database review, except that NICU admission rates were not increased (Cluett, 2009).

Robertson and associates (1998) reported that immersion was not associated with chorioamnionitis or uterine infection. Moreover, Kwee and coworkers (2000) studied the effects of immersion in 20 women and reported that blood pressure decreased, whereas fetal heart rate was unaffected. Neonatal complications unique to underwater birth that have been described include drowning, hyponatremia, waterborne infection, cord rupture, and polycythemia (Austin, 1997; Pinette, 2004).

PREMATURELY RUPTURED MEMBRANES AT TERM

Membrane rupture at term without spontaneous uterine contractions complicates approximately 8 percent of pregnancies. Until recently, management generally included labor stimulation if contractions did not begin after 6 to 12 hours. This intervention evolved more than 50 years ago because of maternal and fetal complications due to chorioamnionitis (Calkins, 1952). Such routine intervention was the accepted practice until challenged by Kappy and colleagues (1979). These investigators reported excessive cesarean delivery in term pregnancies

with ruptured membranes managed with labor stimulation compared with those expectantly managed.

Subsequent research included that of Hannah (1996) and Peleg (1999) and their associates, who enrolled a total of 5042 pregnancies with ruptured membranes in a randomized investigation. They measured the effects of induction versus expectant management and also compared induction using intravenous oxytocin with that using prostaglandin E₂ gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was the preferred management. This determination was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and coworkers (2000) indicated increased adverse outcomes when expectant management at home was compared with in-hospital observation. Mozurkewich and associates (2009) reported lower rates of chorioamnionitis, metritis, and NICU admissions for women with term ruptured membranes whose labors were induced compared with those managed expectantly. At Parkland Hospital, labor is induced soon after admission when ruptured membranes are confirmed at term. The benefit of prophylactic antibiotics in women with ruptured membranes before labor at term is unclear (Passos, 2012).

PRECIPITOUS LABOR AND DELIVERY

Labor can be too slow, but it also can be abnormally rapid. *Precipitous labor and delivery* is extremely rapid labor and delivery. It may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or rarely from the absence of painful sensations and thus a lack of awareness of vigorous labor.

According to Hughes (1972), precipitous labor terminates in expulsion of the fetus in < 3 hours. Using this definition, 89,047 live births—2 percent—were complicated by precipitous labor in the United States during 2006 (Martin, 2009). Despite this incidence, there is little published information concerning adverse effects.

Maternal Effects

Precipitous labor and delivery seldom are accompanied by serious maternal complications if the cervix is effaced appreciably and compliant, if the vagina has been stretched previously, and if the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a non-compliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum. It is in these latter circumstances that the rare condition of *amniotic fluid embolism* most likely develops (Chap. 41, p. 812).

Precipitous labor is frequently followed by uterine atony. *The uterus that contracts with unusual vigor before delivery is likely to be hypotonic after delivery.* Postpartum hemorrhage from uterine atony is discussed in Chapter 41 (p. 784).

Mahon and colleagues (1994) described 99 pregnancies delivered within 3 hours of labor onset. *Short labors* were

defined as a rate of cervical dilatation of 5 cm/hr or faster for nulliparas and 10 cm/hr for multiparas. Such short labors were more common in multiparas who typically had contractions at intervals less than 2 minutes and were associated with placental abruption, meconium, postpartum hemorrhage, cocaine abuse, and low Apgar scores.

Fetal and Neonatal Effects

Adverse perinatal outcomes from precipitous labor may be increased considerably for several reasons. The tumultuous uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Resistance of the birth canal may rarely cause intracranial trauma. Acker and coworkers (1988) reported that Erb or Duchenne brachial palsy was associated with such labors in a third of cases (Chap. 33, p. 648). Finally, during an unattended birth, the newborn may fall to the floor and be injured, or it may need resuscitation that is not immediately available.

Treatment

Unusually forceful spontaneous uterine contractions are not likely to be modified to a significant degree by analgesia. The use of tocolytic agents such as magnesium sulfate is unproven in these circumstances. Use of general anesthesia with agents that impair uterine contractility, such as isoflurane, is often excessively heroic. Certainly, any oxytocin agents being administered should be stopped immediately.

FETOPELVIC DISPROPORTION

Pelvic Capacity

Fetopelvic disproportion arises from diminished pelvic capacity, excessive fetal size, or more usually both. Any contraction of the pelvic diameters that diminishes its capacity can create dystocia during labor. There may be a contraction of the pelvic inlet, the midpelvis, or the pelvic outlet, or a generally contracted pelvis may be caused by combinations of these. Normal pelvic dimensions are additionally discussed in Chapter 2 (p. 32).

Contracted Inlet

The pelvic inlet usually is considered to be contracted if its shortest anteroposterior diameter is < 10 cm or if the greatest transverse diameter is < 12 cm. The anteroposterior diameter of the inlet is commonly approximated by manually measuring the diagonal conjugate, which is approximately 1.5 cm greater (Chap. 2, p. 33). Therefore, inlet contraction usually is defined as a diagonal conjugate < 11.5 cm.

Using clinical and at times, imaging pelvimetry, it is important to identify the shortest anteroposterior diameter through which the fetal head must pass. Occasionally, the body of the first sacral vertebra is displaced forward so that the shortest distance may actually be between this abnormal sacral promontory and the symphysis pubis.

Before labor, the fetal biparietal diameter has been shown to *average* from 9.5 to as much as 9.8 cm. Therefore, it might prove difficult or even impossible for some fetuses to pass

through an inlet that has an anteroposterior diameter of less than 10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries is increased to a similar degree when either the anteroposterior diameter of the inlet is < 10 cm or the transverse diameter is < 12 cm. As expected, when both diameters are contracted, dystocia is much greater than when only one is contracted.

A small woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found that the mean birthweight of their offspring was significantly lower—280 g—in women with a small pelvis than in those with a medium or large pelvis. In veterinary obstetrics, in most species, maternal size rather than paternal size is the important determinant of fetal size.

Normally, cervical dilatation is aided by hydrostatic action of the unruptured membranes or after their rupture, by direct application of the presenting part against the cervix (Fig. 21-7, p. 414). In contracted pelvis, however, because the head is arrested in the pelvic inlet, the entire force exerted by the uterus acts directly on the portion of membranes that contact the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, absent pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilatation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. The better the adaptation, the more efficient the contractions. Thus, cervical response to labor provides a prognostic view of labor outcome in women with inlet contraction.

A contracted inlet also plays an important part in the production of abnormal presentations. In normal nulliparas, the presenting part at term commonly descends into the pelvic cavity before labor onset. When the inlet is contracted considerably or there is marked asynclitism, descent usually does not take place until after labor onset, if at all. Cephalic presentations still predominate, but the head floats freely over the pelvic inlet or rests more laterally in one of the iliac fossae. Accordingly, very slight influences may cause the fetus to assume other presentations. In women with contracted pelvis, face and shoulder presentations are encountered three times more frequently, and the cord prolapses four to six times more often.

Contracted Midpelvis

This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae (Chap. 2, p. 33). A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions. The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded

dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrospinous notch.

Average midpelvis measurements are as follows: *transverse*, or interischial spinous, 10.5 cm; *anteroposterior*, from the lower border of the symphysis pubis to the junction of S₄₋₅, 11.5 cm; and *posterior sagittal*, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interspinous and posterior sagittal diameters of the midpelvis—normally, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or less. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. There is reason to suspect midpelvic contraction whenever the interspinous diameter is < 10 cm. When it measures < 8 cm, the midpelvis is contracted.

Although there is no precise manual method of measuring midpelvic dimensions, a suggestion of contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrospinous notch is narrow. Moreover, Eller and Mengert (1947) noted that the relationship between the intertuberos and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberos diameter is narrow. A normal intertuberos diameter, however, does not always exclude a narrow interspinous diameter.

Contracted Outlet

This finding usually is defined as an interischial tuberos diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberos diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferoposterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra—not the tip of the coccyx. Diminution of the intertuberos diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself but by an often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Although the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in perineal tears. With increased narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to risk of laceration.

Pelvic Fractures

Vallier (2012) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause. Moreover, they note that fracture pattern, minor malalignment, and retained hardware are not absolute indications for cesarean delivery. A history of pelvic fracture

warrants careful review of previous radiographs and possibly pelvimetry later in pregnancy.

Estimation of Pelvic Capacity

The techniques for clinical evaluation using digital examination of the bony pelvis during labor are described in detail in Chapter 2 (p. 32). Briefly, the examiner attempts to judge the anteroposterior diameter of the inlet—the diagonal conjugate, the interspinous diameter of the midpelvis, and the intertuberos distances of the pelvic outlet. A narrow pelvic arch of less than 90 degrees can signify a narrow pelvis. An unengaged fetal head can indicate either excessive fetal head size or reduced pelvic inlet capacity.

The value of radiologic imaging to assess pelvic capacity has also been examined. First, with x-ray pelvimetry alone, the prognosis for successful vaginal delivery in any given pregnancy cannot be established (Mengert, 1948). Thus, the American College of Obstetricians and Gynecologists (2009) considers x-ray pelvimetry to be of limited value in the management of labor with a cephalic presentation.

Advantages of pelvimetry with computed tomography (CT), such as that shown in [Figure 23-4](#), compared with those of conventional x-ray pelvimetry include reduced radiation exposure, greater accuracy, and easier performance. With either method, costs are comparable, and x-ray exposure is small (Chap. 46, p. 934). Depending on the machine and technique employed, fetal doses with CT pelvimetry may range from 250 to 1500 mrad (Moore, 1989).

Advantages of magnetic resonance (MR) pelvimetry include lack of ionizing radiation, accurate measurements, complete fetal imaging, and the potential for evaluating soft tissue dystocia (McCarthy, 1986; Stark, 1985). Zaretsky and colleagues (2005) used MR imaging to measure pelvic and fetal head volume to identify those women at greatest risk of undergoing cesarean delivery for dystocia. Although significant associations were found with some of the measures and cesarean delivery for dystocia, these researchers could not with accuracy predict which individual women would require cesarean delivery. Others have reported similar findings (Sporri, 1997).

Fetal Dimensions in Fetopelvic Disproportion

Fetal size alone is seldom a suitable explanation for failed labor. Even with the evolution of current technology, a fetal size threshold to predict fetopelvic disproportion is still elusive. Most cases of disproportion arise in fetuses whose weight is well within the range of the general obstetrical population. As shown in [Figure 23-5](#), two thirds of neonates who required cesarean delivery after failed forceps delivery weighed less than 3700 g. Thus, other factors—for example, malposition of the head—obstruct fetal passage through the birth canal. These include asynclitism, occiput posterior position, and face and brow presentations.

Estimation of Fetal Head Size

Efforts to clinically and radiographically predict fetopelvic disproportion based on fetal head size have proved disappointing.

FIGURE 23-4 **A.** Anteroposterior view of a digital radiograph. Illustrated is the measurement of the transverse diameter of the pelvic inlet using an electronic cursor. The fetal body is clearly outlined. **B.** Lateral view of a digital radiograph. Illustrated are measurements of the anteroposterior diameters of the inlet using the electronic cursor. **C.** An axial computed tomographic section through the midpelvis. The level of the fovea of the femoral heads was ascertained from the anteroposterior digital radiograph because it corresponds to the level of the ischial spines. The interspinous diameter is measured using the electronic cursor. The total fetal radiation dose using these three exposures is approximately 250 mrad.

Mueller (1885) and Hillis (1930) described a clinical maneuver to predict disproportion. The fetal brow and the suboccipital region are grasped through the abdominal wall with the fingers, and firm pressure is directed downward in the axis of the inlet. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. Thorp and coworkers (1993) performed a prospective evaluation of the *Mueller-Hillis*

maneuver and concluded that there was no relationship between dystocia and failed descent during the maneuver.

Measurements of fetal head diameters using plain radiographic techniques are not used because of parallax distortions. The biparietal diameter and head circumference can be measured sonographically, and there have been attempts to use this information in the management of dystocia. Thurnau and

FIGURE 23-5 Birthweight distribution of 362 newborns born by cesarean delivery at Parkland Hospital (1989–1999) after a failed forceps attempt. Only 12 percent ($n = 44$) of the newborns weighed > 4000 g (dark bars).

colleagues (1991) used the *fetal-pelvic index* to identify labor complications. Unfortunately, the sensitivity of such measurements to predict cephalopelvic disproportion is poor (Ferguson, 1998). We are of the view that there is no currently satisfactory method for accurate prediction of fetopelvic disproportion based on head size.

Face Presentation

With this presentation, the head is hyperextended so that the occiput is in contact with the fetal back, and the chin (mentum) is presenting (Fig. 23-6). The fetal face may present with the chin (mentum) anteriorly or posteriorly, relative to the maternal symphysis pubis (Chap. 22, p. 436). Although some mentum posterior presentations persist, most convert spontaneously to anterior even in late labor (Duff, 1981). If not, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion of the fetal head necessary to negotiate the birth canal. Thus, a mentum posterior presentation is undeliverable except with a very preterm fetus.

Face presentations rarely deliver as such vaginally. Cruikshank and White (1973) reported an incidence of 1 in 600, or 0.17 percent. As shown in Table 22-1 (p. 434), among more than 70,000 singleton newborns delivered at Parkland Hospital, approximately 1 in 2000 had a face presentation at delivery.

Etiology

Causes of face presentations are numerous and include conditions that favor extension or prevent head flexion. Preterm infants, with their smaller head dimensions, can engage before conversion to vertex position (Shaffer, 2006). In exceptional instances, marked enlargement of the neck or coils of cord around the neck may cause extension. Bashiri and associates (2008) reported that fetal malformations and hydramnios were risk factors for face or brow presentations. Anencephalic fetuses naturally present by the face.

FIGURE 23-6 Face presentation. The occiput is the longer end of the head lever. The chin is directly posterior. Vaginal delivery is impossible unless the chin rotates anteriorly.

Extended positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and coworkers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction should be kept in mind when considering management.

High parity is a predisposing factor to face presentation (Fuchs, 1985). In these cases, a pendulous abdomen permits the back of the fetus to sag forward or laterally, often in the same direction in which the occiput points. This promotes extension of the cervical and thoracic spine.

Diagnosis

Face presentation is diagnosed by vaginal examination and palpation of facial features. As discussed in Chapter 28 (p. 560), it is possible to mistake a breech for a face presentation because the anus may be mistaken for the mouth and the ischial tuberosities for the malar prominences. The radiographic demonstration of the hyperextended head with the facial bones at or below the pelvic inlet is characteristic.

Mechanism of Labor

Face presentations rarely are observed above the pelvic inlet. Instead, the brow generally presents early and is usually converted to present the face after further extension of the head during descent. The mechanism of labor in these cases consists of the cardinal movements of descent, internal rotation, and flexion, and the accessory movements of extension and external rotation (Fig. 23-7). Descent is brought about by the same

FIGURE 23-7 Mechanism of labor for right mentoposterior position with subsequent rotation of the mentum anteriorly and delivery.

factors as in cephalic presentations. Extension results from the relation of the fetal body to the deflected head, which is converted into a two-armed lever, the longer arm of which extends from the occipital condyles to the occiput. When resistance is encountered, the occiput must be pushed toward the back of the fetus while the chin descends.

The objective of internal rotation of the face is to bring the chin under the symphysis pubis. Only in this way can the neck traverse the posterior surface of the symphysis pubis. If the chin rotates directly posteriorly, the relatively short neck cannot span the anterior surface of the sacrum, which measures about 12 cm in length. Moreover, the fetal brow (bregma) is pressed against the maternal symphysis pubis. This position precludes flexion necessary to negotiate the birth canal. Hence, birth of the head from a mentum posterior position is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except when the fetus is extremely small or macerated. Internal rotation results from the same factors as in vertex presentations.

After anterior rotation and descent, the chin and mouth appear at the vulva, the undersurface of the chin presses against the symphysis, and the head is delivered by flexion. The nose, eyes, brow (bregma), and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus.

Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations.

Edema may sometimes significantly distort the face. At the same time, the skull undergoes considerable molding, manifested by an increase in length of the occipitomenal diameter of the head.

Management

In the absence of a contracted pelvis, and with effective labor, successful vaginal delivery usually will follow. Fetal heart rate monitoring is probably better done with external devices to avoid damage to the face and eyes. Because face presentations among term-size fetuses are more common when there is some degree of pelvic inlet contraction, cesarean delivery frequently is indicated. Attempts to convert a face presentation manually into a vertex presentation, manual or forceps rotation of a persistently posterior chin to a mentum anterior position, and internal podalic version and extraction are dangerous and should not be attempted.

Brow Presentation

This rare presentation is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel

FIGURE 23-8 Brow posterior presentation.

presents at the pelvic inlet. As shown in [Figure 23-8](#), the fetal head thus occupies a position midway between full flexion (occiput) and extension (face). Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists.

Etiology and Diagnosis

The causes of persistent brow presentation are the same as those for face presentation. A brow presentation is commonly unstable and often converts to a face or an occiput presentation (Cruikshank, 1973). The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose are felt on vaginal examination, but neither the mouth nor the chin is palpable.

Mechanism of Labor

With a very small fetus and a large pelvis, labor is generally easy, but with a larger fetus, it is usually difficult. This is because engagement is impossible until there is marked molding that shortens the occipitomenal diameter or more commonly, until there is either flexion to an occiput presentation or extension to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomenal diameter is diminished.

In transient brow presentations, the prognosis depends on the ultimate presentation. If the brow persists, prognosis is poor for vaginal delivery unless the fetus is small or the birth canal is large. Principles of management are the same as those for a face presentation.

Transverse Lie

In this position, the long axis of the fetus is approximately perpendicular to that of the mother. When the long axis forms an acute angle, an *oblique lie* results. The latter is usually only transitory, because either a longitudinal or transverse lie commonly results when labor supervenes. For this reason, the oblique lie is called an *unstable lie* in Great Britain.

In a transverse lie, the shoulder is usually positioned over the pelvic inlet. The head occupies one iliac fossa, and the breech the other. This creates a *shoulder presentation* in which the side of the mother on which the acromion rests determines the designation of the lie as right or left acromial. And because in either position the back may be directed anteriorly or posteriorly, superiorly or inferiorly, it is customary to distinguish varieties as dorsoanterior and dorsoposterior ([Fig. 23-9](#)).

Transverse lie was found once in 322 singleton deliveries (0.3 percent) at both the Mayo Clinic and the University of Iowa Hospital (Cruikshank, 1973; Johnson, 1964). This is remarkably similar to the incidence at Parkland Hospital of approximately 1 in 335 singleton fetuses.

Etiology

Some of the more common causes of transverse lie include: (1) abdominal wall relaxation from high parity, (2) preterm fetus, (3) placenta previa, (4) abnormal uterine anatomy, (5) hydramnios, and (6) contracted pelvis.

Women with four or more deliveries have a tenfold incidence of transverse lie compared with nulliparas. A relaxed and pendulous abdomen allows the uterus to fall forward, deflecting the long axis of the fetus away from the axis of the birth canal and into an oblique or transverse position. Placenta previa and pelvic contraction act similarly. A transverse or oblique lie occasionally develops in labor from an initial longitudinal position.

Diagnosis

A transverse lie is usually recognized easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballotable head is found in one iliac fossa and the breech in the other. The position of the back is readily identifiable. When the back is anterior ([Fig. 23-9](#), p. 469), a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodulations representing fetal small parts are felt through the abdominal wall.

On vaginal examination, in the early stages of labor, if the side of the thorax can be reached, it may be recognized by the “gridiron” feel of the ribs. With further dilatation, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed.

FIGURE 23-9 Leopold maneuver performed on a woman with a fetal transverse lie, right acromiodorsoanterior position. **A.** First maneuver. **B.** Second maneuver. **C.** Third maneuver. **D.** Fourth maneuver.

Mechanism of Labor

Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses (Fig. 23-10). After some descent, the shoulder is arrested by the margins of the pelvic inlet, with the head in one iliac fossa and the breech in the other. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a retraction ring rises increasingly higher and becomes more marked. With this *neglected transverse lie*, the uterus will eventually rupture. Even without this complication, morbidity is increased because of the frequent association with placenta previa, the increased likelihood of cord prolapse, and the necessity for major operative efforts.

If the fetus is small—usually < 800 g—and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against its abdomen. A portion of the thoracic wall below the

shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time. The fetus, which is doubled upon itself and thus sometimes referred to as *conduplicato corpore*, is expelled.

Management

Active labor in a woman with a transverse lie is usually an indication for cesarean delivery. Before labor or early in labor, with the membranes intact, attempts at external version are worthwhile in the absence of other complications. If the fetal head can be maneuvered by abdominal manipulation into the pelvis, it should be held there during the next several contractions in an attempt to fix the head in the pelvis.

With cesarean delivery, because neither the feet nor the head of the fetus occupies the lower uterine segment, a low transverse incision into the uterus may lead to difficult fetal extraction. This is especially true of dorsoanterior presentations. Therefore, a vertical incision is typically indicated (Chap. 30, p. 598).

Compound Presentation

Incidence and Etiology

In a compound presentation, an extremity prolapses alongside the presenting part, and both present simultaneously in the pelvis (Fig. 23-11). Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. At Parkland Hospital, compound presentations were identified in only 68 of more than 70,000 singleton fetuses—an incidence of approximately 1 in 1000. Causes of compound presentations are conditions that prevent complete occlusion of the pelvic inlet by the fetal head, including preterm labor.

Management and Prognosis

In most cases, the prolapsed part should be left alone, because most often it will not interfere with labor. If the arm is prolapsed alongside the head, the condition should be observed closely to ascertain whether the arm retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed arm should be pushed gently upward and the head simultaneously downward by fundal pressure. Tebes and coworkers (1999) described a tragic outcome in a newborn delivered spontaneously with the hand alongside the head. The infant developed

FIGURE 23-10 Neglected shoulder presentation. A thick muscular band forming a pathological retraction ring has developed just above the thin lower uterine segment. The force generated during a uterine contraction is directed centripetally at and above the level of the pathological retraction ring. This serves to stretch further and possibly to rupture the thin lower segment below the retraction ring.

ischemic necrosis of the presenting forearm, which required amputation. In general, rates of perinatal mortality and morbidity are increased as a result of concomitant preterm delivery, prolapsed cord, and traumatic obstetrical procedures.

COMPLICATIONS WITH DYSTOCIA

Maternal Complications

Dystocia, especially if labor is prolonged, is associated with an increased incidence of several common obstetrical and neonatal complications. Intrapartum chorioamnionitis and postpartum pelvic infection are more common with desultory and prolonged labors. Postpartum hemorrhage from atony is increased with prolonged and augmented labors. There is also a higher incidence of uterine tears with hysterotomy if the fetal head is impacted in the pelvis.

Uterine Rupture

Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor, particularly in women of high parity and in those with a prior cesarean delivery (Chap. 41, p. 790). When disproportion is so pronounced that there is no engagement or descent, the lower uterine segment becomes increasingly stretched, and rupture may follow. In such cases, there is usually an exaggeration of the normal *contraction ring* shown in Figure 23-1.

FIGURE 23-11 Compound presentation. **A.** The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal, and the head may then descend normally. **B.** Photograph of a small 34-week fetus with a compound presentation that delivered uneventfully with the hand presenting first. (Photograph contributed by Dr. Elizabeth Mosier.)

Pathological Retraction Ring. Localized rings or constrictions of the uterus develop in association with prolonged obstructed labors that are seldom encountered today. The *pathological retraction ring of Bandl* is associated with marked stretching and thinning of the lower uterine segment. The ring may be seen clearly as a uterine indentation and signifies impending rupture of the lower uterine segment.

Following birth of a first twin, a pathological ring may still develop occasionally as hourglass constrictions of the uterus. The ring can sometimes be relaxed and delivery effected with appropriate general anesthesia, but occasionally prompt

cesarean delivery offers a better prognosis for the second twin (Chap. 45, p. 917).

Fistula Formation

With dystocia, the presenting part is firmly wedged into the pelvic inlet and does not advance for a considerable time. Tissues of the birth canal lying between the leading part and the pelvic wall may be subjected to excessive pressure. Because of impaired circulation, necrosis may result and become evident several days after delivery as vesicovaginal, vesicocervical, or rectovaginal fistulas. Most often, pressure necrosis follows a very prolonged second stage. They are rarely seen today except in undeveloped countries.

Pelvic Floor Injury

During childbirth, the pelvic floor is exposed to direct compression from the fetal head and to downward pressure from maternal expulsive efforts. These forces stretch and distend the pelvic floor, resulting in functional and anatomical alterations in the muscles, nerves, and connective tissues. There is accumulating evidence that such effects on the pelvic floor during childbirth lead to urinary incontinence and to pelvic organ prolapse (Handa, 2011). As discussed in Chapter 27 (p. 548), the anal sphincter is torn in 3 to 6 percent of deliveries, and many of these women report subsequent fecal or gas incontinence. Many of these long-term sequelae have contributed to the current trend of *cesarean delivery on maternal request* discussed in Chapter 30 (p. 589).

Postpartum Lower Extremity Nerve Injury

Wong and colleagues (2003) reviewed neurological injury involving the lower extremities in association with labor and delivery. The most common mechanism is external compression of the common fibular (formerly common peroneal) nerve. This is usually caused by inappropriate leg positioning in stirrups, especially during prolonged second-stage labor. These and other injuries are discussed in Chapter 36 (p. 676). Fortunately, symptoms resolve within 6 months of delivery in most women.

Perinatal Complications

Similar to the mother, the incidence of peripartum fetal sepsis is increased with longer labors. *Caput succedaneum* and *molding* develop commonly and may be impressive (Fig. 22-19, p. 444) (Buchmann, 2008). Mechanical trauma such as nerve injury, fractures, and cephalohematoma are also more frequent and discussed fully in Chapter 33 (p. 645).

FETAL DISTRESS	491
MECONIUM IN THE AMNIONIC FLUID	493
FETAL HEART RATE PATTERNS AND BRAIN DAMAGE	495
CURRENT RECOMMENDATIONS	497
INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY	497

Following earlier work by Hon (1958), continuous electronic fetal monitoring (EFM) was introduced into obstetrical practice in the late 1960s. No longer were intrapartum fetal surveillance and the suspicion of fetal distress based on periodic auscultation with a fetoscope. Instead, the continuous graph-paper portrayal of the fetal heart rate was potentially diagnostic in assessing pathophysiological events affecting the fetus. Indeed, there were great expectations: (1) that electronic fetal heart rate monitoring provided accurate information, (2) that the information was of value in diagnosing fetal distress, (3) that it would direct intervention to prevent fetal death or morbidity, and (4) that continuous electronic fetal heart rate monitoring was superior to intermittent methods.

When first introduced, electronic fetal heart rate monitoring was used primarily in complicated pregnancies, but gradually became used in most pregnancies. By 1978, it was estimated that nearly two thirds of American women were being monitored electronically during labor (Banta, 1979). Currently, more than 85 percent of all live births in the United States undergo electronic fetal monitoring (Ananth, 2013). Indeed,

fetal monitoring has become the most prevalent obstetrical procedure in this country.

ELECTRONIC FETAL MONITORING

Internal (Direct) Electronic Monitoring

The fetus can be monitored electronically by direct or indirect methods. Direct fetal heart measurement is accomplished by attaching a bipolar spiral electrode directly to the fetus (Fig. 24-1). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. Vaginal body fluids create a saline electrical bridge that completes the circuit and permits measurement of the voltage differences between the two poles. The two wires of the bipolar electrode are attached to a reference electrode on the maternal thigh to eliminate electrical interference. The electrical fetal cardiac signal—P wave, QRS complex, and T wave—is amplified and fed into a cardiometer for heart rate calculation. The peak R-wave voltage is the portion of the fetal electrocardiogram most reliably detected.

An example of the method of fetal heart rate processing employed when a scalp electrode is used is shown in Figure 24-2. Time (t) in milliseconds between fetal R waves is fed into a cardiometer, where a new fetal heart rate is set with the arrival of each new R wave. As also shown in Figure 24-2, a premature atrial contraction is computed as a heart rate acceleration because the interval (t_2) is shorter than the preceding one (t_1). The phenomenon of continuous R-to-R wave fetal heart rate computation is known as *beat-to-beat variability*. The physiological event being counted, however, is not a mechanical event corresponding to a heartbeat but rather an electrical event.

Electrical cardiac complexes detected by the electrode include those generated by the mother. Although the maternal

FIGURE 24-1 Internal electronic fetal monitoring. **A.** Scalp electrode penetrates the fetal scalp by means of a coiled electrode. **B.** Schematic representation of a bipolar electrode attached to the fetal scalp for detection of fetal QRS complexes (F). Also shown is the maternal heart and corresponding electrical complex (M) that is detected.

electrocardiogram (ECG) signal is approximately five times stronger than the fetal ECG, its amplitude is diminished when it is recorded through the fetal scalp electrode. In a live fetus, this low maternal ECG signal is detected but masked by the fetal ECG. If the fetus is dead, the weaker maternal signal will be amplified and displayed as the “fetal” heart rate (Freeman, 2003). Shown in [Figure 24-3](#) are simultaneous recordings of maternal chest wall ECG signals and fetal scalp electrode ECG signals. This fetus is experiencing premature atrial contractions, which cause the cardiometer to rapidly and erratically seek new heart rates, resulting in the “spiking” shown in the standard fetal monitor tracing. Importantly, when the fetus

FIGURE 24-2 Schematic representation of fetal electrocardiographic signals used to compute continuing beat-to-beat heart rate with scalp electrodes. Time intervals (t_1 , t_2 , t_3) in milliseconds between successive fetal R waves are used by a cardiometer to compute instantaneous fetal heart rate. ECG = electrocardiogram; PAC = premature atrial contraction.

is dead, the maternal R waves are still detected by the scalp electrode as the next best signal and are counted by the cardiometer ([Fig. 24-4](#)).

External (Indirect) Electronic Monitoring

Membrane rupture may be avoided by use of external detectors to monitor fetal heart action. External monitoring, however, does not provide the precision of fetal heart rate measurement afforded by internal monitoring (Nunes, 2014).

The fetal heart rate is detected through the maternal abdominal wall using the *ultrasound Doppler principle* ([Fig. 24-5](#)). Ultrasound waves undergo a shift in frequency as they are reflected from moving fetal heart valves and from pulsatile blood ejected during systole (Chap. 10, p. 209). The unit consists of a transducer that emits ultrasound and a sensor to detect a shift in frequency of the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound waves poorly. The device is held in position by a belt. Care should be taken that maternal arterial pulsations are not confused with fetal cardiac motion (Neilson, 2008).

Ultrasound Doppler signals are edited electronically before fetal heart rate data are printed onto monitor paper. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the fetal heart rate has regularity whereas “noise” is random and without regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the fetal heart rate is printed. Such electronic editing has greatly improved the tracing quality of the externally recorded fetal heart rate.

FIGURE 24-3 The top tracing shows standard fetal monitor tracing of heart rate using a fetal scalp electrode. Spiking of the fetal rate in the monitor tracing is due to premature atrial contractions. The second panel displays accompanying contractions. The bottom two tracings represent cardiac electrical complexes detected from fetal scalp and maternal chest wall electrodes. ECG = electrocardiogram; F = fetus; M = mother; PAC = fetal premature atrial contraction.

FIGURE 24-4 Placental abruption. In the upper panel, the fetal scalp electrode first detected the heart rate of the dying fetus. After fetal death, the maternal electrocardiogram complex is detected and recorded. The second panel displays an absence of uterine contractions.

Fetal Heart Rate Patterns

It is now generally accepted that interpretation of fetal heart rate patterns can be problematic because of the lack of agreement on definitions and nomenclature (American College of Obstetricians and Gynecologists, 2013b). In one example, Blackwell and colleagues (2011) asked three maternal-fetal medicine specialists to independently interpret 154 fetal heart rate tracings. Interobserver agreement was poor for the most ominous tracings and “moderate” for less severe patterns. The authors cautioned that their results represented idealized circumstances that should not be considered reflective of routine clinical practice.

The National Institute of Child Health and Human Development (NICHD) Research Planning Workshop

FIGURE 24-5 Ultrasound Doppler principle used externally to measure fetal heart motions. Pulsations of the maternal aorta also may be detected and erroneously counted. (Adapted from Klavan, 1977.)

(1997) brought together investigators with expertise in the field to propose standardized, unambiguous definitions for interpretation of fetal heart rate patterns during labor. This workshop was repeated in 2008. The definitions proposed and shown in [Table 24-1](#) as a result of this second workshop are used in this chapter. First, it is important to recognize that interpretation of electronic fetal heart rate data is based on the visual pattern of the heart rate as portrayed on chart recorder graph paper.

Thus, the choice of vertical and horizontal scaling greatly affects the appearance of the fetal heart rate. Scaling factors recommended by the workshop are 30 beats per minute (beats/min or bpm) per vertical cm (range, 30 to 240 bpm) and 3 cm/min chart recorder paper speed. Fetal heart rate variation is falsely displayed at the slower 1 cm/min paper speed compared with that of the smoother baseline recorded at 3 cm/min ([Fig. 24-6](#)). Thus, pattern recognition can be considerably distorted depending on the scaling factors used.

Baseline Fetal Heart Activity

This refers to the modal characteristics that prevail apart from periodic accelerations or decelerations associated with uterine contractions. Descriptive characteristics of baseline fetal heart activity include *rate*, *beat-to-beat variability*, *fetal arrhythmia*, and distinct patterns such as *sinusoidal* or *saltatory* fetal heart rates.

Rate

With increasing fetal maturation, the heart rate decreases. This continues postnatally such that the average rate is 90 bpm by age 8 (Behrman, 1992). Pillai and James (1990) longitudinally studied fetal heart rate characteristics in 43 normal pregnancies. The baseline fetal heart rate decreased an average of 24 bpm between 16 weeks and term, or approximately 1 beat/min per week. This normal gradual slowing of the fetal heart rate is thought to correspond to maturation of parasympathetic (vagal) heart control (Renou, 1969).

The baseline fetal heart rate is the approximate mean rate rounded to increments of 5 bpm during a 10-minute tracing

FIGURE 24-6 Fetal heart rate obtained by scalp electrode (*upper panel*) and recorded at 1 cm/min compared with that at 3 cm/min chart recorder paper speed. Concurrent uterine contractions are shown (*lower panel*).

TABLE 24-1. Electronic Fetal Monitoring Definitions

Pattern	Definition
Baseline	<ul style="list-style-type: none"> The mean FHR rounded to increments of 5 bpm during a 10-min segment, excluding: <ul style="list-style-type: none"> —Periodic or episodic changes —Segments of baseline that differ by more than 25 bpm The baseline must be for a minimum of 2 min in any 10-min segment or the baseline for that time period is indeterminate. In this case, one may refer to the prior 10-min window for determination of baseline. Normal FHR baseline: 110–160 bpm Tachycardia: FHR baselines > 160 bpm Bradycardia: FHR baseline < 110 bpm
Baseline variability	<ul style="list-style-type: none"> Fluctuations in the baseline FHR that are irregular in amplitude and frequency Variability is visually quantified as the amplitude of peak-to-trough in bpm <ul style="list-style-type: none"> —Absent: amplitude range undetectable —Minimal: amplitude range detectable but ≤ 5 bpm or fewer —Moderate (normal): amplitude range 6–25 bpm —Marked: amplitude range > 25 bpm
Acceleration	<ul style="list-style-type: none"> A visually apparent abrupt increase (onset to peak in < 30 sec) in the FHR At 32 weeks and beyond, an acceleration has a peak of 15 bpm or more above baseline, with a duration of 15 sec or more but less than 2 min from onset to return Before 32 weeks, an acceleration has a peak of 10 bpm or more above baseline, with a duration of ≥ 10 sec but < 2 min from onset to return Prolonged acceleration lasts ≥ 2 min, but < 10 min If an acceleration lasts 10 min, it is a baseline change
Early deceleration	<ul style="list-style-type: none"> Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction A gradual FHR decrease is defined as from the onset to the FHR nadir of ≥ 30 sec The decrease in FHR is calculated from the onset to the nadir of the deceleration The nadir of the deceleration occurs at the same time as the peak of the contraction In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively
Late deceleration	<ul style="list-style-type: none"> Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction A gradual FHR decrease is defined as from the onset to the FHR nadir of ≥ 30 sec The decrease in FHR is calculated from the onset to the nadir of the deceleration The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively
Variable deceleration	<ul style="list-style-type: none"> Visually apparent abrupt decrease in FHR An abrupt FHR decrease is defined as from the onset to the FHR nadir of < 30 sec The decrease in FHR is calculated from the onset to the nadir of the deceleration The decrease in FHR is ≥ 15 bpm, lasting ≥ 15 sec, and < 2 min in duration When variable decelerations are associated with uterine contraction, their onset, depth, and duration commonly vary with successive uterine contractions
Prolonged deceleration	<ul style="list-style-type: none"> Visually apparent decrease in the FHR below the baseline Decrease in FHR from the baseline that is ≥ 15 bpm, lasting ≥ 2 min but < 10 min in duration If a deceleration lasts ≥ 10 min, it is a baseline change
Sinusoidal pattern	<ul style="list-style-type: none"> Visually apparent, smooth, sine wave-line undulating pattern in FHR baseline with a cycle frequency of 3–5 per minute which persists for 20 min or more

bpm = beats per minute; FHR = fetal heart rate.

Summarized from the National Institute of Child Health and Human Development Research Planning Workshop, 1997.

segment. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes. If the baseline fetal heart rate is less than 110 bpm, it is termed *bradycardia*. If the baseline rate is greater than 160 bpm, it is termed *tachycardia*. The average fetal heart rate is considered the result of tonic balance between *accelerator* and *decelerator* influences on pacemaker cells. In this concept, the sympathetic system is the accelerator influence, and the parasympathetic system is the decelerator factor mediated via vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. More severe and prolonged hypoxia, with a rising blood lactate level and severe metabolic acidemia, induces a prolonged fall in heart rate (Thakor, 2009).

Bradycardia. In the third trimester, the normal mean baseline fetal heart rate has generally been accepted to range between 120 and 160 bpm. The lower normal limit is disputed internationally, with some investigators recommending 110 bpm (Manassiev, 1996). Pragmatically, a rate between 100 and 119 bpm, in the absence of other changes, usually is not considered to represent fetal compromise. Such low but potentially normal baseline heart rates also have been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor (Young, 1976). Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged approximately 50 minutes in duration. Freeman and associates (2003) have concluded that bradycardia within the range of 80 to 120 bpm with good variability is reassuring. Interpretation of rates less than 80 bpm is problematic, and such rates generally are considered nonreassuring.

Some causes of fetal bradycardia include congenital heart block and serious fetal compromise (Jaeggi, 2008; Larma, 2007). **Figure 24-7** shows bradycardia in a fetus dying from placental abruption. Maternal hypothermia under general anesthesia for repair of a cerebral aneurysm or during maternal cardiopulmonary bypass for open-heart surgery also can cause fetal bradycardia. Sustained fetal bradycardia in the setting of severe pyelonephritis and maternal hypothermia also has been reported (Hankins, 1997). These infants apparently are not harmed by several hours of such bradycardia.

Tachycardia. Fetal tachycardia is defined as a baseline heart rate greater than 160 bpm. The most common explanation for fetal tachycardia is maternal fever from chorioamnionitis, although fever from any source can increase baseline fetal heart rate. Such infections also have been observed to induce fetal tachycardia before overt maternal fever is diagnosed (Gilstrap, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless there are associated periodic heart rate changes or fetal sepsis.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic (atropine) or sympathomimetic (terbutaline) drugs. The key feature to distinguish fetal compromise in association

FIGURE 24-7 Fetal bradycardia measured with a scalp electrode (*upper panel*) in a pregnancy complicated by placental abruption and subsequent fetal death. Concurrent uterine contractions are shown in the lower panel.

with tachycardia seems to be concomitant heart rate decelerations. Prompt relief of the compromising event, such as correction of maternal hypotension caused by epidural analgesia, can result in fetal recovery.

Wandering Baseline. This baseline rate is unsteady and “wanders” between 120 and 160 bpm (Freeman, 2003). This rare finding is suggestive of a neurologically abnormal fetus and may occur as a preterminal event.

Beat-to-Beat Variability

Baseline variability is an important index of cardiovascular function and appears to be regulated largely by the autonomic nervous system (Kozuma, 1997). That is, a sympathetic and parasympathetic “push and pull” mediated via the sinoatrial node produces moment-to-moment or beat-to-beat oscillation of the baseline heart rate. Such heart rate change is defined as baseline variability. Variability can be further divided into short term and long term, although these terms have fallen out of use. *Short-term variability* reflects the instantaneous change in fetal heart rate from one beat—or R wave—to the next. This variability is a measure of the time interval between cardiac systoles (**Fig. 24-8**). Short-term variability can most reliably be determined to be normally present only when electrocardiac cycles are measured directly with a scalp electrode. *Long-term variability* is used to describe the oscillatory changes during 1 minute and result in the waviness of the baseline (**Fig. 24-9**). The normal frequency of such waves is three to five cycles per minute (Freeman, 2003).

It should be recognized that precise quantitative analysis of both short- and long-term variability presents a number

FIGURE 24-8 Schematic representation of short-term beat-to-beat variability measured by a fetal scalp electrode. t = time interval between successive fetal R waves. (Adapted from Klavan, 1977.)

of frustrating problems due to technical and scaling factors. For example, Parer and coworkers (1985) evaluated 22 mathematical formulas designed to quantify heart rate variability and found most to be unsatisfactory. Consequently, most clinical interpretation is based on visual analysis with subjective judgment of the smoothness or flatness of the baseline. According to Freeman and colleagues (2003), there is no current evidence that the distinction between short- and long-term variability has any clinical relevance. Similarly, the NICHD Workshop (1997) did not recommend differentiating short- and long-term variability because in actual practice they are visually determined as a unit. The workshop panel defined baseline variability as those baseline fluctuations of two cycles per minute or greater. They recommended the criteria shown in [Figure 24-10](#) for quantification of variability. Normal beat-to-beat variability was accepted to be 6 to 25 bpm.

Increased Variability. Several physiological and pathological processes can affect or interfere with beat-to-beat variability. Dawes and associates (1981) described increased variability during *fetal breathing*. In healthy infants, short-term variability is attributable to respiratory sinus arrhythmia (Divon, 1986). *Fetal body movements* also affect variability (Van Geijn, 1980). Pillai and James (1990) reported increased baseline variability with *advancing gestation*. Up to 30 weeks, baseline characteristics were similar during both fetal rest and activity. After 30 weeks, fetal inactivity was associated with diminished baseline variability and conversely, variability was increased during fetal activity. Fetal gender does not affect heart rate variability (Oguch, 1998).

The baseline fetal heart rate becomes more physiologically fixed (less variable) as the rate increases. Conversely, there is more instability or variability of the baseline at lower heart

FIGURE 24-9 Schematic representation of long-term beat-to-beat variability of the fetal heart rate ranging between 125 and 135 bpm. (Adapted from Klavan, 1977.)

rates. This phenomenon presumably reflects less cardiovascular physiological wandering as beat-to-beat intervals shorten due to increasing heart rate.

Decreased Variability. Diminished beat-to-beat variability can be an ominous sign indicating a seriously compromised fetus. Paul and coworkers (1975) reported that loss of variability in combination with decelerations was associated with *fetal acidemia*. They analyzed variability in the 20 minutes preceding delivery in 194 pregnancies. Decreased variability was defined as 5 or fewer bpm excursion of the baseline (see [Fig. 24-10](#)), whereas acceptable variability exceeded this range. Fetal scalp pH was measured 1119 times in these pregnancies, and mean values were found to be increasingly acidemic when decreased variability was added to progressively intense heart rate decelerations. For example, mean fetal scalp pH of approximately 7.10 was found when severe decelerations were combined with 5 bpm or less variability, compared with a pH of approximately 7.20 when greater variability was associated with similarly severe decelerations. Severe *maternal acidemia* also can cause decreased fetal beat-to-beat variability, as shown in [Figure 24-11](#) in a mother with diabetic ketoacidosis.

The precise pathological mechanisms by which fetal hypoxemia results in diminished beat-to-beat variability are not totally understood. Interestingly, mild degrees of fetal hypoxemia have been reported actually to *increase* variability, at least at the outset of the hypoxic episode (Murotsuki, 1997). According to Dawes (1985), it seems probable that the loss of variability is a result of metabolic acidemia that causes depression of the fetal brainstem or the heart itself. Thus, diminished beat-to-beat variability, when it reflects fetal compromise, likely reflects acidemia rather than hypoxia.

A common cause of diminished beat-to-beat variability is administration of *analgesic drugs* during labor (Chap. 25, p. 506). Various central nervous system depressant drugs can cause transient diminished beat-to-beat variability. Included are narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. Variability regularly diminishes within 5 to 10 minutes following intravenous meperidine administration, and the effects may last up to 60 minutes or longer depending on the dosage given (Petrie, 1993). Butorphanol given intravenously diminishes fetal heart rate reactivity (Schucker, 1996). In a study performed at Parkland Hospital, Hill and colleagues (2003) found that 5 bpm or less variability occurred in 30 percent of women given continuous intravenous meperidine compared with 7 percent in those given continuous labor epidural analgesia.

Magnesium sulfate, widely used in the United States for tocolysis as well as management of hypertensive women, has been arguably associated with diminished beat-to-beat variability. Hallak and associates (1999) randomly assigned 34 normal, nonlaboring women to standard magnesium sulfate infusion versus isotonic saline. Magnesium sulfate was associated with statistically decreased variability only in the third hour of the infusion. The average decrease in variability was deemed clinically insignificant, however, because the mean variability was

FIGURE 24-10 Grades of baseline fetal heart rate variability shown in the following five panels. **1.** Undetectable, absent variability. **2.** Minimal variability, ≤ 5 bpm. **3.** Moderate (normal) variability, 6 to 25 bpm. **4.** Marked variability, > 25 bpm. **5.** Sinusoidal pattern. This differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability. (Adapted from National Institute of Child Health and Human Development Research Planning Workshop, 1997.)

FIGURE 24-11 **A.** External fetal heart recording showing lack of long-term variability at 31 weeks during maternal diabetic keto-acidosis (pH 7.09). **B.** Recovery of fetal long-term variability after correction of maternal acidemia.

2.7 bpm in the third hour of magnesium infusion compared with 2.8 bpm at baseline. Magnesium sulfate also blunted the frequency of accelerations.

It is generally believed that reduced baseline heart rate variability is the single most reliable sign of fetal compromise. Smith and coworkers (1988) performed a computerized analysis of beat-to-beat variability in growth-restricted fetuses before labor. They observed that diminished variability (4.2 bpm or less) that was maintained for 1 hour was diagnostic of developing acidemia and imminent fetal death. By contrast, Samueloff and associates (1994) evaluated variability as a predictor of fetal outcome during labor in 2200 consecutive deliveries. They concluded that variability by itself could not be used as the only indicator of fetal well-being. Conversely, they also concluded that good variability should not be interpreted as necessarily reassuring. Blackwell and associates (2011) found that even experts often disagreed as to whether variability was absent or minimal (< 5 beats per minute).

In summary, beat-to-beat variability is affected by various pathological and physiological mechanisms. Variability has considerably different meaning depending on the clinical setting. The development of decreased variability in the absence of decelerations is unlikely to be due to fetal hypoxia (Davidson, 1992). A persistently flat fetal heart rate baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a previous insult to the fetus that has resulted in neurological damage (Freeman, 2003).

FIGURE 24-12 Internal fetal monitoring at term demonstrated occasional abrupt beat-to-beat fetal heart rate spiking due to erratic extrasystoles shown in the corresponding fetal electrocardiogram. The normal infant was delivered spontaneously and had normal cardiac rhythm in the nursery.

Cardiac Arrhythmia

When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, *abrupt baseline spiking* (Fig. 24-12). Intermittent baseline bradycardia is frequently due to congenital heart block. As discussed in Chapter 59 (p. 1172), conduction defects, most commonly complete atrioventricular (AV) block, usually are found in association with maternal connective-tissue diseases. An arrhythmia can only be documented, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an electrocardiographic recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.

Southall and associates (1980) studied antepartum fetal cardiac rate and rhythm disturbances in 934 normal pregnancies between 30 and 40 weeks. Arrhythmias, episodes of bradycardia < 100 bpm, or tachycardia > 180 bpm were encountered in 3 percent. Most supraventricular arrhythmias are of little significance during labor unless there is coexistent heart failure as evidenced by fetal hydrops. Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects (Api, 2008). Copel and coworkers (2000) used echocardiography to evaluate 614 fetuses referred for auscultated irregular heart rate without hydrops. Only 10 fetuses (2 percent) were found to have significant arrhythmias, and all but one of these infants survived.

Boldt and colleagues (2003) followed 292 consecutive fetuses diagnosed with a cardiac arrhythmia through birth and into childhood. Atrial extrasystoles were the most common

arrhythmia (68 percent), followed by atrial tachycardias (12 percent), atrioventricular block (12 percent), sinus bradycardia (5 percent), and ventricular extrasystoles (2.5 percent). Chromosomal anomalies were found in 1.7 percent of the fetuses. Fetal hydrops developed in 11 percent, and 2 percent had intrauterine death. Fetal hydrops was a bad prognostic finding. Overall, 93 percent of the study population was alive at a median follow-up period of 5 years, and 3 percent—seven infants—had neurological handicaps. Of the infants with atrial extrasystoles, 97 percent lived, and none suffered neurological injury. Only 6 percent required postnatal cardiac medications. Lopriore and associates (2009) found low rates of death and long-term neurological impairment in fetuses with supraventricular tachycardia or atrial flutter. In contrast, higher mortality rates were noted in those with atrioventricular block.

Although most fetal arrhythmias are of little consequence during labor when there is no evidence of fetal hydrops, such arrhythmias impair interpretation of intrapartum heart rate tracings. Sonographic evaluation of fetal anatomy and echocardiography may be useful. Some clinicians use fetal scalp sampling as an adjunct. Generally, in the absence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially those associated with clear amniotic fluid, are managed conservatively. Freeman and colleagues (2003) have extensively reviewed interpretation of the fetal electrocardiogram during labor.

Sinusoidal Heart Rate

A true sinusoidal pattern such as that shown in panel 5 of Figure 24-10 may be observed with fetal intracranial hemorrhage, with severe fetal asphyxia, and with severe fetal anemia from Rh alloimmunization, fetomaternal hemorrhage, twin-twin transfusion syndrome, or vasa previa with bleeding (Modanlou, 2004). Insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982). Shown in Figure 24-13 is a sinusoidal pattern seen with maternal meperidine administration. An important

FIGURE 24-13 Sinusoidal fetal heart rate pattern associated with maternal intravenous meperidine administration. Sine waves are occurring at a rate of 6 cycles per minute.

characteristic of this pattern when due to narcotics is the sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with chorioamnionitis, fetal distress, and umbilical cord occlusion (Murphy, 1991). Young (1980a) and Johnson (1981) with their coworkers concluded that intrapartum sinusoidal fetal heart patterns were not generally associated with fetal compromise.

Modanlou and Freeman (1982), based on their extensive review, proposed adoption of a strict definition:

1. Stable baseline heart rate of 120 to 160 bpm with regular oscillations,
2. Amplitude of 5 to 15 bpm (rarely greater),
3. Long-term variability frequency of 2 to 5 cycles per minute,
4. Fixed or flat short-term variability,
5. Oscillation of the sinusoidal waveform above or below a baseline, and
6. Absent accelerations.

Although these criteria were selected to define a sinusoidal pattern that is most likely ominous, they observed that the pattern associated with alphaprodine is indistinguishable. Other investigators have proposed a classification of sinusoidal heart rate patterns into mild—amplitude 5 to 15 bpm, intermediate—16 to 24 bpm, and major—25 or more bpm to quantify fetal risk (Murphy, 1991; Neesham, 1993).

Some investigators have defined intrapartum sine wavelike baseline variation with periods of acceleration as *pseudosinusoidal*. Murphy and colleagues (1991) reported that pseudosinusoidal patterns were seen in 15 percent of monitored labors. Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. Egley and associates (1991) reported that 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor. These authors observed patterns for up to 90 minutes in some cases and also in association with oxytocin or alphaprodine usage, or both.

The pathophysiology of sinusoidal patterns is unclear, in part due to various definitions. There seems to be general agreement that *antepartum* sine wave baseline undulation portends severe fetal anemia. Still, few D-alloimmunized fetuses develop this pattern (Nicolaidis, 1989). The sinusoidal pattern has been reported to develop or disappear after fetal transfusion (Del Valle, 1992; Lowe, 1984). Ikeda and associates (1999) have proposed, based on studies in fetal lambs, that the sinusoidal fetal heart rate pattern is related to waves of arterial blood pressure, reflecting oscillations in the baroreceptor-chemoreceptor feedback mechanism for control of the circulation.

Periodic Fetal Heart Rate Changes

The periodic fetal heart rate refers to deviations from baseline that are temporally related to uterine contractions. *Acceleration* refers to an increase in fetal heart rate above baseline and *deceleration* to a decrease below the baseline rate. The nomenclature most commonly used in the United States is based on the

timing of the deceleration in relation to contractions—thus, *early*, *late*, or *variable* in onset related to the corresponding uterine contraction. The waveform of these decelerations is also significant for pattern recognition. In early and late decelerations, the slope of fetal heart rate change is gradual, resulting in a curvilinear and uniform or symmetrical waveform. With variable decelerations, the slope of fetal heart rate change is abrupt and erratic, giving the waveform a jagged appearance. The 1997 workshop proposed that decelerations be defined as *recurrent* if they occur with 50 percent or more of contractions in any 20-minute period.

Another system now used less often to describe decelerations is based on the pathophysiological events considered most likely to cause the pattern. In this system, early decelerations are termed *head compression*, late decelerations are termed *uteroplacental insufficiency*, and variable decelerations become *cord compression patterns*.

Accelerations

These are visually apparent abrupt increases—defined as onset of acceleration to a peak in less than 30 seconds—in the fetal heart rate baseline (American College of Obstetricians and Gynecologists, 2013b). At 32 weeks' gestation and beyond, the acceleration has a peak of 15 bpm with a duration of 15 seconds or more but less than 2 minutes (see Table 24-1). Before 32 weeks, a peak of 10 bpm for 15 seconds to 2 minutes is considered normal. Prolonged acceleration was defined as 2 minutes or more but less than 10 minutes.

According to Freeman and coworkers (2003), accelerations most often occur antepartum, in early labor, and in association with variable decelerations. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, and fetal stimulation during pelvic examination. Fetal scalp blood sampling and acoustic stimulation also incite fetal heart rate acceleration (Clark, 1982). Finally, accelerations can occur during labor without any apparent stimulus. Indeed, they are common in labor and are nearly always associated with fetal movement. These accelerations are virtually always reassuring and almost always confirm that the fetus is not acidemic at that time.

Accelerations seem to have the same physiological explanations as beat-to-beat variability in that they represent intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. Krebs and colleagues (1982) analyzed electronic heart rate tracings in nearly 2000 fetuses and found sporadic accelerations during labor in 99.8 percent. Fetal heart accelerations during the first or last 30 minutes during labor, or both, was a favorable sign for fetal well-being. The absence of such accelerations during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. There is an approximately 50-percent chance of acidemia in the fetus who fails to respond to stimulation in the presence of an otherwise nonreassuring pattern (Clark, 1984; Smith, 1986).

Early Deceleration

This consists of a gradual decrease and return to baseline associated with a contraction (Fig. 24-14). Such early deceleration

FIGURE 24-14 Features of early fetal heart rate deceleration. Characteristics include a gradual decline in the heart rate with both onset and recovery coincident with the onset and recovery of the contraction. The nadir of the deceleration is 30 seconds or more after the deceleration onset.

was first described by Hon (1958), who observed that there was a heart rate drop with contractions and that this was related to cervical dilatation. He considered these findings to be physiological.

Freeman and associates (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm dilatation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 bpm or 20 to 30 bpm below baseline. Such decelerations are common during active labor and not associated with tachycardia, loss of variability, or other fetal heart rate changes. Importantly, early decelerations are not associated with fetal hypoxia, acidemia, or low Apgar scores.

Head compression probably causes vagal nerve activation as a result of dural stimulation, and this mediates the heart rate deceleration (Paul, 1964). Ball and Parer (1992) concluded that fetal head compression is a likely cause not only of the deceleration shown in Figure 24-14 but also of those shown in Figure 24-15, which typically occur during second-stage labor. Indeed, they observed that head compression is the likely cause of many variable decelerations classically attributed to cord compression.

Late Deceleration

The fetal heart rate response to uterine contractions can be an index of either uterine perfusion or placental function. A late deceleration is a smooth, gradual, symmetrical decrease in fetal heart rate beginning at or after the contraction peak and returning to baseline only after the contraction has ended. A gradual decrease is defined as 30 seconds or more from the onset of the deceleration to the nadir. In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively (Fig. 24-16). The magnitude of late decelerations is seldom more than 30 to 40 bpm below baseline and typically not more

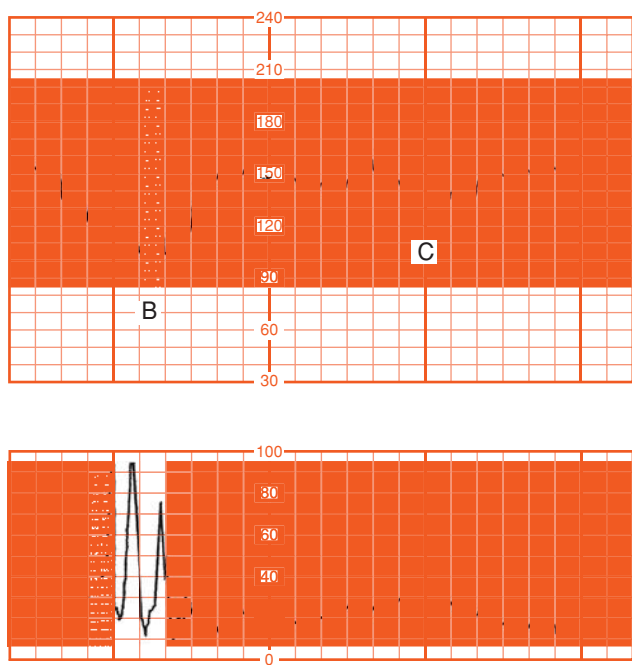

FIGURE 24-15 Two different fetal heart rate patterns during second-stage labor that are likely both due to head compression (*upper panel*). Maternal pushing efforts (*lower panel*) correspond to the spikes with uterine contractions. Fetal heart rate deceleration (C) is consistent with the pattern of head compression shown in Figure 24-14. Deceleration (B), however, is “variable” in appearance because of its jagged configuration and may alternatively represent cord occlusion.

than 10 to 20 bpm. Late decelerations usually are not accompanied by accelerations.

Myers and associates (1973) studied monkeys in which they compromised uteroplacental perfusion by lowering maternal aortic blood pressure. The interval or lag from the contraction onset until the late deceleration onset was directly related to basal fetal oxygenation. They demonstrated that the length of the lag phase was predictive of the fetal PO_2 but not fetal pH.

FIGURE 24-16 Features of late fetal heart rate deceleration. Characteristics include gradual decline in the heart rate with the contraction nadir, and recovery occurring after the end of the contraction. The nadir of the deceleration occurs 30 seconds or more after the onset of the deceleration.

FIGURE 24-17 Late decelerations due to uteroplacental insufficiency resulting from placental abruption. Immediate cesarean delivery was performed. Umbilical artery pH was 7.05 and the PO_2 was 11 mm Hg.

The lower the fetal PO_2 before contractions, the shorter the lag phase to onset of late decelerations. This lag period reflected the time necessary for the fetal PO_2 to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediated decelerations.

Murata and coworkers (1982) also showed that a late deceleration was the first fetal heart rate consequence of uteroplacental-induced hypoxia. During the course of progressive hypoxia that led to death over 2 to 13 days, monkey fetuses invariably exhibited late decelerations before development of acidemia. Variability of the baseline heart rate disappeared as acidemia developed.

Numerous clinical circumstances can result in late decelerations. Generally, any process that causes maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common causes are hypotension from epidural analgesia and uterine hyperactivity caused by oxytocin stimulation. Maternal diseases such as hypertension, diabetes, and collagen-vascular disorders can cause chronic placental dysfunction. Placental abruption can cause acute late decelerations (Fig. 24-17).

Variable Deceleration

The most common deceleration patterns encountered during labor are variable decelerations attributed to umbilical cord occlusion. Melchior and Bernard (1985) identified variable decelerations in 40 percent of more than 7000 monitor tracings when labor had progressed to 5 cm dilatation and in 83 percent by the end of the first stage of labor. Variable deceleration is defined as an abrupt decrease in the fetal heart rate beginning with the onset of the contraction and reaching a nadir in less than 30 seconds. The decrease must last between ≥ 15 seconds and 2 minutes and must be ≥ 15 bpm in amplitude. The onset of deceleration typically varies with successive contractions (Fig. 24-18).

FIGURE 24-18 Features of variable fetal heart rate decelerations. Characteristics include an abrupt decline in the heart rate, and onset that commonly varies with successive contractions. The decelerations measure ≥ 15 bpm for ≥ 15 seconds and have an onset-to-nadir phase of < 30 seconds. Total duration is < 2 minutes.

Very early in the development of electronic monitoring, Hon (1959) tested the effects of umbilical cord compression on fetal heart rate (Fig. 24-19). Similar complete occlusion of the umbilical cord in experimental animals produces abrupt, jagged-appearing deceleration of the fetal heart rate (Fig. 24-20). Concomitantly, fetal aortic pressure increases. Itskovitz and colleagues (1983) observed that variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent.

Two types of variable decelerations are shown in Figure 24-21. The deceleration denoted by “A” is very much like that

FIGURE 24-19 A. The effects of 25-second cord compression compared with those of 40 seconds in panel (B). (Redrawn from Hon, 1959, with permission.)

FIGURE 24-20 Total umbilical cord occlusion (arrow) in the sheep fetus is accompanied by an increase in fetal aortic blood pressure. Blood pressure changes in the umbilical vessels are also shown. (Redrawn from Künzel, 1985, with permission.)

seen with complete umbilical cord occlusion in experimental animals (see Fig. 24-20). Deceleration “B,” however, has a different configuration because of the “shoulders” of acceleration before and after the deceleration component. Lee and coworkers (1975) proposed that this form of variable deceleration was caused by differing degrees of partial cord occlusion. In this physiological scheme, occlusion of only the vein reduces fetal blood return, thereby triggering a baroreceptor-mediated acceleration. With increasing intrauterine pressure and subsequent complete cord occlusion, fetal systemic hypertension develops due to obstruction of umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming shoulder of acceleration represents the same events occurring in reverse (Fig. 24-22).

Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a decrease in fetal arterial oxygen content (chemoreceptor). These both result in vagal activity leading to

deceleration. In fetal monkeys, the baroreceptor reflexes appear to operate during the first 15 to 20 seconds of umbilical cord occlusion followed by decline in PO_2 at approximately 30 seconds, which then serves as a chemoreceptor stimulus (Mueller-Heubach, 1982).

Thus, variable decelerations represent fetal heart rate reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The frequency and inevitability of cord occlusion undoubtedly have provided the fetus with these physiological mechanisms as a means of coping. The great dilemma for the obstetrician in managing variable fetal heart rate decelerations is determining when variable decelerations are pathological. According to the American College of Obstetricians and Gynecologists (2013a), recurrent variable decelerations with minimal to moderate variability are *indeterminate*, whereas those with absent variability are *abnormal*.

Other fetal heart rate patterns have been associated with umbilical cord compression. *Saltatory* baseline heart rate (Fig. 24-23) was first described by Hammacher and colleagues (1968) and linked to umbilical cord complications during labor. The pattern consists of rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the baseline fetal heart rate. We also observed a relationship between cord occlusion and the saltatory pattern (Leveno, 1984). In the absence of other fetal heart rate findings, these do not signal fetal compromise. *Lambda* is a pattern involving an acceleration followed by a variable deceleration with no acceleration at the end of the deceleration. This pattern typically is seen in early labor and is not ominous (Freeman, 2003). This lambda pattern may result from mild cord compression or

FIGURE 24-22 Schematic representation of the fetal heart rate effects with partial and complete umbilical cord occlusion. Uterine pressures generated early in a contraction cause cord compression predominantly of the thin-walled umbilical vein. The resulting decrease in fetal cardiac output leads to an initial compensatory rise in fetal heart rate. As cord compression intensifies, umbilical arteries are then also compressed. The resulting rise in fetal systolic blood pressure leads to a vagal-mediated fetal heart rate deceleration. As the contraction abates and compression is relieved first on the umbilical arteries, elevated fetal systolic blood pressures drop and the deceleration resolves. A final increase in fetal heart rate is seen as a result of persistent umbilical vein occlusion. With completion of the uterine contraction and cord compression, the fetal heart rate returns to baseline. BP = blood pressure. (Adapted from Lee, 1975.)

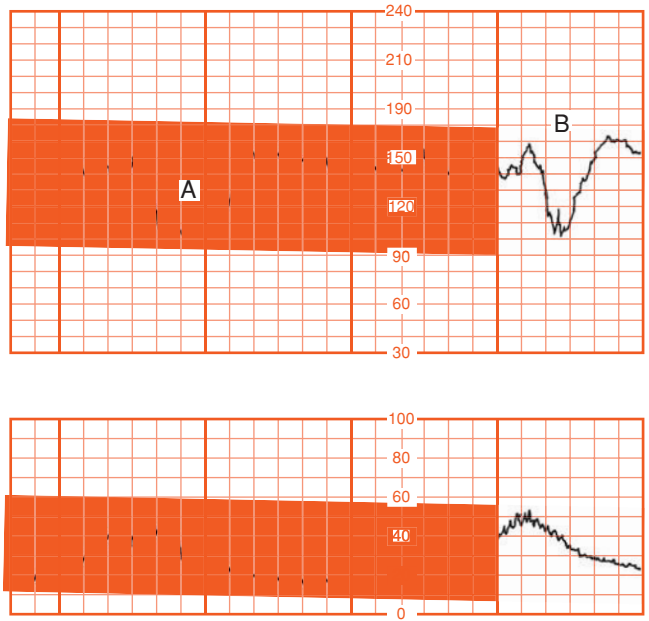

FIGURE 24-21 Varying (variable) fetal heart rate decelerations. Deceleration (B) exhibits “shoulders” of acceleration compared with deceleration (A). (Adapted from Künzel, 1985, with permission.)

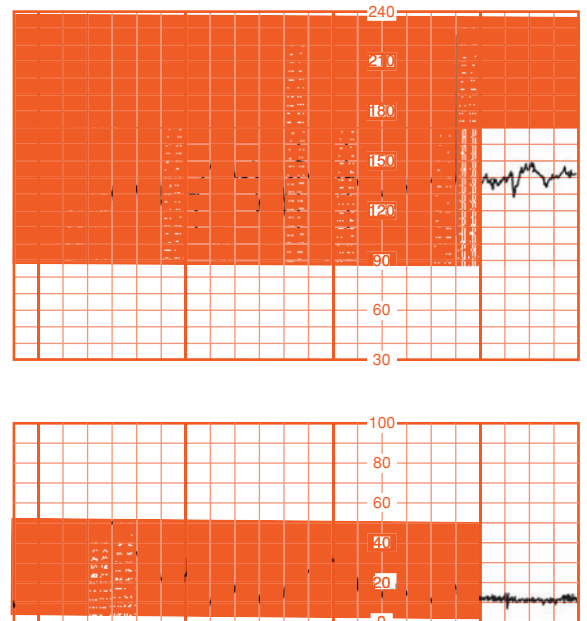

FIGURE 24-23 Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.

stretch. *Overshoot* is a variable deceleration followed by acceleration. The clinical significance of this pattern is controversial (Westgate, 2001).

Prolonged Deceleration

This pattern, which is shown in [Figure 24-24](#), is defined as an isolated deceleration greater than 15 bpm lasting 2 minutes or longer but < 10 minutes from onset to return to baseline. Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Some of the more common causes include cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension.

Epidural, spinal, or paracervical analgesia may induce prolonged deceleration of the fetal heart rate. For example, Eberle and coworkers (1998) reported that prolonged decelerations occurred in 4 percent of normal parturients given either epidural or intrathecal labor analgesia. Hill and associates (2003) observed prolonged deceleration in 1 percent of women given epidural analgesia during labor at Parkland Hospital. Other causes of prolonged deceleration include maternal hypoperfusion or hypoxia from any cause, placental abruption, umbilical cord knots or prolapse, maternal seizures including eclampsia and epilepsy, application of a fetal scalp electrode, impending birth, or even maternal Valsalva maneuver.

The placenta is very effective in resuscitating the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of beat-to-beat variability, baseline tachycardia, and even a period of late decelerations, all of which resolve as the fetus recovers. Freeman and colleagues (2003) emphasize rightfully that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely

tenuous. Management of isolated prolonged decelerations is based on bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-Stage Labor

Decelerations are virtually ubiquitous during the second stage. Melchior and Bernard (1985) reported that only 1.4 percent of more than 7000 deliveries lacked decelerations during second-stage labor. Both cord compression and fetal head compression have been implicated as causes of decelerations and baseline bradycardia during second-stage labor. The high incidence of such patterns minimized their potential significance during the early development and interpretation of electronic monitoring. For example, Boehm (1975) described profound, prolonged fetal heart rate deceleration in the 10 minutes preceding vaginal delivery of 18 healthy infants. However, Herbert and Boehm (1981) later reported another 18 pregnancies with similar prolonged second-stage decelerations. There was one stillbirth and one neonatal death. These experiences attest to the unpredictability of the fetal heart rate during second-stage labor.

Spong and associates (1998) analyzed the characteristics of second-stage variable fetal heart rate decelerations in 250 deliveries and found that as the total number of decelerations to < 70 bpm increased, the 5-minute Apgar score decreased. Put another way, the longer a fetus was exposed to variable decelerations, the lower the Apgar score was at 5 minutes.

Picquard and coworkers (1988) analyzed heart rate patterns during second-stage labor in 234 women in an attempt to identify specific patterns to diagnose fetal compromise. Loss of beat-to-beat variability and baseline fetal heart rate < 90 bpm were predictive of fetal acidemia. Krebs and associates (1981) also found that persistent or progressive baseline bradycardia and baseline tachycardia were associated with low Apgar scores. Gull and colleagues (1996) observed that abrupt fetal heart rate deceleration to < 100 bpm associated with loss of beat-to-beat variability for 4 minutes or longer was predictive of fetal acidemia. Thus, abnormal baseline heart rate—either bradycardia or tachycardia, absent beat-to-beat variability, or both—in the presence of second-stage decelerations, is associated with increased but not inevitable fetal compromise ([Fig. 24-25](#)).

Admission Fetal Monitoring in Low-Risk Pregnancies

With this approach, women with low-risk pregnancies are monitored for a short time on admission for labor, and continuous monitoring is used only if fetal heart rate abnormalities are subsequently identified. Mires and coworkers (2001) randomly assigned 3752 low-risk women in spontaneous labor at admission either to auscultation of the fetal heart or to 20 minutes of electronic fetal monitoring. Use of admission electronic fetal monitoring did not improve infant outcome. Moreover, its use

FIGURE 24-24 Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

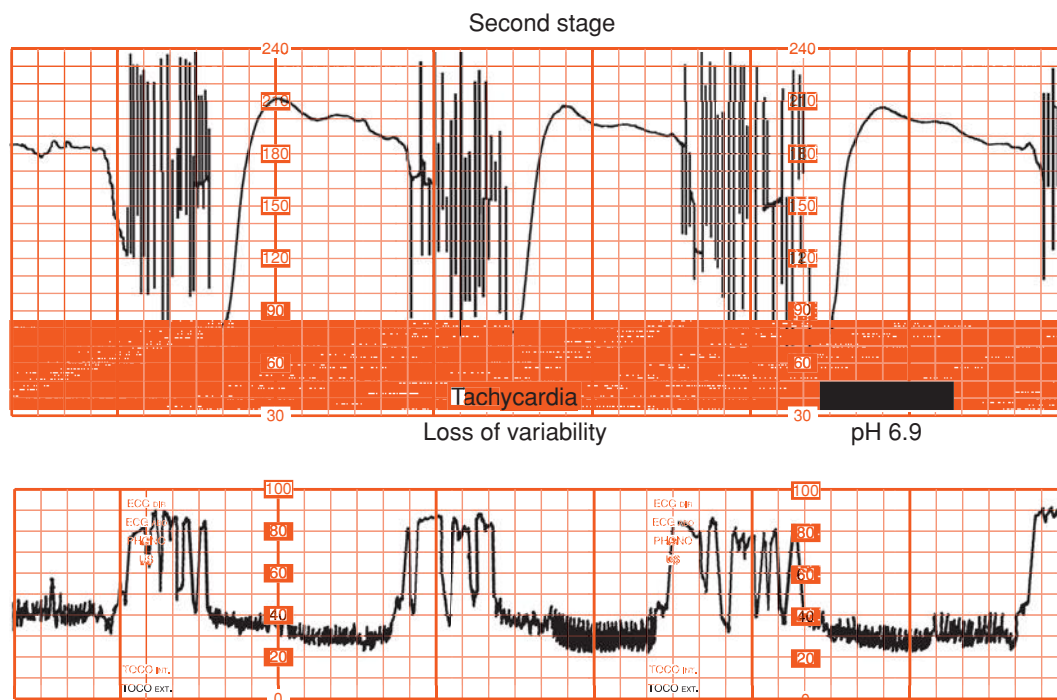

FIGURE 24-25 Cord-compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

resulted in increased interventions, including operative delivery. Impey and associates (2003) performed a similar study in 8588 low-risk women and also found no improvement in infant outcome. More than half of the women enrolled in these studies, whether they received admission electronic monitoring or auscultation, eventually required continuous monitoring for diagnosed abnormalities in the fetal heart rate.

With the increasing rate of scheduled cesarean deliveries in the United States, clinicians and hospitals must decide whether fetal monitoring is required before the procedure in low-risk women. The American College of Obstetricians and Gynecologists (2010) has concluded that data are insufficient to determine the value of fetal monitoring under these circumstances.

Centralized Monitoring

Technological advances have made it possible to observe fetal heart rate monitors from a remote, centralized location. Such intrapartum monitoring equipment has become common in American labor and delivery units. The rationale behind centralized monitoring is that the ability to monitor several patients simultaneously would lead to better outcomes. What is the evidence that this rationale is correct? To our knowledge, only one study on centralized fetal monitoring has been reported. Anderson and colleagues (2011) measured the ability of 12 individuals to detect critical signals in fetal heart rate tracings on one, two, or four monitors. The results showed that detection accuracy declined as the number of displays increased.

OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

Fetal Scalp Blood Sampling

According to the American College of Obstetricians and Gynecologists (2009), measurements of the pH in capillary scalp blood may help to identify the fetus in serious distress. That said, it also emphasized that neither normal nor abnormal scalp pH results have been shown to be predictive of infant outcome. The College also indicated that the procedure is now used uncommonly and is not even available at some hospitals.

For completion, an illuminated endoscope is inserted through the dilated cervix after membrane rupture so as to press firmly against the fetal scalp (Fig. 24-26). The skin is wiped clean with a cotton swab and coated with a silicone gel to cause the blood to accumulate as discrete globules. An incision is made through the skin to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube. The pH of the blood is measured promptly.

The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. Zalar and Quilligan (1979) recommended a protocol to try to confirm fetal distress. If the pH is > 7.25 , labor is observed, and if between 7.20 and 7.25, the pH measurement is repeated within 30 minutes. If the pH is < 7.20 , another scalp blood sample is collected immediately, and the mother is taken to an operating room and prepared for surgery. Delivery is performed promptly if the low pH is confirmed. Otherwise, labor is allowed to continue, and scalp blood samples are repeated periodically.

FIGURE 24-26 The technique of fetal scalp sampling using an amnioscope. The end of the endoscope is displaced from the fetal vertex approximately 2 cm to show the disposable blade against the fetal scalp before incision. (Adapted from Hamilton, 1974.)

The only benefits reported for scalp pH testing are fewer cesarean deliveries for fetal distress (Young, 1980b). Goodwin and coworkers (1994), however, in a study of 112,000 deliveries, showed a decrease in the scalp pH sampling rate. The rate dropped from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992 but with no increased delivery rate for fetal distress. They concluded that scalp pH sampling was unnecessary. Kruger and colleagues (1999) have advocated the use of fetal scalp blood lactate concentration as an adjunct to pH. Wiberg-Itzel and associates (2008) randomized 1496 fetuses to scalp blood pH analysis and 1496 to scalp blood lactate analysis. They found either to be equivalent in predicting fetal acidemia. The advantage of lactate measurement was that a smaller amount of blood was needed, which led to a lower procedural failure rate compared with scalp sampling for pH.

■ Scalp Stimulation

Clark and coworkers (1984) have suggested that scalp stimulation is an alternative to scalp blood sampling. This proposal was based on the observation that heart rate acceleration in response to pinching of the scalp with an Allis clamp just before obtaining blood was invariably associated with a normal pH. Conversely, failure to provoke acceleration was not uniformly predictive of fetal acidemia. Later, Elimian and associates (1997) reported that of 58 cases in which the fetal heart rate accelerated ≥ 10 bpm after 15 seconds of gentle digital stroking of the scalp, 100 percent had a scalp pH of ≥ 7.20 . Without an acceleration, however, only 30 percent had a scalp pH < 7.20 .

■ Vibroacoustic Stimulation

Fetal heart rate acceleration in response to vibroacoustic stimulation has been recommended as a substitute for scalp sampling (Edersheim, 1987). The technique uses an electronic artificial

larynx placed approximately 1 cm from or directly onto the maternal abdomen (Chap. 17, p. 341). Response to vibroacoustic stimulation is considered normal if a fetal heart rate acceleration of at least 15 bpm for at least 15 seconds occurs within 15 seconds after the stimulation and with prolonged fetal movements (Sherer, 1994). Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate to severe variable or late fetal heart rate decelerations. They concluded that this technique is an effective predictor of fetal acidosis in the setting of variable decelerations. The predictability for fetal acidosis, however, is limited in the setting of late decelerations. Other investigators have reported that although vibroacoustic stimulation in second-stage labor is associated with fetal heart rate reactivity, the quality of the response did not predict neonatal outcome or enhance labor management (Anyagbunam, 1994).

Skupski and coworkers (2002) performed a metaanalysis of reports on intrapartum fetal stimulation tests published between 1966 and 2000. Four types of fetal stimulation were analyzed and included scalp puncture for pH testing, Allis clamp pinching of the fetal scalp, vibroacoustic stimulation, and digital stroking of the scalp. Results were similar for all four methods. These investigators concluded that intrapartum stimulation tests were useful to exclude fetal acidemia. They cautioned, however, that these tests are “less than perfect.”

■ Fetal Pulse Oximetry

Using technology similar to that of adult pulse oximetry, instrumentation has been developed that may allow assessment of fetal oxyhemoglobin saturation once membranes are ruptured. A unique padlike sensor such as shown in [Figure 24-27](#) is inserted through the cervix and positioned against the fetal face, where it is held in place by the uterine wall. A transabdominal fetal pulse oximeter has also been described in

FIGURE 24-27 Schematic diagram of fetal pulse oximeter sensor placement.

FIGURE 24-28 Frequency distribution of umbilical artery oxygen saturation values in 1281 vigorous newborn infants. Dotted line indicates normal distribution. (Redrawn from Arikan, 2000, with permission.)

a preliminary study (Vintzileos, 2005). As reviewed by Yam and coworkers (2000), the transcervical device has been used extensively by many investigators. It has been reported to reliably register fetal oxygen saturation in 70 to 95 percent of women throughout 50 to 88 percent of their labors. The lower limit for normal fetal oxygen saturation is generally considered to be 30 percent by investigators (Gorenberg, 2003; Stiller, 2002). As shown in [Figure 24-28](#), however, fetal oxygen saturation normally varies greatly when measured in umbilical artery blood (Arikan, 2000). Bloom and associates (1999) reported that brief, transient fetal oxygen saturations below 30 percent were common during labor because such values were observed in 53 percent of fetuses with normal outcomes. Saturation values below 30 percent, however, when persistent for 2 minutes or longer, were associated with an increased risk of potential fetal compromise.

Garite and colleagues (2000) randomly assigned 1010 women with term pregnancies and in whom predefined abnormal fetal heart rate patterns developed. Patients received either conventional fetal monitoring alone or fetal monitoring plus continuous fetal pulse oximetry. Cesarean delivery for fetal distress was performed when pulse oximetry values remained < 30 percent for the entire interval between two contractions or when the fetal heart rate patterns met predefined guidelines. The use of fetal pulse oximetry significantly reduced the cesarean delivery rate for nonreassuring fetal status from 10.2 to 4.5 percent. Alternatively, the cesarean delivery rate for dystocia increased significantly from 9 to 19 percent when pulse oximetry was used. There were no neonatal benefits or adverse effects associated with fetal pulse oximetry. Based on these observations, in 2000, the Obstetrics and Gynecology Devices Panel of the Medical Devices Advisory Committee of the Food and Drug Administration (FDA) (2012) approved marketing of the Nellcor N-400 Fetal Oxygen Monitoring System.

Since then, another three randomized trials of fetal pulse oximetry have been reported. Of these, Klauser and colleagues (2005) randomly assigned 360 women with nonreassuring fetal heart rate patterns to standard fetal monitoring plus fetal pulse oximetry or to standard monitoring alone and found no benefits for oximetry. East and coworkers (2006) randomized 600 women with nonreassuring fetal heart rate patterns to standard monitoring either alone or with added fetal pulse oximetry. These investigators reported that addition of oximetry significantly reduced cesarean delivery rates for a nonreassuring fetal heart rate pattern. They further reported, however, that neonatal outcomes were not different between the study groups. Also, Bloom and associates (2006) reported the largest trial, which was performed by the Maternal-Fetal Units Network. A total of 5341 women in labor at term underwent placement of the fetal oximetry sensor, but the information was randomly withheld from care providers. Unlike the earlier studies, participants were not required to have nonreassuring fetal heart rate patterns. Sensor application was generally successful and fetal oxygen saturation values were registered 75 percent of the time. Knowledge of fetal oxygen saturation did not change the cesarean delivery rates in the overall population or in the subgroup of 2168 women who had nonreassuring fetal heart rate patterns. Moreover, neonatal outcomes were not improved by knowledge of fetal oxygen saturation status. Because of these findings, in 2005, the manufacturer discontinued sale of the fetal oximeter system in the United States.

Fetal Electrocardiography

As fetal hypoxia worsens, there are changes in the T-wave and in the ST segment of the fetal ECG. Because of this, several investigators have assessed the value of analyzing these parameters as an adjunct to conventional fetal monitoring. The technique requires internal fetal heart monitoring and special equipment to process the fetal ECG. The rationale behind this technology is based on the observation that the mature fetus exposed to hypoxemia develops an elevated ST segment with a progressive rise in T-wave height that can be expressed as a T:QRS ratio ([Fig. 24-29](#)). It is postulated that increasing T:QRS ratios reflect fetal cardiac ability to adapt to hypoxia and appears before neurological damage. Worsening hypoxia results in an increasingly negative ST-segment deflection such that it appears as a biphasic waveform ([Fig. 24-30](#)). In 2005, the manufacturer—Neovanta Medical—received FDA (2012) approval for their ST analysis program—the STAN system.

There have been a few studies of ST-segment changes with fetal monitoring. Westgate and coworkers (1993) conducted a randomized trial of 2400 pregnancies. Infant outcomes were not improved compared with those in whom conventional fetal monitoring alone was used. There was, however, a reduction in the cesarean delivery rate for fetal distress. In another randomized trial of 4966 Swedish women, Amer-Wählin and colleagues (2001, 2007) found that the addition of ST-segment analysis to conventional fetal monitoring significantly reduced cesarean delivery rates for fetal distress and metabolic acidemia.

FIGURE 24-29 A. ST segment changes in normal and hypoxic conditions. **B.** Generation of T:QRS ratios. (Redrawn from Devoe, 2006, with permission.)

in umbilical artery blood. Subsequently, Doria and associates (2007) introduced STAN as a clinical practice in a London hospital and reported no changes in the incidence of operative delivery or neonatal encephalopathy. Most recently, Becker and colleagues (2012) performed a metaanalysis of five randomized trials comprising 15,352 patients and found that use of ST-segment analysis did not reduce the rates of cesarean delivery or fetal metabolic acidemia at birth.

It must be considered that ST-segment abnormalities might occur late in the course of fetal compromise. Neilson (2013) reviewed the Cochrane Database to assess fetal ECG analysis during labor. There were 16,295 women in which such monitoring was performed. He concluded that fetal ST-segment waveform analysis was perhaps useful in preventing fetal acidosis and neonatal encephalopathy when standard fetal heart rate monitoring suggested abnormal patterns. Although no randomized trials have yet been performed in the United States, the Maternal-Fetal Medicine Units Network has one in progress.

Intrapartum Doppler Velocimetry

Doppler analysis of the umbilical artery has been studied as another potential adjunct to conventional fetal monitoring. Further described in Chapter 10 (p. 219), abnormal Doppler waveforms may signify pathological umbilical-placental

vessel resistance. From their review, Farrell and associates (1999) concluded that this technique was a poor predictor of adverse perinatal outcomes. They concluded that Doppler velocimetry had little if any role in fetal surveillance during labor.

FETAL DISTRESS

The terms *fetal distress* and *birth asphyxia* are too broad and vague to be applied with any precision to clinical situations (American College of Obstetricians and Gynecologists, 2005). Uncertainty regarding the diagnosis based on interpretation of fetal heart rate patterns has given rise to descriptions such as *reassuring* or *nonreassuring*. The term “reassuring” suggests a restoration of confidence by a particular pattern, whereas “nonreassuring” suggests inability to remove doubt. These patterns during labor are dynamic—they can rapidly change from reassuring to nonreassuring and vice versa. In this situation, obstetricians experience surges of both confidence and doubt. Put another way, most diagnoses of fetal distress using heart rate patterns occur when obstetricians lose confidence or cannot assuage doubts about fetal condition. *These assessments are subjective clinical judgments that are inevitably subject to imperfection and must be recognized as such.*

Pathophysiology

Why is the diagnosis of fetal distress based on heart rate patterns so tenuous? One explanation is that these patterns are more a reflection of fetal physiology than of pathology. Physiological control of heart rate includes various interconnected mechanisms that depend on blood flow and oxygenation. Moreover, the activity of these control mechanisms is influenced by the preexisting state of fetal oxygenation, for example, as seen with chronic placental insufficiency. Importantly, the fetus is tethered by an umbilical cord, whereby blood flow is constantly in jeopardy. Moreover, normal labor is a process of increasing

FIGURE 24-30 Biphasic ST-segment waveform with progressive fetal hypoxia. (Adapted from Devoe, 2006.)

acidemia (Rogers, 1998). Thus, normal labor is a process of repeated fetal hypoxic events resulting inevitably in acidemia. Put another way, and assuming that “asphyxia” can be defined as hypoxia leading to acidemia, normal parturition is an asphyxiating event for the fetus.

■ **Diagnosis**

Because of the above uncertainties, it follows that identification of “fetal distress” based on fetal heart rate patterns is imprecise and controversial. It is well known that experts in interpretation of these patterns often disagree with each other. In fact, Parer (1997), a strong advocate of electronic fetal heart rate monitoring and an organizer of the 1997 NICHD fetal monitoring workshop, light-heartedly compared the experts in attendance to marine iguanas of the Galapagos Islands, to wit: “all on the same beach but facing different directions and spitting at one another constantly!”

Ayres-de-Campos and colleagues (1999) investigated interobserver agreement of fetal heart rate pattern interpretation and found that agreement—or conversely, disagreement—was related to whether the pattern was normal, suspicious, or pathological. Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. Keith and coworkers (1995) asked each of 17 experts to review 50 tracings on two occasions, at least 1 month apart. Approximately 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues. And although Murphy and associates (2003) concluded that at least part of the interpretation problem is due to a lack of formalized education in American training programs, this is obviously only a small modifier. Put another way, how can the teacher enlighten the student if the teacher is uncertain?

■ **National Institutes of Health Workshops Three-Tier Classification System**

The NICHD (1997) held a succession of workshops in 1995 and 1996 to develop standardized and unambiguous definitions of fetal heart rate (FHR) tracings and published recommendations for interpreting these patterns. In 2008, a second workshop was convened to reevaluate the 1997 recommendations and to clarify terminology (see Table 24-1)(Macones, 2008). A major result was the recommendation of a three-tier system for classification of FHR patterns (Table 24-2). The American College of Obstetricians and Gynecologists (2013b) subsequently recommended use of this tiered system.

A few studies have been done to assess the three-tiered system. Jackson and coworkers (2011) studied 48,444 women in labor and found that category I (normal FHR) patterns were observed during labor in 99.5 percent of tracings. Category II (indeterminate FHR) patterns were found in 84.1 percent of tracings, and category III (abnormal FHR) patterns were seen in 0.1 percent (54 women). Most—84 percent of women—had a mix of categories during labor. Cahill and colleagues (2012) retrospectively studied the incidence of umbilical cord acidemia (pH ≤ 7.10) correlated with fetal heart rate characteristics during the 30 minutes preceding delivery. None of the three categories demonstrated a significant association with cord

TABLE 24-2. Three-Tier Fetal Heart Rate Interpretation System

Category I—Normal Include all of the following: <ul style="list-style-type: none">• Baseline rate: 110–160 bpm• Baseline FHR variability: moderate• Late or variable decelerations: absent• Early decelerations: present or absent• Accelerations: present or absent
Category II—Indeterminate Include all FHR tracings not categorized as Category I or III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples include any of the following: Baseline rate <ul style="list-style-type: none">• Bradycardia not accompanied by absent baseline variability• Tachycardia Baseline FHR variability <ul style="list-style-type: none">• Minimal baseline variability• Absent baseline variability not accompanied by recurrent decelerations• Marked baseline variability Accelerations <ul style="list-style-type: none">• Absence of induced accelerations after fetal stimulation Periodic or episodic decelerations <ul style="list-style-type: none">• Recurrent variable decelerations accompanied by minimal or moderate baseline variability• Prolonged deceleration ≥ 2 min but < 10 min• Recurrent late decelerations with moderate baseline variability• Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders”
Category III—Abnormal Include either: <ul style="list-style-type: none">• Absent baseline FHR variability and any of the following:<ul style="list-style-type: none">Recurrent late decelerationsRecurrent variable decelerationsBradycardia• Sinusoidal pattern

bpm = beats per minute; FHR = fetal heart rate.

blood acidemia. The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2014) concluded that a category I or II tracing with a 5-minute Apgar score > 7 or normal arterial blood acid-base values was not consistent with an acute hypoxic-ischemic event. Sholapurkar (2012) also challenged the validity of the three-tier system because most abnormal fetal heart rate patterns fall into the indeterminate category II, that is, one for which no definite management recommendations can be made. It was further suggested that this resulted from most fetal heart rate decelerations being inappropriately classified as *variable* decelerations due to cord compression.

Parer and King (2010) compared the current situation in the United States with that of other countries in which a consensus on classification and management has been reached by a number of professional societies. Some of these include the Royal College of Obstetricians and Gynecologists, the Society of Obstetricians and Gynecologists of Canada, the Royal Australian and New Zealand College of Obstetricians and Gynecologists, and the Japan Society of Obstetrics and Gynecology. Parer and King (2010) further comment that the NICHD three-tier system is inadequate because category II—indeterminate FHR—consists of a “vast heterogeneous mixture of patterns” that prevents development of a management strategy. Parer and Ikeda (2007) had previously proposed a color-coded five-tier system for both FHR interpretation *and* management. There have been two reports comparing the five-tier and three-tier systems. Bannerman and associates (2011) found that the two systems were similar in fetal heart rate interpretations for tracings that were either very normal or very abnormal. Coletta and coworkers (2012) found that the five-tier system had better sensitivity than the three-tier system. It is apparent that, after 50 years of continuous electronic fetal heart rate monitoring use, there is not a consensus on interpretation and management recommendations for FHR patterns (Parer, 2011).

■ Meconium in the Amnionic Fluid

Obstetrical teaching throughout the past century has included the concept that meconium passage is a potential warning of fetal asphyxia. In 1903, J. Whitridge Williams observed and attributed meconium passage to “relaxation of the sphincter ani muscle induced by faulty aeration of the (fetal) blood.” Even so, obstetricians have also long realized that the detection of meconium during labor is problematic in the prediction of fetal distress or asphyxia. In their review, Katz and Bowes (1992) emphasized the prognostic uncertainty of meconium by referring to the topic as a “murky subject.” Indeed, although 12 to 22 percent of labors are complicated by meconium, only a few are linked to infant mortality. In an investigation from Parkland Hospital, meconium was found to be a “low-risk” obstetrical hazard because the perinatal mortality rate attributable to meconium was 1 death per 1000 live births (Nathan, 1994).

Three theories have been suggested to explain fetal passage of meconium and in part may explain the tenuous connection between its detection and infant mortality. First, the pathological explanation proposes that fetuses pass meconium in response to hypoxia and that meconium therefore signals fetal compromise (Walker, 1953). Second, the physiological explanation is that in utero passage of meconium represents normal gastrointestinal tract maturation under neural control (Mathews, 1979). A final theory posits that meconium passage follows vagal stimulation from common but transient umbilical cord entrapment with resultant increased bowel peristalsis (Hon, 1961). Thus, meconium release may represent physiological processes.

Ramin and associates (1996) studied almost 8000 pregnancies with meconium-stained amnionic fluid delivered

at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum heart rate abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery. Analysis of the type of fetal acidemia based on umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event. This is because most acidemic fetuses had abnormally increased PCO_2 values rather than a pure metabolic acidemia.

Dawes and coworkers (1972) observed that such hypercarbia in fetal lambs induces gasping and resultant increased amniotic fluid inhalation. Jovanovic and Nguyen (1989) observed that meconium gasped into the fetal lungs caused aspiration syndrome only in asphyxiated animals. Ramin and colleagues (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli. Lung parenchymal injury is secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amniotic fluid is a fetal environmental hazard rather than a marker of preexistent compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus was not acidemic at birth.

Thus, it was concluded that the high incidence of meconium observed in the amniotic fluid during labor often represents fetal passage of gastrointestinal contents in conjunction with normal physiological processes. Although normal, such meconium becomes an environmental hazard when fetal acidemia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable. Moreover, Greenwood and colleagues (2003) showed that clear amniotic fluid was also a poor predictor. In a prospective study of 8394 women with clear amniotic fluid, they found that clear fluid was an unreliable sign of fetal well-being.

Growing evidence indicates that many infants with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini, 2001). Blackwell and associates (2001) found that 60 percent of infants diagnosed with meconium aspiration syndrome had umbilical artery blood pH ≥ 7.20 , implying that the syndrome was unrelated to the neonatal condition at delivery. Similarly, markers of chronic hypoxia, such as fetal erythropoietin levels and nucleated red blood cell counts in newborn infants, suggest that chronic hypoxia is involved in many meconium aspiration syndrome cases (Dollberg, 2001; Jazayeri, 2000).

In the recent past, routine obstetrical management of a newborn with meconium-stained amniotic fluid included intrapartum suctioning of the oropharynx and nasopharynx. Guidelines from the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, however, recommend that such infants no longer routinely receive intrapartum suctioning because it does not prevent meconium aspiration syndrome (Perlman, 2010). As discussed in Chapter 32

(p. 626), if the infant is depressed, the trachea is intubated, and meconium suctioned from beneath the glottis. If the newborn is vigorous, defined as having strong respiratory efforts, good muscle tone, and a heart rate > 100 bpm, then tracheal suction is not necessary and may injure the vocal cords.

Management Options

The principal management options for significantly variable fetal heart rate patterns consist of correcting any fetal insult, if possible. Measures suggested by the American College of Obstetricians and Gynecologists (2013b,c) are listed in Table 24-3. Moving the mother to the lateral position, correcting maternal hypotension caused by regional analgesia, and discontinuing oxytocin serve to improve uteroplacental perfusion. Examination is done to exclude prolapsed cord or impending delivery. Simpson and James (2005) assessed benefits of three maneuvers in 52 women with fetal oxygen saturation sensors already in place. They used intravenous hydration—500 to 1000 mL of lactated Ringer solution given over 20 minutes; lateral versus supine position; and using a nonbreathing mask that administered supplemental oxygen at 10 L/min. Each of these maneuvers significantly increased fetal oxygen saturation levels, although the increments were small.

Tocolysis

A single intravenous or subcutaneous injection of 0.25 mg of terbutaline sulfate given to relax the uterus has been described as a temporizing maneuver in the management of nonreassuring fetal heart rate patterns during labor. The rationale is that inhibition of uterine contractions might improve fetal oxygenation, thus achieving in utero resuscitation. Cook and Spinnato (1994) described their experience during 10 years

with terbutaline tocolysis for fetal resuscitation in 368 pregnancies. Such resuscitation improved fetal scalp blood pH values, although all fetuses underwent cesarean delivery. These investigators concluded that although the studies were small and rarely randomized, most reported favorable results with terbutaline tocolysis for nonreassuring patterns. Small intravenous doses of nitroglycerin—60 to 180 µg—also have been reported to be beneficial (Mercier, 1997). The American College of Obstetricians and Gynecologists (2013b) has concluded that there is insufficient evidence to recommend tocolysis for nonreassuring fetal heart rate patterns.

Amnioinfusion

Gabbe and coworkers (1976) showed in monkeys that removal of amniotic fluid produced variable decelerations and that replenishment of fluid with saline relieved the decelerations. Miyazaki and Taylor (1983) infused saline through an intra-uterine pressure catheter in laboring women who had either variable decelerations or prolonged decelerations attributed to cord entrapment. Such therapy improved the heart rate pattern in half of the women studied. Later, Miyazaki and Nevarez (1985) randomly assigned 96 nulliparous women in labor with cord compression patterns and found that those who were treated with amnioinfusion required cesarean delivery for fetal distress less often.

Based on many of these early reports, transvaginal amnioinfusion has been extended into three clinical areas. These include: (1) treatment of variable or prolonged decelerations, (2) prophylaxis for women with oligohydramnios, as with prolonged ruptured membranes, and (3) attempts to dilute or wash out thick meconium (Chap. 33, p. 638).

Many different amnioinfusion protocols have been reported, but most include a 500- to 800-mL bolus of warmed normal

TABLE 24-3. Some Resuscitative Measures for Category II or Category III Tracings

Goal	Associated Fetal Heart Rate Abnormality ^a	Potential Intervention(s) ^b
Improve fetal oxygenation and uteroplacental blood flow	Recurrent late decelerations Prolonged decelerations or bradycardia Minimal or absent FHR variability	Initial lateral decubitus positioning Administer maternal oxygen Administer intravenous fluid bolus Reduce uterine contraction frequency
Take steps to diminish uterine activity	Tachysystole with category II or III tracing	Discontinue oxytocin or prostaglandins Tocolytics, e.g., terbutaline, magnesium sulfate
Relieve umbilical cord compression	Recurrent variable decelerations Prolonged decelerations or bradycardia	Reposition mother Amnioinfusion With prolapse of cord, manually elevate the presenting part while preparing for immediate delivery

^aSimultaneous evaluation of the suspected cause(s) is also an important step in management of abnormal FHR tracings.
^bThe combination of multiple interventions simultaneously may be appropriate and potentially more effective than doing them individually or serially.
FHR = fetal heart rate.

TABLE 24-4. Complications Associated with Amnioinfusion from a Survey of 186 Obstetrical Units

Complication	Centers No. (%)
Uterine hypertonus	27 (14)
Abnormal fetal heart rate tracing	17 (9)
Chorioamnionitis	7 (4)
Cord prolapse	5 (2)
Uterine rupture	4 (2)
Maternal cardiac or respiratory compromise	3 (2)

saline followed by a continuous infusion of approximately 3 mL per minute (Owen, 1990; Pressman, 1996). In another study, Rinehart and colleagues (2000) randomly gave a 500-mL bolus of normal saline at room temperature alone or 500-mL bolus plus continuous infusion of 3 mL per minute. Their study included 65 women with variable decelerations, and the investigators found neither method to be superior. Wenstrom and associates (1995) surveyed use of amnioinfusion in teaching hospitals in the United States. The procedure was used in 96 percent of the 186 centers surveyed, and it was estimated that 3 to 4 percent of all women delivered at these centers received such infusion. Potential complications of amnioinfusion are summarized in [Table 24-4](#).

Prophylactic Amnioinfusion for Variable Decelerations.

Hofmeyr and Lawrie (2012) used the Cochrane Database to specifically analyze the effects of amnioinfusion in the management of fetal heart rate patterns associated with umbilical cord compression. Nineteen suitable studies were identified, most with fewer than 200 participants. It was concluded that amnioinfusion appeared to be useful in reducing the occurrence of variable decelerations, improving neonatal outcome, and reducing cesarean delivery rates. The American College of Obstetricians and Gynecologists (2013a) recommends consideration of amnioinfusion with persistent variable decelerations.

Prophylactic Amnioinfusion for Oligohydramnios.

Amnioinfusion in women with oligohydramnios has been used prophylactically to avoid intrapartum fetal heart rate patterns from cord occlusion. Nageotte and coworkers (1991) found that this resulted in significantly decreased frequency and severity of variable decelerations in labor. However, the cesarean delivery rate or condition of term infants was not improved. In a randomized investigation, Macri and colleagues (1992) studied prophylactic amnioinfusion in 170 term and postterm pregnancies complicated by both thick meconium and oligohydramnios. Amnioinfusion significantly reduced cesarean delivery rates for fetal distress and meconium aspiration syndrome. In contrast, Ogundipe and associates (1994) randomly assigned 116 term pregnancies with an amniotic fluid index < 5 cm to receive prophylactic amnioinfusion or

standard obstetrical care. There were no significant differences in overall cesarean delivery rates, delivery rates for fetal distress, or umbilical cord acid-base studies.

Amnioinfusion for Meconium-Stained Amniotic Fluid.

Pierce and associates (2000) summarized the results of 13 prospective trials of intrapartum amnioinfusion in 1924 women with moderate to thick meconium-stained fluid. Infants born to women treated by amnioinfusion were significantly less likely to have meconium below the vocal cords and were less likely to develop meconium aspiration syndrome than infants born to women not undergoing amnioinfusion. The cesarean delivery rate was also lower in the amnioinfusion group. Similar results were reported by Rathore and coworkers (2002). In contrast, several investigators were not supportive of amnioinfusion for meconium staining. For example, Usta and associates (1995) reported that amnioinfusion was not feasible in half of women with moderate or thick meconium who were randomized to this treatment. These investigators were unable to demonstrate any improvement in neonatal outcomes. Spong and coworkers (1994) also concluded that although prophylactic amnioinfusion did dilute meconium, it did not improve perinatal outcome. Last, Fraser and colleagues (2005) randomized amnioinfusion in 1998 women with thick meconium staining of the amniotic fluid in labor and found no benefits. Because of these findings, the American College of Obstetricians and Gynecologists (2012a, 2013c) does not recommend amnioinfusion to dilute meconium-stained amniotic fluid. According to Xu and coworkers (2007), in areas lacking continuous monitoring, amnioinfusion may be used to lower the incidence of meconium aspiration syndrome.

Fetal Heart Rate Patterns and Brain Damage

Attempts to correlate fetal heart rate patterns with brain damage have been based primarily on studies of infants identified as a result of medicolegal actions. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive fetal heart rate tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominantly before arrival to the hospital. When they looked retrospectively at heart rate patterns in 209 brain-damaged infants, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn, 1996). Graham and associates (2006) reviewed the world literature published between 1966 and 2006 on the effect of fetal heart rate monitoring to prevent perinatal brain injury and found no benefit.

Experimental Evidence

Fetal heart rate patterns necessary for perinatal brain damage have been studied in experimental animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys in studies of brain damage due to perinatal asphyxia. Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration ([Fig. 24-31](#)). Fetal arterial pH did not drop to 7.0 until approximately

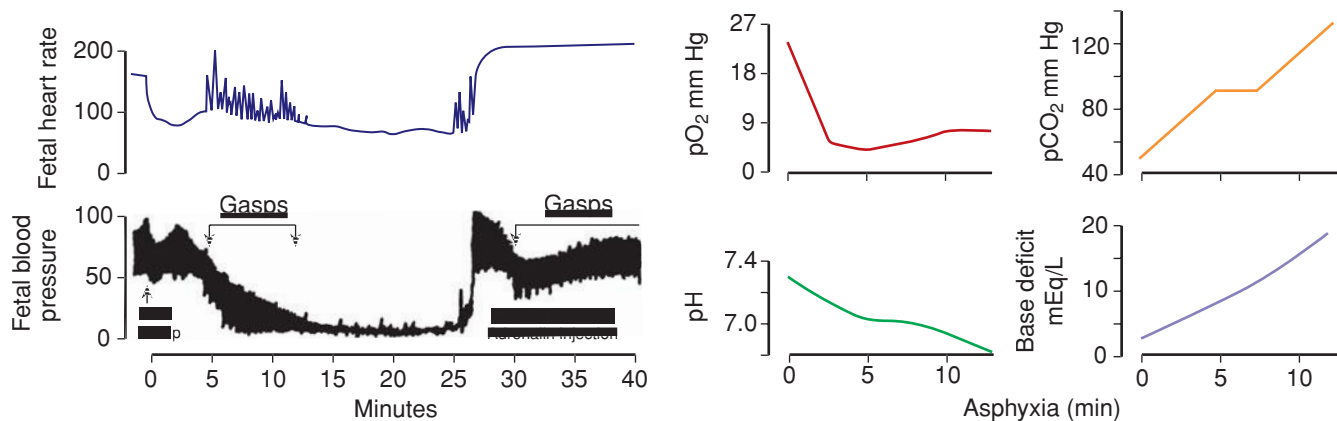

FIGURE 24-31 Prolonged deceleration in a rhesus monkey shown with blood pressure and biochemical changes during total occlusion of umbilical cord blood flow. (Adapted from Myers, 1972.)

8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration was required before there was evidence of brain damage in surviving fetuses.

Myers (1972) also produced partial asphyxia in rhesus monkeys by impeding maternal aortic blood flow. This resulted in late decelerations due to uterine and placental hypoperfusion. He observed that several hours of these late decelerations did not damage the fetal brain unless the pH fell below 7.0. Indeed, Adamsons and Myers (1977) reported subsequently that late decelerations were a marker of partial asphyxia long before brain damage occurred.

The most common fetal heart rate pattern during labor—due to umbilical cord occlusion—requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep. Rocha and associates (2004) totally occluded the umbilical cord for 90 seconds every 30 minutes for 3 to 5 hours a day for 4 days without producing necrotic brain cell injury. Results from such studies suggest that the effects of umbilical cord entrapment depend on the degree of occlusion—partial versus total, the duration of individual occlusions, and the frequency of such occlusions.

Human Evidence

The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated, as discussed in further detail in Chapter 33 (p. 638). It is clear that for brain damage to occur, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Because of this, the American College of Obstetricians and Gynecologists (2012b) recommends umbilical cord blood gases be obtained whenever there is cesarean delivery for fetal compromise, a low 5-minute Apgar score, severe fetal-growth restriction, an abnormal fetal heart rate tracing, maternal thyroid disease, or multifetal gestation (Chap. 32, p. 628). Fetal heart rate patterns consistent with these sublethal conditions are fortunately rare.

Benefits of Electronic Fetal Heart Rate Monitoring

There are several fallacious assumptions behind expectations of improved perinatal outcome with electronic monitoring. One assumption is that fetal distress is a slowly developing phenomenon and that electronic monitoring permits early detection of the compromised fetus. This assumption is illogical—that is, how can all fetuses die slowly? Another presumption is that all fetal damage develops in the hospital. Within the past 20 years, attention has been focused on the reality that most damaged fetuses suffered insults before arrival at labor units. The very term *fetal monitor* implies that this inanimate technology in some fashion “monitors.” The assumption is made that if a dead or damaged infant is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. All of these assumptions led to great expectations and fostered the belief that all neonatal deaths or injuries were preventable.

By the end of the 1970s, questions regarding the efficacy, safety, and costs of electronic monitoring were being voiced from the Office of Technology Assessment, the United States Congress, and the Centers for Disease Control and Prevention. Banta and Thacker (2002) reviewed 25 years of the controversy on the benefits, or lack thereof, of electronic fetal monitoring. Using the Cochrane Database, Alfirevic and colleagues (2013) reviewed 13 randomized trials involving more than 37,000 women. They concluded that electronic fetal monitoring increased the rate of cesarean and operative vaginal deliveries but produced no declines in rates of perinatal mortality, neonatal seizures, or cerebral palsy. Grimes and Peipert (2010) wrote a *Current Commentary* on electronic fetal monitoring in *Obstetrics & Gynecology*. They summarized that such monitoring, although it has been used in 85 percent of the almost 4 million annual births in the United States, has failed as a public health screening program. They noted that the positive predictive value of electronic fetal monitoring for fetal death in labor or cerebral palsy is near zero—meaning that “almost every positive test result is wrong.”

There have been two recent attempts to study the epidemiological effects of electronic fetal monitoring in the United States,

each using national vital statistics of births linked to infant deaths. Chen and coworkers (2011) used 2004 data on 1,732,211 singleton live births, 89 percent of which underwent electronic fetal monitoring. They reported that monitoring increased operative delivery rates but decreased early neonatal mortality rates. This benefit was gestational age dependent, however, and the highest impact was seen in preterm fetuses. Most recently, Ananth and colleagues (2013) reported a similar but larger epidemiological study using United States birth certificate data linked with infant death certificate data. They studied 57,983,286 nonanomalous singleton livebirths born between 1990 and 2004. The temporal increase in fetal monitoring use between 1990 and 2004 was associated with a decline in neonatal mortality rates, especially in preterm gestations. In an accompanying editorial, Resnik (2013) cautioned that an epidemiological association between fetal monitoring and reduced neonatal death does not establish causation. He suggested that the limitations of the study by Ananth “should make the reader skeptical of the findings.” He opined that the electronic fetal monitoring debate “goes on . . . and on . . . and on.” And it does indeed.

■ Parkland Hospital Experience: Selective versus Universal Monitoring

In July 1982, an investigation began at Parkland Hospital to ascertain whether all women in labor should undergo electronic monitoring (Leveno, 1986). In alternating months, universal electronic monitoring was rotated with selective heart rate monitoring, which was the prevailing practice. During the 3-year investigation, 17,410 labors were managed using universal electronic monitoring, and these outcomes were compared with a similar-sized cohort of women selectively monitored electronically. No significant differences were found in any perinatal outcomes. There was a small but significant increase in the cesarean delivery rate for fetal distress associated with universal monitoring. Thus, increased application of electronic monitoring at Parkland Hospital did not improve perinatal results, but it slightly increased the frequency of cesarean delivery for fetal distress.

■ Current Recommendations

The methods most commonly used for intrapartum fetal heart rate monitoring include auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of the heart rate and uterine contractions. No scientific evidence has identified the most effective method, including the frequency or duration of fetal surveillance that ensures optimum results. Summarized in Table 24-5 are the recommendations of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse–patient ratio be used if auscultation is employed. The position taken

TABLE 24-5. Guidelines for Methods of Intrapartum Fetal Heart Rate Monitoring

Surveillance	Low-Risk Pregnancies	High-Risk Pregnancies
Acceptable methods		
Intermittent auscultation	Yes	Yes ^a
Continuous electronic monitoring (internal or external)	Yes	Yes ^b
Evaluation intervals		
First-stage labor (active)	30 min	15 min ^{a,b}
Second-stage labor	15 min	5 min ^{a,c}

^aPreferably before, during, and after a uterine contraction.

^bIncludes tracing evaluation and charting at least every 15 min.

^cTracing should be evaluated at least every 5 min.

From the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012.

by the American College of Obstetricians and Gynecologists (2013b) in their *Practice Bulletin*, however, is somewhat different. While acknowledging that the available data do not show a clear benefit for the use of electronic monitoring over intermittent auscultation, the committee recommends limiting use of auscultation to low-risk pregnancies and further recommends recording the fetal heart rate every 15 minutes in active first stage labor and every 5 minutes in the second stage.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns to labor outcome. There is considerable normal variation, however, and caution must be exercised before judging true labor or its absence solely from a monitor tracing. Uterine muscle efficiency to effect delivery varies greatly. To use an analogy, 100-meter sprinters all have the same muscle groups yet cross the finish line at different times.

■ Internal Uterine Pressure Monitoring

Amnionic fluid pressure is measured between and during contractions by a fluid-filled plastic catheter with its distal tip located above the presenting part (Fig. 24-32). The catheter is connected to a strain-gauge pressure sensor adjusted to the same level as the catheter tip in the uterus. The amplified electrical signal produced in the strain gauge by variation in pressure within the fluid system is recorded on a calibrated moving paper strip simultaneously with the fetal heart rate recording (see Fig. 24-6). Intrauterine pressure catheters are now available that have the pressure sensor in the catheter tip, which obviates the need for the fluid column.

FIGURE 24-32 Placement of an intrauterine pressure catheter to monitor contractions and their pressures. **A.** The white catheter, contained within the blue introducer, is inserted into the birth canal and placed along one side of the fetal head. **B.** The catheter is then gently advanced into the uterus, and the introducer is withdrawn.

External Monitoring

Uterine contractions can be measured by a displacement transducer in which the transducer button, or “plunger,” is held against the abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction. It has generally been accepted to not give an accurate measure of intensity. Bakker and associates (2010) performed a randomized trial comparing internal versus external monitoring of uterine contractions in 1456 women. The two methods were equivalent in terms of operative deliveries and neonatal outcomes.

Patterns of Uterine Activity

Caldeyro-Barcia and Poseiro (1960), from Montevideo, Uruguay, were pioneers who have done much to elucidate

the patterns of spontaneous uterine activity throughout pregnancy. Contractile waves of uterine activity were usually measured using intraamniotic pressure catheters. But early in their studies, as many as four simultaneous intra-myometrial microballoons were also used to record uterine pressure. These investigators also introduced the concept of *Montevideo units* to define uterine activity (Chap. 23, p. 458). By this definition, uterine performance is the product of the intensity—increased uterine pressure above baseline tone—of a contraction in mm Hg multiplied by contraction frequency per 10 minutes. For example, three contractions in 10 minutes, each of 50 mm Hg intensity, would equal 150 Montevideo units.

During the first 30 weeks of pregnancy, uterine activity is comparatively quiescent. Contractions are seldom greater than 20 mm Hg, and these have been equated with those first described in 1872 by John Braxton Hicks. Uterine activity increases gradually after 30 weeks, and it is noteworthy that these *Braxton Hicks contractions* also increase in intensity and frequency. Further increases in uterine activity are typical of the last weeks of pregnancy, termed *prelabor*. During this phase, the cervix ripens (Chap. 21, p. 410).

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes. Importantly, there is no clear-cut division between prelabor and labor, but rather a gradual and progressive transition.

During first-stage labor, uterine contractions increase progressively in intensity from approximately 25 mm Hg at commencement of labor to 50 mm Hg at the end. At the same time, frequency increases from three to five contractions per 10 minutes, and uterine baseline tone from 8 to 12 mm Hg. Uterine activity further increases during second-stage labor, aided by maternal pushing. Indeed, contractions of 80 to 100 mm Hg are typical and occur as frequently as five to six per 10 minutes. Interestingly, the duration of uterine contractions—60 to 80 seconds—does not increase appreciably from early active labor through the second stage (Bakker, 2007; Pontonnier, 1975). Presumably, this duration constancy serves fetal respiratory gas exchange. During a uterine contraction, as the intrauterine pressure exceeds that of the intervillous space, respiratory gas exchange is halted. This leads to functional fetal “breath holding,” which has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensity, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their intensity exceeds 15 mm Hg, presumably because this is the minimum pressure required for distending the lower uterine segment and cervix. It follows that Braxton Hicks contractions exceeding 15 mm Hg may be perceived as uncomfortable because distention of the uterus, cervix, and birth canal is generally thought to produce discomfort.

FIGURE 24-33 Intrauterine pressure recorded through a single catheter. **A.** Prelabor. **B.** Early labor. **C.** Active labor. **D.** Late labor. **E.** Spontaneous activity ½ hour postpartum. **F.** Spontaneous activity 2½ hours postpartum. (Redrawn from Hendricks, 1968, with permission.)

Hendricks (1968) observed that “the clinician makes great demands upon the uterus.” The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. **Figure 24-33** demonstrates an example of normal uterine activity during labor. Uterine activity progressively and gradually increases from prelabor through late labor. Interestingly, as shown in **Figure 24-33**, uterine contractions after birth are identical to those resulting in delivery of the infant. It is therefore not surprising that the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

■ Origin and Propagation of Contractions

The uterus has not been studied extensively in terms of its nonhormonal physiological mechanisms of function. The normal contractile wave of labor originates near the uterine end

of one of the fallopian tubes. Thus, these areas act as “pacemakers” (**Fig. 24-34**). The right pacemaker usually predominates over the left and starts most contractile waves. Contractions spread from the pacemaker area throughout the uterus at 2 cm/sec, depolarizing the whole organ within 15 seconds. This depolarization wave propagates downward toward the cervix. Intensity is greatest in the fundus, and it diminishes in the lower uterus. This phenomenon is thought to reflect reductions in myometrial thickness from the fundus to the cervix. Presumably, this descending gradient of pressure serves to direct fetal descent toward the cervix and to efface the cervix. Importantly, all parts of the uterus are synchronized and reach their peak pressure almost simultaneously, giving rise to the curvilinear waveform shown in **Figure 24-34**. Young and Zhang (2004) have shown that the initiation of each contraction is triggered by a tissue-level bioelectric event.

The pacemaker theory also serves to explain the varying intensity of adjacent coupled contractions shown in panels A and B of **Figure 24-33**. Such coupling was termed *incoordination* by Caldeyro-Barcia and Poseiro (1960). A contractile wave begins in one cornual-region pacemaker, but does not synchronously depolarize the entire uterus. As a result, another contraction begins in the contralateral pacemaker and produces the second contractile wave of the couplet. These small contractions alternating with larger ones appear to be typical of early labor. Indeed, labor may progress with such uterine activity, albeit at a slower pace. These authors also

observed that labor would progress slowly if regular contractions were hypotonic—that is, contractions with intensity less than 25 mm Hg or frequency less than 2 per 10 minutes.

Hauth and coworkers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia.

■ New Terminology for Uterine Contractions

This has been recommended by the American College of Obstetricians and Gynecologists (2013b), for the description and quantification of uterine contractions. *Normal uterine activity* is defined as five or fewer contractions in 10 minutes, averaged over a 30-minute window. *Tachysystole* was defined

FIGURE 24-34 Schematic representation of the normal contractile wave of labor. Large uterus on the left shows the four points at which intramyometrial pressure was recorded with microballoons. Four corresponding pressure tracings are shown in relation to each other by shading on the small uteri at top. (Adapted from Caldeyro-Barcia, 1960.)

as more than five contractions in 10 minutes, averaged over 30 minutes. Tachysystole can be applied to spontaneous or induced labor (Chap. 26, p. 527). The term *hyperstimulation* was abandoned. Stewart and associates (2012) prospectively studied uterine tachysystole in 584 women undergoing labor induction with misoprostol at Parkland Hospital. There was no association of adverse infant outcomes with increasing number of contractions per 10 minutes or per 30 minutes. Six or more contractions in 10 minutes, however, were significantly associated with fetal heart rate decelerations.

Complications of Electronic Fetal Monitoring

Electrodes for fetal heart rate evaluation and catheters for uterine contraction measurement are both associated with infrequent but potentially serious complications. Rarely, an intrauterine pressure catheter during placement may lacerate a fetal vessel in the placenta. Also with insertion, placental and possibly uterine perforation can cause hemorrhage, serious morbidity, and spurious recordings that have resulted in inappropriate management. Severe cord compression has been described from entanglement with the pressure catheter. Injury to the fetal scalp or breech by a heart rate electrode is rarely severe. However, application at some other site—such as the eye in face presentations—can be serious.

Both the fetus and the mother may be at increased risk of infection from internal monitoring (Faro, 1990). Scalp wounds

from the electrode may become infected, and subsequent cranial osteomyelitis has been reported (Brook, 2005; Eggink, 2004; McGregor, 1989). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have recommended that certain maternal infections, including human immunodeficiency virus (HIV), herpes simplex virus, and hepatitis B and C virus, are relative contraindications to internal fetal monitoring.

CHAPTER 25

Obstetrical Analgesia and Anesthesia

GENERAL PRINCIPLES 504

ANALGESIA AND SEDATION DURING LABOR 506

NERVE BLOCKS 507

PUDENDAL BLOCK 508

SPINAL (SUBARACHNOID) BLOCK 510

EPIDURAL ANALGESIA 513

LOCAL INFILTRATION FOR CESAREAN DELIVERY 517

GENERAL ANESTHESIA 517

Obstetrical anesthesia presents unique challenges. Labor begins without warning, and anesthesia may be required within minutes of a full meal. Vomiting with aspiration of gastric contents is a constant threat. The usual physiological adaptations of pregnancy require special consideration, especially with disorders such as preeclampsia, placental abruption, or sepsis syndrome.

Of all anesthesia-related deaths in the United States from 1995 to 2005, 3.6 percent were in pregnant women (Li, 2009). Berg and colleagues (2010) analyzed deaths of women during or within 1 year of pregnancy in the United States from 1998 through 2005. They found that 54 of 4693—1.2 percent—such deaths were attributable to anesthesia complications. Hawkins and associates (2011) analyzed anesthesia-related maternal mortality in this country between 1979 and 2002. As shown in Table 25-1, anesthetic-related maternal mortality rates decreased nearly 60 percent during this time, and there currently is approximately one anesthetic death per million live births. About two thirds of deaths associated with general anesthesia were caused by intubation failure or induction problems during cesarean delivery. Deaths associated with regional analgesia were caused by high spinal or epidural blocks—26 percent;

respiratory failure—19 percent; and drug reaction—19 percent. The improved case-fatality rate for general anesthesia was especially notable considering that such anesthesia is now used for the highest-risk patients and the most hurried emergencies, that is, decision-incision intervals < 15 minutes (Bloom, 2005).

Several factors have contributed to improved obstetrical anesthesia safety (Hawkins, 2011). The most significant is the increased use of regional analgesia. Increased availability of in-house anesthesia coverage almost certainly is another important reason. Despite these encouraging results suggesting the safety of general anesthesia, there are now reports of increasing complications with regional analgesia techniques.

GENERAL PRINCIPLES

Obstetrical Anesthesia Services

- The American College of Obstetricians and Gynecologists (2008) reaffirmed its joint position with the American Society of Anesthesiologists that a woman’s request for labor pain relief is sufficient medical indication for its provision. Identification of any of the risk factors shown in Table 25-2 should prompt consultation with anesthesia personnel to permit a joint management plan. This plan should include strategies to minimize the need for emergency anesthesia in women for whom such anesthesia would be especially hazardous.
- Goals for optimizing obstetrical anesthesia services have been jointly established by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2009) and include:
1. Availability of a licensed practitioner who is credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency
 2. Availability of anesthesia personnel to permit the start of a cesarean delivery within 30 minutes of the decision to perform the procedure

TABLE 25-1. Case-Fatality Rates and Rate Ratios of Anesthesia-Related Deaths During Cesarean Delivery by Type of Anesthesia in the United States, 1979–2002

Year of Death	Case-Fatality Rates ^a		Rate Ratios
	General Anesthesia	Regional Analgesia	
1979–1984	20.0	8.6	2.3 (95% CI 1.9–2.9)
1985–1990	32.3	1.9	16.7 (95% CI 12.9–21.8)
1991–1996	16.8	2.5	6.7 (95% CI 3.0–14.9)
1997–2002	6.5	3.8	1.7 (95% CI 0–4.6)

^aDeaths per million general or regional anesthetics.
CI = confidence interval.
Data from Hawkins, 2011.

3. Anesthesia personnel immediately available to perform an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after cesarean (Chap. 31, p. 615)
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during administration of anesthesia
6. Availability of equipment, facilities, and support personnel equal to that provided in the surgical suite

TABLE 25-2. Maternal Factors That May Prompt Anesthetic Consultation

Morbid obesity
Severe edema or anatomical abnormalities of the face, neck, or spine, including trauma or surgery
Abnormal dentition, small mandible, or difficulty opening the mouth
Extremely short stature, short neck, or neck arthritis
Goiter
Serious maternal medical problems, such as cardiac, pulmonary, or neurological disease
Bleeding disorders
Severe preeclampsia
Prior anesthetic complications
Obstetrical complications likely to lead to operative delivery—examples include placenta previa, preterm breech presentation, or higher-order multifetal gestation

Adapted from the American Academy of Pediatrics and American College of Obstetricians and Gynecologists: Guidelines for Perinatal Care, 7th ed. Washington, 2012.

7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of a depressed newborn (Chap. 32, p. 625).

To meet these goals, 24-hour in-house anesthesia coverage is usually necessary. Providing such service in smaller facilities is more challenging—a problem underscored by the fact that approximately a third of all hospitals providing obstetrical care have fewer than 500 deliveries per year (American College of Obstetricians and Gynecologists, 2009).

Bell and coworkers (2000) calculated the financial burden that may be incurred to provide 24/7 obstetrical anesthesia coverage. Given the average indemnity and Medicaid reimbursement for labor epidural analgesia, they concluded that such coverage could not operate profitably at their tertiary referral institution. Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication—an approach repudiated by the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2008).

Role of an Obstetrician

Every obstetrician should be proficient in local and pudendal analgesia that may be administered in appropriately selected circumstances. In general, however, it is preferable for an anesthesiologist or anesthetist to provide pain relief so that the obstetrician can focus attention on the laboring woman and her fetus.

Principles of Pain Relief

In a scholarly review, Hawkins (2010) emphasized that labor pain is a highly individual response to variable stimuli that are uniquely received and interpreted (Fig. 25-1). These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. Labor pain caused by uterine contractions and cervical dilation is transmitted through visceral afferent sympathetic nerves entering the spinal cord from T₁₀ through L₁. Later in labor, perineal stretching transmits painful stimuli through the pudendal nerve and sacral nerves S₂ through S₄. Cortical responses to pain and anxiety during labor are complex and may be influenced by maternal expectations for childbirth, her age and preparation through education, the presence of emotional support, and other factors. Pain perception is heightened by fear and the need to move into various positions. A woman may be motivated to have a certain type of birthing experience, and these opinions will influence her judgment regarding pain management and other choices during labor and delivery.

Maternal physiological responses to labor pain may influence maternal and fetal well-being and labor progress. For example, hyperventilation may induce hypocarbia. An increased metabolic rate increases oxygen consumption. Increases in cardiac output and vascular resistance may increase maternal blood pressure. Pain, stress, and anxiety cause release of stress hormones such as cortisol and β -endorphins. The sympathetic nervous system response to pain leads to a marked increase

FIGURE 25-1 Sources of pain during labor and maternal physiological responses. (From Hawkins, 2010, with permission.)

in circulating catecholamines that can adversely affect uterine activity and uteroplacental blood flow. Effective analgesia attenuates or eliminates these responses.

ANALGESIA AND SEDATION DURING LABOR

If uterine contractions and cervical dilatation cause discomfort, pain relief with a narcotic such as meperidine (Demerol), plus one of the tranquilizer drugs such as promethazine (Phenergan), is usually appropriate. With a successful program of analgesia and sedation, the mother should rest quietly between contractions. In this circumstance, discomfort usually is felt at the acme of an effective uterine contraction. Appropriate drug selection and

administration of the medications shown in [Table 25-3](#) should safely accomplish these objectives.

Parenteral Agents

Meperidine and Promethazine

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly at intervals of 2 to 4 hours. A more rapid effect is achieved by giving meperidine intravenously in doses of 25 to 50 mg every 1 to 2 hours. Whereas analgesia is maximal 30 to 45 minutes after an intramuscular injection, it develops almost immediately following intravenous administration. Meperidine readily crosses the placenta, and its half-life in the newborn is approximately 13 hours or longer (American College of Obstetricians and Gynecologists, 2013b). Its depressant effect in the fetus follows closely behind the peak maternal analgesic effect.

According to Bricker and Lavender (2002), meperidine is the most common opioid used worldwide for pain relief from labor. Tsui and associates (2004) found meperidine to be superior to placebo for pain relief in the first stage of labor. In a randomized investigation of epidural analgesia conducted at Parkland Hospital, patient-controlled intravenous analgesia with meperidine was found to be an inexpensive and reasonably effective method for labor analgesia (Sharma, 1997). Women randomized to self-administered analgesia were given 50-mg meperidine with 25-mg promethazine intravenously as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed

until delivery. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, was identified in 3 percent of newborns.

Butorphanol (Stadol)

This synthetic narcotic, given in 1- to 2-mg doses, compares favorably with 40 to 60 mg of meperidine (Quilligan, 1980). Its major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is reported to be less than with meperidine. Importantly, the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Hatjis and Meis (1986) described a transient sinusoidal fetal heart rate pattern

TABLE 25-3. Some Parenteral Analgesic Agents for Labor Pain

Agent	Usual Dose	Frequency	Onset	Neonatal Half-Life
Meperidine	25–50 mg (IV)	Q 1–2 hr	5 min (IV)	~18–20 hr
	50–100 mg (IM)	Q 2–4 hr	30–45 min (IM)	~60 hr
Fentanyl	50–100 µg (IV)	Q 1 hr	1 min	~5 hr
Nalbuphine	10 mg (IV or IM)	Q 3 hr	2–3 min (IV)	~4 hr
			15 min (IM)	
Butorphanol	1–2 mg (IV or IM)	Q 4 hr	1–2 min (IV)	Unknown
			10–30 min (IM)	
Morphine	2–5 mg (IV)	Q 4 hr	5 min (IV)	~7 hr
	10 mg (IM)		30–40 min (IM)	

IV = intravenously; IM = intramuscularly; Q = every.

following butorphanol administration but with no short-term maternal or neonatal adverse sequelae (Chap. 24, p. 482).

Fentanyl

This short-acting and potent synthetic opioid may be given in doses of 50 to 100 µg intravenously every hour. Its main disadvantage is a short duration of action, which requires frequent dosing or use of a patient-controlled intravenous pump. Moreover, Atkinson and coworkers (1994) reported that butorphanol provided better initial analgesia than fentanyl and was associated with fewer requests for additional medication or for epidural analgesia.

Efficacy and Safety of Parenteral Agents

Parenteral sedation is not without risks. Hawkins and colleagues (1997) reported that 4 of 129 maternal anesthetic-related deaths were from such sedation—one from aspiration, two from inadequate ventilation, and one from overdosage.

Narcotics used during labor may cause newborn respiratory depression. Naloxone is a narcotic antagonist capable of reversing respiratory depression induced by opioid narcotics. It acts by displacing the narcotic from specific receptors in the central nervous system. Withdrawal symptoms may be precipitated in recipients who are physically dependent on narcotics. For this reason, naloxone is contraindicated in a newborn of a narcotic-addicted mother (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). After adequate ventilation has been established, naloxone may be given to reverse respiratory depression in a newborn infant whose mother received narcotics (Chap. 32, p. 626).

Nitrous Oxide

A self-administered mixture of 50-percent nitrous oxide (N_2O) and oxygen may provide satisfactory analgesia during labor (Rosen, 2002a). Some preparations are premixed in a single cylinder (Entonox), and in others, a blender mixes the two gases from separate tanks (Nitronox). The gases are connected to a breathing circuit through a valve that opens only when the patient inspires. The use of intermittent nitrous oxide for labor pain has been reviewed by Rosen (2002a).

NERVE BLOCKS

Various nerve blocks have been developed over the years to provide pain relief during labor and/or delivery. These include pudendal, paracervical, and neuraxial blocks such as spinal, epidural, and combined spinal-epidural techniques.

Anesthetic Agents

Some of the more commonly used nerve block anesthetics, along with their usual concentrations, doses, and durations of action, are summarized in Table 25-4. The dose of each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by increasing the dose. This can be done safely only by incrementally administering small-volume boluses of the agent and by carefully monitoring early warning signs of toxicity. Administration of these agents must be followed by appropriate monitoring for adverse reactions. Equipment and personnel to manage these reactions must be immediately available.

Most often, serious toxicity follows inadvertent intravenous injection. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems. For this reason, when epidural analgesia is initiated, dilute epinephrine is sometimes added and given as a test dose. A sudden significant rise in the maternal heart rate or blood pressure immediately after administration suggests intravenous catheter placement. Local analgesic agents are manufactured in more than one concentration and ampule size, which increases the potential for dosing errors.

Central Nervous System Toxicity

Early symptoms are those of *stimulation* but, as serum levels increase, *depression* follows. Symptoms may include lightheadedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may show bizarre behavior, slurred speech, muscle fasciculation and excitation, and ultimately, generalized convulsions, followed by loss of consciousness.

For management, the convulsions should be controlled, an airway established, and oxygen delivered. Succinylcholine

TABLE 25-4. Local Anesthetic Agents Commonly Used in Obstetrics

Anesthetic Agent ^a	Usual Concentration (%)	Usual Volume (mL)	Onset	Average Duration (min)	Maximum Dose (mg)	Clinical Use

abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Diazepam (Valium) can be used to inhibit convulsions. Magnesium sulfate, administered according to the regimen for eclampsia, also controls convulsions (Chap. 40, p. 758). Abnormal fetal heart rate patterns such as late decelerations or persistent bradycardia may develop from maternal hypoxia and lactic acidosis induced by convulsions. With arrest of convulsions, administration of oxygen, and application of other supportive measures, the fetus usually recovers more quickly in utero than following immediate cesarean delivery. Moreover, the mother is better served if delivery is forestalled until the intensity of hypoxia and metabolic acidosis has diminished.

Cardiovascular Toxicity

These manifestations generally develop later than those from cerebral toxicity, and they may not develop at all because they are induced by higher serum drug levels. The notable exception is bupivacaine, which is associated with the development of neurotoxicity and cardiotoxicity at virtually identical levels (Mulroy, 2002). Because of this risk of systemic toxicity, use of 0.75-percent solution of bupivacaine for epidural injection has been proscribed by the Food and Drug Administration. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, there is hypertension and tachycardia, which soon is followed by hypotension, cardiac arrhythmias, and impaired uteroplacental perfusion.

Hypotension is managed initially by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with intravenously administered ephedrine. Emergency cesarean delivery is considered if maternal vital signs have not been restored within 5 minutes of cardiac arrest (Chap. 47, p. 956). As with convulsions, however, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

Pudendal Block

Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, vulva, and clitoris. The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. Sensory nerve fibers of the pudendal nerve are derived from ventral branches of the S₂ through S₄ nerves.

The pudendal nerve block is a relatively safe and simple method of providing analgesia for spontaneous delivery. As shown in Figure 25-2, a tubular introducer is used to sheath and guide a 15-cm 22-gauge needle into position over the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine.

FIGURE 25-2 Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament to reach the pudendal nerve.

The introducer allows 1.0 to 1.5 cm of needle to protrude beyond its tip, and the needle is pushed beyond the introducer tip into the mucosa. A mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (see Table 25-3). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The needle is advanced farther through the ligament. As it pierces the loose areolar tissue behind the ligament, the resistance of the plunger decreases. Another 3 mL of solution is injected into this region. Next, the needle is withdrawn into the introducer, which is moved to just above the ischial spine. The needle is inserted through the mucosa and 3 more mL is deposited. The procedure is then repeated on the other side.

Within 3 to 4 minutes of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva bilaterally without pain. If delivery occurs before the pudendal block becomes effective and an episiotomy is indicated, then the fourchette, perineum, and adjacent vagina can be infiltrated with 5 to 10 mL of 1-percent lidocaine solution directly at the planned episiotomy site. By the time of repair, the pudendal block usually has become effective.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Moreover, such analgesia is usually inadequate for women in whom complete visualization of the cervix and upper vagina or manual exploration of the uterine cavity is indicated.

Infrequently, complications may follow this block. As previously described, intravascular injection of a local anesthetic

agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel is most likely when there is a coagulopathy (Lee, 2004). Rarely, severe infection may originate at the injection site. The infection may spread posteriorly to the hip joint, into the gluteal musculature, or into the retrospas space (Svancarek, 1977).

Paracervical Block

This block usually provides satisfactory pain relief during first-stage labor. However, because the pudendal nerves are not blocked, additional analgesia is required for delivery. For paracervical blockade, usually lidocaine or chlorprocaine, 5 to 10 mL of a 1-percent solution, is injected into the cervix laterally at 3 and 9 o'clock. Because these anesthetics are relatively short acting, paracervical block may have to be repeated during labor. We do not use it at Parkland Hospital.

Fetal bradycardia is a worrisome complication that occurs in approximately 15 percent of paracervical blocks (Rosen, 2002b).

Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Doppler studies have shown an increase in the pulsatility index of the uterine arteries following paracervical blockade (Chap. 10, p. 219). These observations support the hypothesis of drug-induced arterial vasospasm as a cause of fetal bradycardia (Manninen, 2000). For these reasons, paracervical block should not be used in situations of potential fetal compromise.

Neuraxial Regional Blocks

Epidural, spinal, or combined spinal-epidural techniques were the more common methods used for relief of pain during labor and/or delivery in the United States in 2008 (Osterman, 2011b). Nearly two out of three mothers receive neuraxial anesthesia for relief of pain either during labor or during vaginal or cesarean delivery. Neuraxial techniques were more common in vaginal deliveries assisted by forceps—84 percent or vacuum extraction—77 percent than spontaneous vaginal deliveries—60 percent (Osterman, 2011a). Among first births, 68 percent of women delivered vaginally received neuraxial pain relief compared with 57 percent of women delivering their second or higher number child.

Epidural *analgesia* via a catheter as shown in Figure 25-3 is typically used for relief of labor pain, although it can also be used for *anesthesia* during operative vaginal and cesarean delivery. Spinal analgesia is typically given as a single intrathecal injection of a local anesthetic at the time of operative vaginal delivery or cesarean. Continuous spinal analgesia during labor via an indwelling spinal catheter is also under investigation. Combined spinal-epidural analgesia/anesthesia also illustrated in Figure 25-3 consists of a single intrathecal injection followed by a catheter placed into the epidural space

FIGURE 25-3 Neuraxial analgesia. **A.** Combined spinal-epidural analgesia. **B.** Epidural analgesia.

for either patient- or provider-controlled infusion of a local anesthetic and/or an opioid such as fentanyl. The combined spinal-epidural technique has the advantages of immediate pain relief from the spinal injection coupled with a portal for continuous analgesia via the epidural catheter. Unlike the spinal injection, the relief provided by the epidural catheter takes approximately 30 minutes to become effective. Perhaps as many as a third of epidural catheter tips will migrate during labor, resulting in ineffective pain control should cesarean be necessary.

■ Spinal (Subarachnoid) Block

Introduction of a local anesthetic into the subarachnoid space to effect analgesia has long been used for delivery. Advantages include a short procedure time, rapid blockade onset, and high success rate. Because of the smaller subarachnoid space during pregnancy, likely the consequence of internal vertebral venous plexus engorgement, the same amount of anesthetic agent in

the same volume of solution produces a much higher blockade in parturients than in nonpregnant women.

Vaginal Delivery

Low spinal block can be used for operative vaginal delivery. The level of analgesia should extend to the T₁₀ dermatome, which corresponds to the level of the umbilicus. Blockade to this level provides excellent relief from the pain of uterine contractions (Fig. 25-4).

Several local anesthetic agents have been used for spinal analgesia (see Table 25-4). Addition of glucose to any of these agents creates a hyperbaric solution, which is heavier and denser than cerebrospinal fluid. A sitting position causes a hyperbaric solution to settle caudally, whereas a lateral position will have a greater effect on the dependent side. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a rapid onset and relatively short duration. Bupivacaine in an 8.25-percent dextrose solution provides satisfactory anesthesia to the lower

FIGURE 25-4 Dermatome distribution.

vagina and the perineum for more than 1 hour. Neither is administered until the cervix is fully dilated, and all other criteria for safe forceps delivery have been fulfilled (Chap. 29, p. 575). Preanalgesic intravenous hydration with 1 L of crystalloid solution will prevent or minimize hypotension in many cases.

Cesarean Delivery

A level of sensory blockade extending to the T₄ dermatome is desired for cesarean delivery (see Fig. 25-4). Depending on maternal size, 10 to 12 mg of bupivacaine in a hyperbaric solution or 50 to 75 mg of lidocaine hyperbaric solution are administered. The addition of 20 to 25 µg of fentanyl increases the rapidity of blockade onset and reduces shivering. The addition of 0.2 mg of morphine improves pain control during delivery and postoperatively.

TABLE 25-5. Complications of Regional Analgesia

Complication	Incidence (%)
Hypotension (in prehydrated women undergoing cesarean delivery)	
Spinal	25–67
Epidural (in prehydrated women in labor)	28–31
Epidural	8.5–9
Fever > 100.4°F (excess rate over women treated with narcotics)	
Nulliparous women	19
Multiparous women	1
Postdural puncture headache	
Spinal	1.5–3
Epidural	2
Combined spinal epidural	1–2.8
Transient fetal heart decelerations	8
Pruritus (with added opioid only)	
Epidural	1.3–26
Spinal	41–85
Inadequate pain relief: epidural	9–15

Complications

Shown in Table 25-5 are some of the more common complications associated with neuraxial analgesia. Importantly, obese women have significantly impaired ventilation and thus close clinical monitoring is imperative (Vricella, 2011).

Hypotension. This common complication may develop soon after injection of the local anesthetic agent. It is the consequence of vasodilatation from sympathetic blockade and is compounded by obstructed venous return due to uterine compression of the great vessels. In the supine position, even in the absence of maternal hypotension measured in the brachial artery, placental blood flow may still be significantly reduced. Treatment includes uterine displacement by left lateral patient positioning, intravenous crystalloid hydration, and intravenous bolus injections of ephedrine or phenylephrine.

Ephedrine is a sympathomimetic drug that binds to alpha- and beta-receptors but also indirectly enhances norepinephrine release. It raises blood pressure by increasing heart rate and cardiac output and by variably elevating peripheral vascular resistance. In animal studies, ephedrine preserves uteroplacental blood flow during pregnancy compared with alpha₁-receptor agonists. Accordingly, it is a preferred vasopressor for obstetrical use. Phenylephrine is a pure alpha agonist and raises blood pressure solely through vasoconstriction. A metaanalysis of seven randomized trials by Lee (2002a) suggests that the safety profiles of ephedrine and phenylephrine are comparable. Following their systematic review of 14 reports, Lee (2002b) questioned whether routine prophylactic ephedrine is needed for elective cesarean delivery. But although fetal acidemia has

been reported with prophylactic ephedrine use, this was not observed with prophylactic phenylephrine use (Ngan Kee, 2004).

Hypotension is the more common blood pressure perturbation. However, paradoxically, hypertension from ergonovine or methylergonovine injections following delivery is more common in women who have received a spinal or epidural block.

High Spinal Blockade. Most often, complete spinal blockade follows administration of an excessive dose of local anesthetic. This is certainly not always the case, because accidental total spinal block has even occurred following an epidural test dose. With complete spinal blockade, hypotension and apnea promptly develop and must be immediately treated to prevent cardiac arrest. In the undelivered woman: (1) the uterus is immediately displaced laterally to minimize aortocaval compression, (2) effective ventilation is established, preferably with tracheal intubation, and (3) intravenous fluids and ephedrine are given to correct hypotension.

Postdural Puncture Headache. Leakage of cerebrospinal fluid (CSF) from the meningeal puncture site can lead to postdural puncture or “spinal headache.” Presumably, when the woman sits or stands, the diminished CSF volume creates traction on pain-sensitive central nervous system structures.

Rates of this complication can be reduced by using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Vallejo and associates (2000) concluded that Sprotte and Whitacre needles had the lowest risks of postdural puncture headaches. Sprigge and Harper (2008) reported that the incidence of postdural puncture headache was 1 percent in more than 5000 women undergoing spinal analgesia. Postdural puncture headaches are much less frequent with epidural blockade because the dura is not intentionally punctured. The incidence of inadvertent dural puncture with epidural analgesia approximates 0.2 percent (Introna, 2012; Katircioglu, 2008). There is no good evidence that placing a woman absolutely flat on her back for several hours is effective in preventing headache. Vigorous hydration may be of value, but compelling evidence to support its use is also lacking.

If a headache develops, the administration of *caff  ine*, a cerebral vasoconstrictor, has been shown in randomized studies to afford temporary relief (Camann, 1990). With severe headache, an *epidural blood patch* is most effective. Ten to 20 mL of autologous blood are obtained aseptically by venipuncture into a tube *without anticoagulant*. This blood is then injected into the epidural space at the site of dural puncture. Further CSF leakage is halted by either mass effect or coagulation. Relief is immediate, and complications are uncommon. In a randomized trial of 64 women, Scavone and coworkers (2004) found that prophylactic blood patch did not decrease either the incidence of postdural puncture headache or the need for a subsequent therapeutic blood patch.

If a headache does not have the pathognomonic postural characteristics or persists despite treatment with a blood patch, other diagnoses should be considered. For example, Chisholm and Campbell (2001) described a case of superior sagittal

sinus thrombosis that manifested as a postural headache. Chan and Paech (2004) have described persistent CSF leak in three women. Smarkusky and colleagues (2006) described pneumocephalus, which caused immediate cephalgia. Finally, intracranial and intraspinal subarachnoid hematomas have developed after spinal analgesia (Dawley, 2009; Liu, 2008).

Convulsions. In rare instances, postdural puncture cephalgia is associated with temporary blindness and convulsions. Shearer and associates (1995) described eight such cases associated with 19,000 regional analgesic procedures done at Parkland Hospital. It is presumed that these too are caused by CSF hypotension. Immediate treatment of seizures and blood patch was usually effective in these cases.

Bladder Dysfunction. With spinal analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for several hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of intravenous fluid are given. Millet (2012) randomized 146 women with neuraxial analgesia to either intermittent or continuous bladder catheterizations and found that the intermittent method was associated with significantly higher rates of bacteriuria.

Arachnoiditis and Meningitis. Local anesthetics are no longer preserved in alcohol, formalin, or other toxic solutes, and disposable equipment is used by most. These practices, coupled with aseptic technique, have made meningitis and arachnoiditis rare but have not eliminated them (Centers for Disease Control and Prevention, 2010).

Contraindications to Spinal Analgesia

Shown in [Table 25-6](#) are the absolute contraindications to regional analgesia according to the American College of Obstetricians and Gynecologists (2013b). Obstetrical complications that are associated with maternal hypovolemia and hypotension—for example, severe hemorrhage—are contraindications to spinal blockade. The additive cardiovascular effects of spinal blockade in the presence of acute blood loss in nonpregnant patients were documented by Kennedy and coworkers (1968).

Disorders of coagulation and defective hemostasis also preclude spinal analgesia use. Although there are no randomized studies to guide the management of anticoagulation at the time of delivery, consensus opinion suggests that women given

TABLE 25-6. Absolute Contraindications to Neuraxial Analgesia

Refractory maternal hypotension
Maternal coagulopathy
Thrombocytopenia (variously defined)
Low-molecular-weight heparin within 12 hours
Untreated maternal bacteremia
Skin infection over site of needle placement
Increased intracranial pressure caused by a mass lesion

subcutaneous unfractionated heparin or low-molecular-weight heparin should be instructed to stop therapy when labor begins (Krivak, 2007). Subarachnoid puncture is also contraindicated if there is cellulitis at the needle entry site. Neurological disorders are considered by many to be a contraindication, if for no other reason than that exacerbation of the neurological disease might be attributed without cause to the anesthetic agent. Other maternal conditions, such as significant aortic stenosis or pulmonary hypertension, are also relative contraindications to spinal analgesia (Chap. 49, p. 983).

As with significant hemorrhage, severe preeclampsia is another complication in which markedly decreased blood pressure can be predicted when neuraxial analgesia is used. Wallace and associates (1995) randomly assigned 80 women with severe preeclampsia undergoing cesarean delivery at Parkland Hospital to receive general anesthesia or either epidural or combined spinal-epidural analgesia. There were no differences in maternal or neonatal outcomes. Still, 30 percent of women given epidural analgesia and 22 percent of those given spinal-epidural blockade developed hypotension—the average reduction in mean arterial pressure was between 15 and 25 percent.

■ Epidural Analgesia

Relief of labor and childbirth pain, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural or peridural space (see Fig. 25-3). This potential space contains areolar tissue, fat, lymphatics, and the internal vertebral venous plexus. This plexus becomes engorged during pregnancy such that the volume of the epidural space

is appreciably reduced. Entry for obstetrical analgesia is usually through a lumbar intervertebral space. Although only one injection may be given, usually an indwelling catheter is placed for subsequent agent administration or continuous infusion. Infusions use a volumetric pump controlled either by the patient or by a caregiver. The American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists (2008) believe that under appropriate physician supervision, labor and delivery nursing personnel who have been specifically trained in the management of epidural infusions should be able to adjust dosage and also discontinue infusions.

Continuous Lumbar Epidural Block

Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T₁₀ to the S₅ dermatomes (Figs. 25-1 and 25-4). For cesarean delivery, a block extending from the T₄ to the S₁ dermatomes is desired. The effective spread of anesthetic depends upon the catheter tip location; the dose, concentration, and volume of anesthetic agent used; and whether the mother is head-down, horizontal, or head-up (Setayesh, 2001). Individual variations in anatomy or presence of synechiae may preclude a completely satisfactory block. Finally, the catheter tip may migrate from its original location during labor.

Technique. One example of the sequential steps and techniques for performance of epidural analgesia is detailed in Table 25-7. Before injection of the local anesthetic therapeutic dose, a test dose is given. The woman is observed for features of toxicity from intravascular injection and for signs of spinal

TABLE 25-7. Technique for Labor Epidural Analgesia

<p>Informed consent is obtained, and the obstetrician consulted</p> <p>Monitoring includes the following:</p> <ul style="list-style-type: none"> Blood pressure every 1 to 2 minutes for 15 minutes after giving a bolus of local anesthetic Continuous maternal heart rate monitoring during analgesia induction Continuous fetal heart rate monitoring Continual verbal communication <p>Hydration with 500 to 1000 mL of lactated Ringer solution</p> <p>The woman assumes a lateral decubitus or sitting position</p> <p>The epidural space is identified with a loss-of-resistance technique</p> <p>The epidural catheter is threaded 3 to 5 cm into the epidural space</p> <p>A test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine or 3 mL of 0.25% bupivacaine with 1:200,000 epinephrine is injected after careful aspiration to avert intravascular injection and after a uterine contraction. This minimizes the chance of confusing tachycardia that results from labor pain with that of tachycardia from intravenous injection of the test dose</p> <p>If the test dose is negative, one or two 5-mL doses of 0.25% bupivacaine are injected to achieve a sensory T₁₀ level</p> <p>After 15 to 20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is withdrawn 0.5 to 1.0 cm and an additional 3 to 5 mL of 0.25% bupivacaine is injected. If the block remains inadequate, the catheter is replaced</p> <p>The woman is positioned in the lateral or semilateral position to avoid aortocaval compression</p> <p>Subsequently, maternal blood pressure is recorded every 5 to 15 minutes. The fetal heart rate is monitored continuously</p> <p>The level of analgesia and intensity of motor blockade are assessed at least hourly</p>

blockade from subarachnoid injection. If these are absent, only then is a full dose given. Analgesia is maintained by intermittent boluses of similar volume, or small volumes of the drug are delivered continuously by infusion pump (Halpern, 2009). The addition of small doses of a short-acting narcotic—fentanyl or sufentanil—has been shown to improve analgesic efficacy while avoiding motor blockade (Chestnut, 1988). As with spinal blockade, it is imperative that close monitoring, including the level of analgesia, be performed by trained personnel. Appropriate resuscitation equipment and drugs must be available during administration of epidural analgesia.

Complications

Total Spinal Blockade. As shown in Table 25-5, there are certain problems inherent in epidural analgesia use. Dural puncture with inadvertent subarachnoid injection may cause total spinal blockade. Sprigge and Harper (2008) cited an incidence of 0.91 percent recognized accidental dural punctures at the time of epidural analgesia in more than 18,000 women. Personnel and facilities must be immediately available to manage this complication as described on page 504.

Ineffective Analgesia. Using currently popular continuous epidural infusion regimens such as 0.125-percent bupivacaine with 2-mg/mL fentanyl, 90 percent of women rate their pain relief as good to excellent (Sharma, 1997). Alternatively, a few women find epidural analgesia to be inadequate for labor. In a study of almost 2000 parturients, Hess and associates (2001) found that approximately 12 percent complained of three or more episodes of pain or pressure. Risk factors for such breakthrough pain included nulliparity, heavier fetal weights, and epidural catheter placement at an earlier cervical dilatation. Dresner and colleagues (2006) reported that epidural analgesia was more likely to fail as body mass index increased. If epidural analgesia is allowed to dissipate before another injection of anesthetic drug, subsequent pain relief may be delayed, incomplete, or both.

In some women, epidural analgesia is not sufficient for cesarean delivery. For example, in a Maternal Fetal Medicine Units (MFMU) Network study, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom, 2005). Also at times, perineal analgesia for delivery is difficult to obtain, especially with the lumbar epidural technique. When this situation is encountered, pudendal block or systemic analgesia or rarely general anesthesia may be added.

Hypotension. Sympathetic blockade from epidurally injected analgesic agents may cause hypotension and decreased cardiac output. According to Miller and coworkers (2013), hypotension is more common—20 percent—in women with an admission pulse pressure < 45 mm Hg compared with 6 percent in those whose pulse pressure is > 45 mm Hg. In normal pregnant women, hypotension induced by epidural analgesia usually can be prevented by rapid infusion of 500 to 1000 mL of crystalloid solution as described for spinal analgesia. Danilenko-Dixon and associates (1996) showed that maintaining a lateral position compared with the supine position minimized hypotension.

Despite these precautions, hypotension is the most frequent side effect and is severe enough to require treatment in a third of women (Sharma, 1997).

Central Nervous Stimulation. Convulsions are an uncommon but serious complication, the immediate management of which was described previously (p. 507). Also cited was the case described by Smarkusky and coworkers (2006) of acute onset of intrapartum headache due to a postdural pneumocephalus.

Maternal Fever. Fusi and colleagues (1989) observed that the mean temperature increased in laboring women given epidural analgesia. Subsequently, several randomized and retrospective cohort studies have confirmed that some women develop intrapartum fever following this procedure. Many studies are limited by inability to control for other risk factors, such as labor length, duration of ruptured membranes, and number of vaginal examinations. With this in mind, the frequency of intrapartum fever associated with epidural analgesia was found by Lieberman and O'Donoghue (2002) to be 10 to 15 percent above the baseline rate.

The two general theories concerning the etiology of maternal hyperthermia are *maternal-fetal infection* or *dysregulation of body temperature*. Dashe and coworkers (1999) studied placental histopathology in laboring women given epidural analgesia and identified intrapartum fever only when there was placental inflammation. This suggests that fever is due to infection. The other proposed mechanisms include alteration of the hypothalamic thermoregulatory set point, impairment of peripheral thermoreceptor input to the central nervous system with selective blockage of warm stimuli, or imbalance between heat production and heat loss. Sharma (2014) randomized 400 nulliparas with labor epidural analgesia to receive cefoxitin 2 g prophylactically versus placebo. It was hypothesized that epidural-related fever was due to infection and that prophylactic antimicrobial use should significantly reduce the rate of fever. Approximately equal proportions—about 40 percent—of women developed fever $\geq 38^{\circ}\text{C}$ during labor. This result suggested that infection was unlikely to be the cause of fever associated with epidural analgesia during labor. Whatever the mechanism, women with persistent fever are usually treated with antimicrobials for presumed chorioamnionitis.

Back Pain. An association between epidural analgesia and back pain has been reported by some but not all. In a prospective cohort study, Butler and Fuller (1998) reported that back pain after delivery was common with epidural analgesia, however, persistent pain was uncommon. Based on their systematic review, Lieberman and O'Donoghue (2002) concluded that available data do not support an association between epidural analgesia and development of de novo, long-term backache.

Miscellaneous Complications. A spinal or epidural hematoma is a rare complication of an epidural catheter (Grant, 2007). Epidural abscesses are equally rare (Darouiche, 2006). Uncommonly, the plastic epidural catheter is sheared off (Noblett, 2007).

Effect on Labor

Most studies, including the combined five randomized trials from Parkland Hospital shown in Table 25-8, report that epidural analgesia prolongs labor and increases the use of oxytocin stimulation. Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) labor curve described in Chapter 22 (p. 445). There were 459 nulliparas randomly assigned to patient-controlled epidural analgesia or patient-controlled intravenous meperidine. Compared with original Friedman criteria, epidural analgesia prolonged the active phase of labor by 1 hour. As further shown in Table 25-8, epidural analgesia also increased the need for operative vaginal delivery because of prolonged second-stage labor, but importantly, without adverse neonatal effects (Chestnut, 1999). This association between epidural analgesia and prolonged second-stage labor as well as operative vaginal delivery has been attributed to local-anesthetic induced motor blockade and resultant impaired maternal expulsive efforts. Craig and colleagues (2014) randomized 310 nulliparous women with labor epidural analgesia to bupivacaine plus fentanyl or fentanyl alone during second-stage labor. Epidural bupivacaine analgesia did cause motor blockade during the second stage, however, the duration of the second stage was not increased. Neither obstetrical nor neonatal outcomes were different between the two study groups. Patient satisfaction was high, irrespective of the method.

Fetal Heart Rate. Hill and associates (2003) examined the effects of epidural analgesia with 0.25-percent bupivacaine on fetal heart rate patterns. Compared with intravenous meperidine, no deleterious effects were identified. Reduced beat-to-beat variability and fewer accelerations were more common in fetuses

TABLE 25-8. Selected Labor Events in 2703 Nulliparous Women Randomized to Epidural Analgesia or Intravenous Meperidine Analgesia

Event ^a	Epidural Analgesia n = 1339	Intravenous Meperidine n = 1364	p value
Labor outcomes			
First-stage duration (hr) ^b	8.1 ± 5	7.5 ± 5	0.011

whose mothers received meperidine (Chap. 24, p. 479). Based on their systematic review, Reynolds and coworkers (2002) reported that epidural analgesia was associated with improved neonatal acid-base status compared with meperidine.

FIGURE 25-5 Results of five studies comparing the incidence of cesarean delivery in women given either epidural analgesia or intravenous meperidine. The individual odds ratios (ORs) with 95-percent confidence intervals (CIs) for each randomized study, as well as overall crude and adjusted ORs with 95-percent CIs, are shown. An OR of less than 1.0 favored epidural over meperidine analgesia. From Sharma, 2004, with permission.

Cesarean Delivery Rates. A contentious issue in the past was whether epidural analgesia increased the risk for cesarean delivery. Evidence that it did was from the era when dense blocks of local anesthetic agents were used that impaired motor function and therefore likely did contribute to increased rates of cesarean delivery. As techniques were refined, however, many investigators believed that epidural administration of *dilute* anesthetic solutions did not increase cesarean delivery rates. Some observational studies have suggested a decreased risk for cesarean delivery with oxytocin induction (Hants, 2013).

Several studies conducted at Parkland Hospital were designed to answer this and related questions. From 1995 to 2002, a total of 2703 nulliparas at term and in spontaneous labor were enrolled in five trials to evaluate epidural analgesia techniques compared with methods of intravenous meperidine administration. The results from these are summarized in Figure 25-5 and show that epidural analgesia does not significantly increase cesarean delivery rates.

Yancey and colleagues (1999) described the effects of an on-demand labor epidural

analgesia service at Tripler Army Hospital in Hawaii. This followed a policy change in military medical centers. As a result, the incidence of labor epidural analgesia increased from 1 percent before the policy to 60 percent within 2 years. The primary cesarean delivery rate was 13.4 percent before and 13.2 percent after this dramatic change. In a follow-up study, Yancey and coworkers (2001) reported that fetal malpresentations at vaginal delivery were not more common after epidural usage increased. The only significant difference that they found was an increased duration of second-stage labor of approximately 25 minutes (Zhang, 2001).

Based on these randomized studies and a metaanalysis of 14 such trials, Sharma and Leveno (2003) and Leighton and Halpern (2002) concluded that epidural analgesia is not associated with an increased cesarean delivery rate.

Timing of Epidural Placement

In several retrospective studies, epidural placement in early labor was linked to an increased risk of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999). These observations prompted at least five randomized trials, which showed that timing of epidural placement has no effect on the risk of cesarean birth, forceps delivery, or fetal malposition (Chestnut, 1994a,b; Luxman, 1998; Ohel, 2006; Wong, 2005, 2009). Thus, withholding epidural placement until some arbitrary cervical dilation has been attained is unsupportable and serves only to deny women maximal labor pain relief. The American College of Obstetricians and Gynecologists (2013b) recommends that the decision for epidural analgesia should be made individually with each patient and that women should not be required to reach 4 to 5 cm cervical dilation before receiving epidural analgesia.

Safety

The relative safety of epidural analgesia is reflected by the extraordinary experiences reported by Crawford (1985) from the Birmingham Maternity Hospital in England. From 1968 through 1985, more than 26,000 women were given epidural analgesia for labor, and there were no maternal deaths. The nine potentially life-threatening complications followed either inadvertent intravenous or intrathecal injection of lidocaine, bupivacaine, or both. Similarly, according to the Confidential Enquiries into Maternal Deaths in the United Kingdom between 2003 and 2005, there were few anesthesia-related deaths associated with epidural use (Lewis, 2007).

There were no anesthesia-related maternal deaths among nearly 20,000 women who received epidural analgesia in the MFMU Network study cited earlier (Bloom, 2005). And finally, Ruppen and associates (2006) reviewed data from 27 studies involving 1.4 million pregnant women who received epidural analgesia. They calculated risks of 1:145,000 for deep epidural infection, 1:168,000 for epidural hematoma, and 1:240,000 for persistent neurological injury.

Contraindications

As with spinal analgesia, contraindications to epidural analgesia include actual or anticipated serious maternal hemorrhage, infection at or near the puncture site, and suspicion of neurological disease (see Table 25-6).

Thrombocytopenia. Although low platelet counts are intuitively worrisome, the level at which epidural bleeding *might* develop is unknown according to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007). Epidural hematomas are rare, and incidence of nerve damage from a hematoma is estimated to be 1 in 150,000 (Grant, 2007). The American College of Obstetricians and Gynecologists (2013b) has concluded that women with a platelet count of 50,000 to 100,000/ μ L may be candidates for regional analgesia.

Anticoagulation. Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and compression (Chap. 52, p. 1039). The American College of Obstetricians and Gynecologists (2013b) has concluded the following:

1. Women receiving unfractionated heparin therapy should be able to receive regional analgesia if they have a normal activated partial thromboplastin time (aPTT)
2. Women receiving prophylactic doses of unfractionated heparin or low-dose aspirin are not at increased risk and can be offered regional analgesia
3. For women receiving once-daily low-dose low-molecular-weight heparin, regional analgesia should not be placed until 12 hours after the last injection
4. Low-molecular-weight heparin should be withheld for at least 2 hours after epidural catheter removal
5. The safety of regional analgesia in women receiving twice-daily low-molecular-weight heparin has not been studied sufficiently. It is not known whether delaying regional analgesia for 24 hours after the last injection is adequate.

Severe Preeclampsia-Eclampsia. Potential concerns with epidural analgesia in those with severe preeclampsia include hypotension as well as hypertension from pressor agents given to correct hypotension. Additionally, there is the potential for pulmonary edema following infusion of large volumes of crystalloid. These are outweighed by disadvantages of general anesthesia. Tracheal intubation may be difficult because of upper airway edema. Moreover, general anesthesia can lead to severe, sudden hypertension that can cause pulmonary or cerebral edema or intracranial hemorrhage.

With improved techniques for infusion of dilute local anesthetics into the epidural space, most obstetricians and obstetrical anesthesiologists have come to favor epidural blockade for labor and delivery in women with severe preeclampsia. There seems to be no argument that epidural analgesia for women with severe preeclampsia-eclampsia can be safely used when trained anesthesiologists and obstetricians are responsible for the woman and her fetus. In a study from Parkland Hospital, Lucas and colleagues (2001) randomly assigned 738 women with hypertension to epidural analgesia or patient-controlled intravenous analgesia during labor. A standardized protocol for prehydration, incremental epidural administration, and ephedrine use was employed. They concluded that labor epidural analgesia was safe in women with hypertensive disorders.

Women with severe preeclampsia have remarkably diminished intravascular volume compared with normal pregnancy

(Zeeman, 2009). Conversely, total body water is increased because of the capillary leak caused by endothelial cell activation (Chap. 40, p. 734). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement increases the risk for pulmonary edema, especially in the first 72 hours postpartum. In one study, Hogg and associates (1999) reported that 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limitation to volume. Importantly, this risk can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001) cited earlier, there were no instances of pulmonary edema among the women in whom the crystalloid preload was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents. This allows maintenance of blood pressure while simultaneously avoiding infusion of large crystalloid volumes.

With vigorous intravenous crystalloid therapy, there is also concern about development of cerebral edema (Chap. 40, p. 745). Finally, Heller and coworkers (1983) demonstrated that most cases of pharyngolaryngeal edema were related to aggressive volume therapy.

Epidural Opiate Analgesia

Injection of opiates into the epidural space to relieve pain from labor has become popular. Their mechanism of action derives from interaction with specific receptors in the dorsal horn and dorsal roots. Opiates alone usually will not provide adequate analgesia, and they most often are given with a local anesthetic agent such as bupivacaine. The major advantages of using such a combination are the rapid onset of pain relief, a decrease in shivering, and less dense motor blockade. Side effects are common and include pruritus and urinary retention. Naloxone, given intravenously, will abolish these symptoms without affecting the analgesic action.

Combined Spinal-Epidural Techniques

The combination of spinal and epidural techniques has increased in popularity and may provide rapid and effective analgesia for labor and for cesarean delivery. An introducer needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the *needle-through-needle technique* (see Figure 25-3). A single bolus of an opioid, sometimes in combination with a local anesthetic, is injected into the subarachnoid space. The spinal needle is withdrawn, and an epidural catheter is then placed through the introducer needle. A subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade. The epidural catheter permits repeated analgesia dosing. Miro (2008) compared epidural analgesia with combined spinal-epidural analgesia for labor in 6497 women and found the overall outcomes and complications to be similar for the two techniques. In a randomized

comparison, however, Abrão and colleagues (2009) reported that combined spinal-epidural analgesia was associated with a greater incidence of fetal heart rate abnormalities related to uterine hypertonus than was epidural analgesia alone. Beamon and coworkers (2014) reported similar results.

Continuous Spinal Analgesia During Labor

There is emerging interest in continuous spinal analgesia for relief of labor pain. This neuraxial technique was first used more than 60 years ago (Hinebaugh, 1944). Frequent severe postdural puncture headaches led to its abandonment. With redesigned needles and catheters, Arkoosh (2008) subsequently randomized 429 women to either continuous spinal or conventional epidural analgesia during labor. There were no differences in complications between these two neuraxial techniques. However, the technique remains investigational.

Local Infiltration for Cesarean Delivery

A local block is occasionally useful to augment an inadequate or “patchy” regional block that was given emergently. Rarely, local infiltration may be needed to perform an emergency cesarean delivery to save the life of a fetus in the absence of anesthesia support. Young (2012) reviewed regional analgesia techniques used for cesarean delivery that provide analgesia to the parietal peritoneum as well as skin and muscles of the anterior abdominal wall.

In one technique, the skin is infiltrated along the proposed incision, and the subcutaneous, muscle, and rectus sheath layers are injected as the abdomen is opened. A dilute solution of lidocaine—30 mL of 2-percent with 1:200,000 epinephrine diluted with 60 mL of normal saline—is prepared, and a total of 100 to 120 mL is infiltrated. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed.

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves. As shown in Figure 25-6, the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. Only one skin puncture is made at each of the four sites (right and left sides). At the intercostal block site, the needle is directed medially, and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Approximately 5 to 8 mL of 0.5-percent lidocaine is injected. The procedure is repeated at a 45-degree angle cephalad and caudad to this line. The other side is then injected. At the ilioinguinal and genitofemoral sites, the injection is started at a site 2 to 3 cm lateral from the pubic tubercle at a 45-degree angle. Finally, the skin overlying the planned incision is injected.

GENERAL ANESTHESIA

Trained personnel and specialized equipment—including fiberoptic intubation—are mandatory for the safe use of general anesthesia. This is because a common cause of death cited for

FIGURE 25-6 Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in the midaxillary line to block the 10th, 11th, and 12th intercostal nerves. A second injection at the external inguinal ring blocks branches of the genitofemoral and ilioinguinal nerves. These sites are infiltrated bilaterally. A final site is along the line of proposed skin incision.

general anesthesia is failed intubation. This occurs in approximately 1 of every 250 general anesthetics administered to pregnant women—a tenfold higher rate than in nonpregnant patients (Hawkins, 2011; Quinn, 2013). The American College of Obstetricians and Gynecologists (2013b) has concluded that this relative increase in morbidity and mortality rates suggests that neuraxial analgesia is the preferred method of pain control and should be used unless contraindicated (see Table 25-6). Indeed, in two reports from the MFMU Network, 93 percent of more than 54,000 cesarean deliveries were performed using neuraxial analgesia (Bloom, 2005; Brookfield, 2013). Butwick and coworkers (2014) cited a higher incidence of general anesthesia use among non-white women.

■ Patient Preparation

Before anesthesia induction, several steps should be taken to help minimize the complication risks. These include antacid use, lateral uterine displacement, and preoxygenation.

Antacid administration shortly before anesthesia induction has probably decreased mortality rates from general anesthesia more than any other single practice. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) recommends timely administration of a nonparticulate antacid, an H_2 -receptor antagonist, or metoclopramide. For many years, we have recommended administration of 30 mL of Bicitra—sodium citrate with citric acid—a few minutes before anesthesia

induction by either general or major neuraxial block. If more than 1 hour has passed after the first dose was given and anesthesia has not yet been induced, then a second dose is given.

Lateral uterine displacement is also provided as the uterus may compress the inferior vena cava and aorta when the mother is supine. With uterine displacement, the duration of general anesthesia has less effect on neonatal condition than if the woman remains supine (Crawford, 1972).

Last, because functional reserve lung capacity is reduced, the pregnant woman becomes hypoxemic more rapidly during periods of apnea than do nonpregnant patients. Obesity exacerbates this tendency (McClelland, 2009). To minimize hypoxia between the time of muscle relaxant injection and intubation, it is important first to replace nitrogen in the lungs with oxygen. This preoxygenation is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes before anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris, 1985).

■ Induction of Anesthesia

Thiopental given intravenously was widely used and offered easy and rapid induction, prompt recovery, and minimal risk of vomiting. Unfortunately, this thiobarbiturate is no longer available in the United States because the sole European manufacturer stopped production on the basis that the drug was also being used for capital punishment (American Society of Anesthesiologists, 2011). It was deemed “an unfortunate irony that many more lives will be lost or put in jeopardy as a result of not having thiopental available for its legitimate medical use.” Drugs now being used in lieu of thiopental include propofol or etomidate. Propofol has the undesirable side effect of hypotension.

Ketamine also may be used to render a patient unconscious. Doses of 1 mg/kg induce general anesthesia. Alternatively, given intravenously in low doses of 0.2 to 0.3 mg/kg, ketamine may be used to produce analgesia and sedation just before vaginal delivery. Ketamine may also prove useful in women with acute hemorrhage because it is not associated with hypotension. Conversely, it usually causes a rise in blood pressure, and thus it generally should be avoided in women who are already hypertensive. Unpleasant delirium and hallucinations are commonly induced by this agent.

■ Intubation

Immediately after a patient is rendered unconscious, a muscle relaxant is given to aid intubation. *Succinylcholine*, a rapid-onset and short-acting agent, frequently is used. Cricoid pressure—the *Sellick maneuver*—is applied by a trained assistant to occlude the esophagus from the onset of induction until intubation is completed. Before the operation begins, proper placement of the endotracheal tube must be confirmed.

■ Failed Intubation

Although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality. A history of prior difficult intubation and a careful anatomical assessment of the neck and the maxillofacial, pharyngeal, and laryngeal structures

may help predict intubation complications. Even in cases in which the initial airway assessment was unremarkable, edema may develop intrapartum and present considerable challenges. Morbid obesity is also a major risk factor for failed or difficult intubation. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) stresses the importance of appropriate preoperative preparation. This includes the immediate availability of specialized equipment such as different-shaped laryngoscopes, laryngeal mask airways, fiberoptic bronchoscope, and transtracheal ventilation set, as well as liberal use of awake oral intubation techniques.

Management. An important principle is to start the operative procedure only after it has been ascertained that tracheal intubation has been successful and that adequate ventilation can be accomplished. Even with an abnormal fetal heart rate pattern, cesarean delivery initiation will only serve to complicate matters if there is difficult or failed intubation. Frequently, the woman must be allowed to awaken and a different technique used, such as an awake intubation or regional analgesia.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the aspiration risk. Surgery may proceed with mask ventilation, or the woman may be allowed to awaken. In those cases in which the woman has been paralyzed and in which ventilation cannot be reestablished by insertion of an oral airway, by laryngeal mask airway, or by use of a fiberoptic laryngoscope to intubate the trachea, then a life-threatening emergency exists. To restore ventilation, percutaneous or even open cricothyrotomy is performed, and jet ventilation begun. Failed intubation drills have been recommended to optimize response to such an emergency.

Gas Anesthetics

Once the endotracheal tube is secured, a 50:50 mixture of nitrous oxide and oxygen is administered to provide analgesia. Usually, a volatile halogenated agent is added to provide amnesia and additional analgesia. The mechanisms of action of inhaled anesthetics have been reviewed by Campagna and associates (2003).

The most commonly used volatile anesthetics in the United States include *isoflurane* and two of its derivatives, *desflurane* and *sevoflurane*. They are usually added in low concentrations to the nitrous oxide-oxygen mixture to provide amnesia. They are potent, nonexplosive agents that produce remarkable uterine relaxation when given in high concentrations. These are used when relaxation is a requisite, such as for internal podalic version of the second twin, breech decomposition, and replacement of the acutely inverted uterus.

Extubation

The endotracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Consideration should be given to emptying the stomach via a nasogastric tube before extubation. As induction has become safer, extubation may now be more perilous. Of 15 anesthesia-related deaths of pregnant women from 1985 to

2003 in Michigan, none occurred during induction, whereas five resulted from hypoventilation or airway obstruction during emergence, extubation, or recovery (Mhyre, 2007).

Aspiration

Massive gastric acidic inhalation may cause pulmonary insufficiency from aspiration pneumonitis. Such pneumonitis has in the past been the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. To minimize this risk, antacids should be given routinely, intubation should be accompanied by cricoid pressure, and regional analgesia should be employed when possible.

Fasting

According to the American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2007) and the American College of Obstetricians and Gynecologists (2013a), there are insufficient data regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. Recommendations are that modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, and pulp-free fruit juices be allowed in uncomplicated laboring women. Obvious solid foods should be avoided. A fasting period of 6 to 8 hours, depending on the type of food ingested, is recommended for uncomplicated parturients undergoing elective cesarean delivery or puerperal tubal ligation.

O'Sullivan (2009) randomized 2426 low-risk nulliparas to consume either water and ice chips alone or small amounts of bread, biscuits, vegetables, fruits, yogurt, soup, and fruit juice. Approximately 30 percent of women in each arm of the study underwent cesarean delivery. No cases of aspiration occurred during the study, although approximately a third of women in each study arm vomited during labor or delivery. Epidural analgesia during labor was used in this study, although the authors did not report the type of anesthesia used for cesarean deliveries. Presumably neuraxial analgesia was used for cesarean deliveries, and this greatly minimized the pulmonary aspiration risk associated with general anesthesia. Given the low prevalence of aspiration, this trial, albeit large, was not powered to measure whether feeding during labor was safe. Our policy at Parkland Hospital is to prohibit oral intake during labor and delivery.

Pathophysiology

In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. It was later demonstrated that the gastric juice pH of nearly half of women tested intrapartum was < 2.5 (Taylor, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore, the right lower lobe is most often involved. In severe cases, there is bilateral widespread involvement.

The woman who aspirates may develop evidence of respiratory distress immediately or several hours after aspiration, depending in part on the material aspirated and the severity of the response. Aspiration of a large amount of solid material causes obvious airway obstruction signs. Smaller particles

without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the injury sites, there is pulmonary capillary leakage and exudation of protein-rich fluid containing numerous erythrocytes into the lung interstitium and alveoli. This causes decreased pulmonary compliance, shunting of blood, and severe hypoxemia. Radiographic changes may not appear immediately, and these may be variable, although the right lung most often is affected. Therefore, chest radiographs alone should not be used to exclude aspiration.

Treatment

The methods recommended for treatment of aspiration have changed appreciably in recent years, indicating that previous therapy was not very successful. Suspicion of aspiration of gastric contents demands close monitoring for evidence of pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury.

Inhaled fluid should be immediately and thoroughly wiped from the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. There is no convincing clinical or experimental evidence that corticosteroid therapy or prophylactic antimicrobial administration is beneficial (Marik, 2001). If clinical evidence of infection develops, however, then vigorous treatment is given. If acute respiratory distress syndrome develops, mechanical ventilation with positive end-expiratory pressure may prove lifesaving (Chap. 47, p. 944).

CHAPTER 26

Induction and Augmentation of Labor

LABOR INDUCTION	523
PREINDUCTION CERVICAL RIPENING	525
CERVICAL “FAVORABILITY”	525
PHARMACOLOGICAL TECHNIQUES	526
MECHANICAL TECHNIQUES	528
METHODS OF INDUCTION AND AUGMENTATION	528
PROSTAGLANDIN E ₁	529
OXYTOCIN	529
AMNIOTOMY FOR INDUCTION AND AUGMENTATION ..	531

Induction implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. When the cervix is closed and uneffaced, labor induction will often commence with *cervical ripening*, a process that generally employs prostaglandins to soften and open the cervix.

Augmentation refers to enhancement of spontaneous contractions that are considered inadequate because of failed cervical dilation and fetal descent. In the United States, the incidence of labor induction more than doubled from 9.5 percent in 1991 to 23.2 percent in 2011 (Martin, 2013). The incidence is variable between practices. At Parkland Hospital approximately 35 percent of labors are induced or augmented. By comparison, at the University of Alabama at Birmingham Hospital, labor is induced in approximately 20 percent of women, and another 35 percent are given oxytocin for augmentation—a total of 55 percent. This chapter includes an overview of indications for labor induction and augmentation and a description of various techniques to effect preinduction cervical ripening.

LABOR INDUCTION

Indications

Induction is indicated when the benefits to either mother or fetus outweigh those of pregnancy continuation. The more common indications include membrane rupture without labor, gestational hypertension, oligohydramnios, nonreassuring fetal status, postterm pregnancy, and various maternal medical conditions such as chronic hypertension and diabetes (American College of Obstetricians and Gynecologists, 2013b).

Contraindications

Methods to induce or augment labor are contraindicated by most conditions that preclude spontaneous labor or delivery. The few maternal contraindications are related to prior uterine incision type, contracted or distorted pelvic anatomy, abnormally implanted placentas, and uncommon conditions such as active genital herpes infection or cervical cancer. Fetal factors include appreciable macrosomia, severe hydrocephalus, malpresentation, or nonreassuring fetal status.

Techniques

Oxytocin has been used for decades to induce or augment labor. Other effective methods include prostaglandins, such as misoprostol and dinoprostone, and mechanical methods that encompass stripping of membranes, artificial rupture of membranes, extraamniotic saline infusion, transcervical balloons, and hygroscopic cervical dilators. Importantly, and as recommended in *Guidelines for Perinatal Care*, each obstetrical department should have its own written protocols that describe administration of these methods for labor induction and augmentation (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

Risks

Maternal complications associated with labor induction consist of cesarean delivery, chorioamnionitis, uterine scar rupture, and postpartum hemorrhage from uterine atony.

Cesarean Delivery Rate

This is especially increased in nulliparas undergoing induction (Luthy, 2004; Yeast, 1999). Indeed, several investigators have reported a two- to threefold increased risk (Hoffman, 2003; Maslow, 2000; Smith, 2003). Moreover, these rates are inversely related with cervical favorability at induction, that is, the *Bishop score* (Vahratian, 2005; Vrouenraets, 2005). The increased risk for cesarean delivery with labor induction does not appear to be lowered with preinduction cervical ripening in the nullipara with an unfavorable cervix (Mercer, 2005). In fact, the cesarean delivery rate following elective induction was significantly increased even in women with a Bishop score of 7 or greater compared with that in those with spontaneous labor (Hamar, 2001). Station and position of the fetal vertex may also affect success rates. For example, in nulliparas at > 41 weeks' gestation and with an unengaged vertex, the cesarean delivery rate was increased 12-fold compared with that in women with an engaged fetal vertex (Shin, 2004).

The premise that elective labor induction increases the risk of cesarean delivery has been questioned (Macones, 2009). Many studies have compared women undergoing labor induction to those laboring spontaneously. However, using women undergoing expectant management, Osmundson and colleagues (2010, 2011) reported similar cesarean delivery rates in more than 4000 women undergoing elective induction between 39 and nearly 41 weeks with or without a favorable cervix. Currently, this subject remains unresolved.

Chorioamnionitis

Amniotomy is often selected to augment labor (p. 531). Women whose labor is managed with amniotomy have an increased incidence of chorioamnionitis compared with those in spontaneous labor (American College of Obstetricians and Gynecologists, 2013a).

Rupture of a Prior Uterine Incision

Uterine rupture during labor in women with a history of prior uterine surgery can be catastrophic (Chap. 31, p. 613). Some of these risks were quantified by Lydon-Rochelle and associates (2001), who reported that the uterine rupture risk is increased threefold for women in spontaneous labor with a uterine scar. With oxytocin labor induction without prostaglandins, the risk was fivefold increased, and with prostaglandins, it was strikingly increased 15.6-fold. The Maternal-Fetal Medicine Units Network also reported a threefold increased risk of uterine scar rupture with oxytocin, and this was even higher when prostaglandins were also used (Landon, 2004). The American College of Obstetricians and Gynecologists (2013d) recommends against the use of misoprostol for preinduction cervical ripening or labor induction in women with a prior uterine scar (Chap. 31, p. 615).

Uterine Atony

Postpartum hemorrhage from uterine atony is more common in women undergoing induction or augmentation. And, atony with intractable hemorrhage, especially during cesarean delivery, is a frequent indication for peripartum hysterectomy (Shellhaas, 2009). In a study from Parkland Hospital, labor induction was associated with 17 percent of 553 emergency peripartum hysterectomies (Hernandez, 2013). In the United States, Bateman and coworkers (2012) reported that the postpartum hysterectomy rate increased 15 percent between 1994 and 2007. This was largely attributable to increased rates of atony associated with more medical labor inductions and more primary and repeat cesarean deliveries. Finally, elective induction was associated with more than a threefold increased rate of hysterectomy in the analysis by Bailit and colleagues (2010).

Elective Labor Induction

There can be no doubt that elective induction for convenience has become more prevalent. In the United States between 1991 and 2006, rates of early term labor induction increased significantly for all race and ethnicity groups (Murthy, 2011). This was highest for non-Hispanic white women in 2006. In this group, the rate was 20.5 percent if there was either diabetes or hypertension and was 9 percent for women without these indications. Clark and coworkers (2009) reported data from 14,955 deliveries at 37 weeks or greater. They noted that 32 percent were elective deliveries, and 19 percent were elective labor inductions.

The American College of Obstetricians and Gynecologists (2013b) does not endorse this widespread practice. Occasional exceptions might include logistical and other reasons such as a risk of rapid labor, a woman who lives a long distance from the hospital, or psychosocial indications. We are also of the opinion that routine elective induction at term is not justified because of the increased risks for adverse maternal outcomes. Elective delivery before 39 completed weeks is also associated with significant and appreciable adverse neonatal morbidity (Chiossi, 2013; Clark, 2009; Tita, 2009). If elective induction is considered at term, inherent risks must be discussed, informed consent obtained, and guidelines followed as promulgated by the American College of Obstetricians and Gynecologists (2013b), which are detailed in Chapter 31 (p. 610).

Guidelines to discourage elective inductions have been described by Fisch (2009) and Oshiro (2013) and their associates. Both groups reported significant decreases in elective delivery rates following guideline initiation. Tanne (2013) surveyed more than 800 United States hospitals and reported that efforts to reduce early term deliveries are succeeding.

Factors Affecting Successful Induction

Several factors increase or decrease the ability of labor induction to achieve vaginal delivery. Favorable factors include multiparity, body mass index (BMI) < 30, favorable cervix, and birthweight < 3500 g (Peregrine, 2006; Pevzner, 2009). For both nulliparas and multiparas, Kominiarek and colleagues (2011) found that labor duration to reach the active phase and to complete dilatation was adversely affected by a higher BMI.

In many cases, the uterus is simply poorly prepared for labor. One example is an “unripe cervix.” Indeed, investigators with the *Consortium on Safe Labor* reported that elective induction resulted in vaginal delivery in 97 percent of multiparas and 76 percent of nulliparas, but that induction was more often successful with a ripe cervix (Laughon, 2012a). The increased cesarean delivery risk associated with induction is likely also strongly influenced by the induction attempt duration, especially with an unfavorable cervix (Spong, 2012). Simon and Grobman (2005) concluded that a latent phase as long as 18 hours during induction allowed most of these women to achieve a vaginal delivery without a significantly increased risk of maternal or neonatal morbidity. Rouse and associates (2000) recommend a minimum of 12 hours of uterine stimulation with oxytocin after membrane rupture.

PREINDUCTION CERVICAL RIPENING

As noted, the condition of the cervix—described as cervical “ripeness” or “favorability”—is important to successful labor induction. That said, at least some estimates of favorability are highly subjective. In either case, there are pharmacological and

mechanical methods that can enhance cervical favorability—also termed *preinduction cervical ripening*.

Some of the techniques described may have benefits when compared with oxytocin induction alone (Table 26-1). Some are also quite successful for initiating labor. That said, few data support the premise that any of these techniques results in a reduced cesarean delivery rate or in less maternal or neonatal morbidity compared with that in women in whom these methods are not used.

Cervical “Favorability”

One quantifiable method used to predict labor induction outcomes is the score described by Bishop (1964) and presented in Table 26-2. As favorability or Bishop score decreases, the rate of induction to effect vaginal delivery also declines. A *Bishop score* of 9 conveys a high likelihood for a successful induction. Put another way, most practitioners would consider that a woman whose cervix is 2-cm dilated, 80-percent effaced, soft, and mid-position and with the fetal occiput at –1 station would have a successful labor induction. For research purposes, a Bishop score of 4 or less identifies an unfavorable cervix and may be an indication for cervical ripening.

TABLE 26-1. Some Commonly Used Regimens for Preinduction Cervical Ripening and/or Labor Induction

Techniques	Agent	Route/Dose	Comments
Pharmacological			
Prostaglandin E ₂	Dinoprostone gel, 0.5 mg (Prepidil)	Cervical 0.5 mg; repeat in 6 hr; permit 3 doses total	1. Shorter I-D times with oxytocin infusion than oxytocin alone
	Dinoprostone insert, 10 mg (Cervidil)	Posterior fornix, 10 mg	1. Insert has shorter I-D times than gel 2. 6–12 hr interval from last insert to oxytocin infusion
Prostaglandin E ₁ ^a	Misoprostol tablet, 100 or 200 µg (Cytotec) ^b	Vaginal, 25 µg; repeat 3–6 hr prn Oral, 50–100 µg; repeat 3–6 hr prn	1. Contractions within 30–60 min 2. Comparable success with oxytocin for ruptured membranes at term and/or favorable cervix 3. Tachysystole common with vaginal doses > 25 µg
Mechanical			
Transcervical 36F Foley catheter	30-mL balloon		1. Improves Bishop scores rapidly 2. 80-mL balloon more effective 3. Combined with oxytocin infusion is superior to PGE ₁ vaginally 4. Results improved with EASI with possible decreased infection rate
Hygroscopic dilators		Laminaria, magnesium sulfate	1. Rapidly improves Bishop score 2. May not shorten I-D times with oxytocin 3. Uncomfortable, requires speculum and placement on an examination table

^aOff-label use.

^bTablets must be divided for 25- and 50-µg dose, but drug is evenly dispersed.

EASI = extraamniotic saline infusion at 30–40 mL/hr; I-D = induction-to-delivery.

TABLE 26-2. Bishop Scoring System Used for Assessment of Inducibility

Score	Cervical Factor				
	Dilatation (cm)	Effacement (%)	Station (-3 to +2)	Consistency	Position
0	Closed	0-30	-3	Firm	Posterior
1	1-2	40-50	-2	Medium	Midposition
2	3-4	60-70	-1	Soft	Anterior
3	≥ 5	≥ 80	+1, +2	—	—

From Bishop, 1964.

Laughon and coworkers (2011) attempted to simplify the Bishop score by performing a regression analysis on 5610 singleton, uncomplicated deliveries by nulliparas between 37^{0/7} and 41^{6/7} weeks. Only cervical dilation, station, and effacement were significantly associated with successful vaginal delivery. Thus, a simplified Bishop score, which incorporated only these three parameters, had a similar or improved positive- or negative-predictive value compared with that of the original Bishop score.

Transvaginal sonographic measurement of cervical length has been evaluated as a Bishop score alternative. Hatfield and associates (2007) performed a metaanalysis of 20 trials in which cervical length was used to predict successful induction. Because of study criteria heterogeneity—including the definition of “successful induction”—the authors concluded that the question remains unanswered. Both this study and the one by Uzun and colleagues (2013) found that sonographically determined cervical length was not superior to the Bishop score for predicting induction success.

■ Pharmacological Techniques

Unfortunately, women frequently have an indication for induction but also have an unfavorable cervix. Thus, considerable research has been directed toward techniques to “ripen” the cervix before uterine contraction stimulation. Importantly, more often than not, techniques used to improve cervical favorability also stimulate contractions and thereby aid subsequent labor induction or augmentation. Techniques most commonly used for preinduction cervical ripening and induction include several prostaglandin analogues.

Prostaglandin E₂

Dinoprostone is a synthetic analogue of prostaglandin E₂. It is commercially available in three forms: a gel, a time-release vaginal insert, and a 10-mg suppository. The gel and time-release vaginal insert formulations are indicated only for cervical ripening before labor induction. However, the 10-mg suppository is indicated for pregnancy termination between 12 and 20 weeks and for evacuation of the uterus after fetal demise up to 28 weeks.

Local application of dinoprostone is commonly used for cervical ripening (American College of Obstetricians and Gynecologists, 2013b). Its gel form—*Prepidil*—is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. With the woman supine, the tip of a prefilled syringe is placed intracervically, and the gel is deposited just below the internal cervical os. After application, the woman remains reclined for at least

30 minutes. Doses may be repeated every 6 hours, with a maximum of three doses recommended in 24 hours.

A 10-mg dinoprostone vaginal insert—*Cervidil*—is also approved for cervical ripening. This is a thin, flat, rectangular polymeric wafer held within a small, white, mesh polyester sac (Fig. 26-1). The sac has a long attached tail to allow easy removal from the vagina. The insert provides slower release of medication—0.3 mg/hr—than the gel form. *Cervidil* is used as a single dose placed transversely in the posterior vaginal fornix. Lubricant should be used sparingly, if at all, because it can coat the device and hinder dinoprostone release. Following insertion, the woman should remain recumbent for at least 2 hours. The insert is removed after 12 hours or with labor onset and at least 30 minutes before the administration of oxytocin.

Most metaanalyses of dinoprostone efficacy report a reduced time to delivery within 24 hours. However, they do not consistently show a reduction in the cesarean delivery rate. Kelly and coworkers (2009) provided a Cochrane review of 63 trials and 10,441 women given vaginal prostaglandins or either placebo or no treatment. These investigators reported a higher vaginal delivery rate within 24 hours when prostaglandins were used. They also found that cesarean delivery rates were unchanged. Similar results were reported after another Cochrane review of intracervical dinoprostone gel by Boulvain and associates (2008). Compared with placebo or no treatment, a reduced risk of cesarean delivery was found only in a subgroup of women

FIGURE 26-1 Cervidil vaginal insert contains 10 mg of dinoprostone designed to release approximately 0.3 mg/hr during a 10-hour period.

with an unfavorable cervix and intact membranes. Finally, the Foley catheter versus vaginal prostaglandin E₂ gel for induction of labor at term (PROBAAT trials) were unblinded, randomized trials comparing these two options (Jozwiak, 2011, 2013a, 2014). There was no difference in cesarean delivery rate, a finding consistent with accompanying metaanalyses.

Side Effects. Uterine tachysystole has been reported to follow vaginally administered prostaglandin E₂ in 1 to 5 percent of women (Hawkins, 2012). Although definitions of uterine activity vary among studies, most use the definition recommended by the American College of Obstetricians and Gynecologists (2013c):

1. *Uterine tachysystole* is defined as > 5 contractions in a 10-minute period. It should always be qualified by the presence or absence of fetal heart rate abnormalities.
2. *Uterine hypertonus, hyperstimulation, and hypercontractility are terms no longer defined, and their use is not recommended.*

Because uterine tachysystole associated with fetal compromise may develop when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. If tachysystole follows the 10-mg insert, its removal by pulling on the tail of the surrounding net sac will usually reverse this effect. Irrigation to remove the gel preparation has not been shown to be helpful.

The manufacturers recommend caution when these preparations are used in women with ruptured membranes. Caution is also recommended when they are used in women with glaucoma or asthma. In a review of 189 women with asthma, however, dinoprostone was not associated with asthma worsening or exacerbation (Towers, 2004). Other contraindications listed by the manufacturers include a history of dinoprostone hypersensitivity, suspicion of fetal compromise or cephalopelvic disproportion, unexplained vaginal bleeding, women already receiving oxytocin, those with six or more previous term pregnancies, those with a contraindication to vaginal delivery, or women with a contraindication to oxytocin or who may be endangered by prolonged uterine contractions, for example, those with a history of cesarean delivery or uterine surgery.

Administration. Prostaglandin E₂ preparations should only be administered in or near the delivery suite. Moreover, uterine activity and fetal heart rate should be monitored (American College of Obstetricians and Gynecologists, 2013b). These guidelines stem from the risk of uterine tachysystole. When contractions begin, they are usually apparent in the first hour and show peak activity in the first 4 hours. According to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following prostaglandin E₂ gel administration or for at least 30 minutes after removal of the vaginal insert.

Prostaglandin E₁

Misoprostol—*Cytotec*—is a synthetic prostaglandin E₁ that is approved as a 100- or 200-μg tablet for peptic ulcer prevention. It has been used “off label” for preinduction cervical ripening and may be administered orally or vaginally. The tablets

are stable at room temperature. Although widespread, the off-label use of misoprostol has been controversial (Wagner, 2005; Weeks, 2005). Specifically, G. D. Searle & Company (Cullen, 2000) notified physicians that misoprostol is not approved for labor induction or abortion. At the same time, however, the American College of Obstetricians and Gynecologists (2013b) reaffirmed its recommendation for use of the drug because of proven safety and efficacy. It currently is the preferred prostaglandin for cervical ripening at Parkland Hospital.

Vaginal Administration. Numerous studies have reported equivalent or superior efficacy for cervical ripening or labor induction with vaginally administered misoprostol tablets compared with intracervical or intravaginal prostaglandin E₂. A metaanalysis of 121 trials also confirmed these findings (Hofmeyr, 2010). Compared with oxytocin or with intravaginal or intracervical dinoprostone, misoprostol increased the vaginal delivery rate within 24 hours. Moreover, although the uterine tachysystole rate increased, this did not affect cesarean delivery rates. Compared with dinoprostone, misoprostol decreased the need for oxytocin induction, but it increased the frequency of meconium-stained amniotic fluid. Higher doses of misoprostol are associated with a decreased need for oxytocin but more uterine tachysystole with and without fetal heart rate changes. The American College of Obstetricians and Gynecologists (2013b) recommends the 25-μg vaginal dose—a fourth of a 100-μg tablet. The drug is evenly distributed among these quartered tablets.

Wing and colleagues (2013) recently described use of a vaginal polymer insert containing 200 μg of PGE₁. They compared its efficacy with 10-mg dinoprostone inserts, and preliminary observations are favorable.

Oral Administration. Prostaglandin E₁ tablets are also effective when given orally. Ho and coworkers (2010) performed a randomized controlled trial comparing titrated oral misoprostol with oxytocin. They found similar rates of vaginal delivery and side effects. In a metaanalysis of nine trials including nearly 3000 women, however, there were reported improvements in various outcomes with oral misoprostol (Kundodyiwa, 2009). In particular, there was a significantly lower cesarean delivery rate for the five trials comparing oral misoprostol with dinoprostone—relative risk 0.82. For the two trials comparing oral with vaginal misoprostol, oral misoprostol was associated with a lower rate of uterine tachysystole with fetal heart rate changes, but there were no significant differences with respect to rates of cesarean delivery or other outcomes.

Nitric Oxide Donors

Several findings have led to a search for clinical agents that stimulate nitric oxide (NO) production locally (Chanrachakul, 2000a). This is because nitric oxide is likely a mediator of cervical ripening (Chap. 21, p. 423). Also, cervical nitric oxide metabolite concentrations are increased at the beginning of uterine contractions. Last, cervical nitric oxide production is very low in postterm pregnancy (Väisänen-Tommiska, 2003, 2004).

Bullarbo and colleagues (2007) reviewed rationale and use of two nitric oxide donors, *isosorbide mononitrate* and *glyceryl trinitrate*. Isosorbide mononitrate induces cervical cyclooxygenase 2 (COX-2), and it also brings about cervical ultrastructure rearrangement similar to that seen with spontaneous cervical ripening (Ekerhovd, 2002, 2003). Despite this, clinical trials have not shown nitric oxide donors to be as effective as prostaglandin E₂ for cervical ripening (Chanrachakul, 2000b; Osman, 2006). Moreover, the addition of isosorbide mononitrate to either dinoprostone or misoprostol did not enhance cervical ripening either in early or term pregnancy nor did it shorten time to vaginal delivery (Collingham, 2010; Ledingham, 2001; Wölfler, 2006). A metaanalysis of 10 trials including 1889 women concluded that nitric oxide donors do not appear to be useful for cervical ripening during labor induction (Kelly, 2011).

Mechanical Techniques

These include transcervical placement of a Foley catheter with or without extraamniotic saline infusion, hygroscopic cervical dilators, and membrane stripping. In a recent metaanalysis of 71 randomized trials including 9722 women, Jozwiak and associates (2012) reported that mechanical techniques reduced the risk of uterine tachysystole compared with prostaglandins, although cesarean delivery rates were unchanged. Trials comparing mechanical techniques with oxytocin found a lower rate of cesarean delivery with mechanical methods. Trials comparing mechanical techniques with dinoprostone found a higher rate of multiparous women undelivered at 24 hours with mechanical techniques. Another metaanalysis done to compare Foley catheter placement with intravaginal dinoprostone inserts also found similar rates of cesarean delivery and less frequent uterine tachysystole (Jozwiak, 2013a).

Transcervical Catheter

Generally, these techniques are only used when the cervix is unfavorable because the catheter tends to come out as the cervix opens. In most cases, a Foley catheter is placed through the internal cervical os, and downward tension is created by taping the catheter to the thigh (Mei-Dan, 2014). A modification of this—*extraamniotic saline infusion (EASI)*—consists of a constant saline infusion through the catheter into the space between the internal os and placental membranes (Fig. 26-2). Karjane and coworkers (2006) reported that chorioamnionitis was significantly less frequent when infusion was done compared with no infusion—6 versus 16 percent. A systematic review and metaanalysis of 30 trials found that Foley catheter induction alone compared with prostaglandins resulted in higher infection rates unless saline was infused (Heinemann, 2008).

Most studies of transcervical catheters do not show a reduction in the cesarean delivery rate compared with prostaglandins. Cromi and colleagues (2012) compared a double-tipped Foley catheter and the dinoprostone vaginal insert. They found higher rates of delivery within 24 hours with the mechanical technique, but no differences in the cesarean delivery rates. The PROBAAT trials, in which cervical ripening with a Foley catheter was compared with

FIGURE 26-2 Extraamniotic saline infusion (EASI) through a 26F Foley catheter that is placed through the cervix. The 30-mL balloon is inflated with saline and pulled snugly against the internal os, and the catheter is taped to the thigh. Room-temperature normal saline is infused through the catheter port of the Foley at 30 or 40 mL/hour by intravenous infusion pump.

vaginal dinoprostone gel, dinoprostone vaginal inserts, and vaginal misoprostol, reported similar outcomes between the mechanical technique and the prostaglandin agents. Also, fewer overall cases of cardiocotographic changes were seen in the mechanical technique group (Jozwiak, 2011, 2013a, 2014; Wang, 2014).

Hygroscopic Cervical Dilators

Cervical dilatation can be accomplished using hygroscopic osmotic cervical dilators, as described for early pregnancy termination (Chap. 18, p. 365). These mechanical dilators have been successfully used for more than 40 years when inserted before pregnancy termination. They have also been used for cervical ripening before labor induction. Intuitive concerns of ascending infection have not been verified. Thus, their use appears to be safe, although anaphylaxis has rarely followed laminaria insertion (Lichtenberg, 2004). Dilators are attractive because of their low cost. However, placement generally requires a speculum and positioning of the woman on an examination table, which can be cumbersome and uncomfortable. A handful of studies performed in the 1990s compared hygroscopic cervical dilators and prostaglandins. There were few benefits of this mechanical technique other than cost.

METHODS OF INDUCTION AND AUGMENTATION

Labor induction has primarily been effected with the use of amniotomy, prostaglandins, and oxytocin, alone or in combination. Because preinduction cervical ripening frequently eventuates in labor, studies to determine induction efficacy for some

of these agents have produced sometimes confusing results. The use of prostaglandins for labor augmentation has generally been considered experimental.

■ Prostaglandin E₁

As discussed on page 527, both vaginal and oral misoprostol are used for either cervical ripening or labor induction. Hofmeyr and associates (2010) performed a Cochrane systematic review of agents for labor induction. They reported that vaginal misoprostol, followed by oxytocin if needed, compared with oxytocin alone resulted in fewer failures within 24 hours. As expected, prostaglandin use led to a higher incidence of uterine tachysystole, but cesarean delivery rates were similar.

It appears that 100 µg of oral or 25 µg of vaginal misoprostol are similar in efficacy compared with intravenous oxytocin for labor induction in women at or near term with either prematurely ruptured membranes or a favorable cervix (Lin, 2005; Lo, 2003). Misoprostol may be associated with an increased rate of uterine tachysystole, particularly at higher doses. Also, induction with prostaglandin E₁ may prove ineffective and require subsequent induction or augmentation with oxytocin. Thus, although there are trade-offs regarding the risks, costs, and ease of administration of each drug, either is suitable for labor induction.

For *labor augmentation*, results of a randomized controlled trial showed oral misoprostol, 75 µg given at 4-hour intervals for a maximum of two doses, to be safe and effective (Bleich, 2011). The 75-µg dose was based on a previous dose-finding study (Villano, 2011). Although there was more uterine tachysystole among women with labor augmented with misoprostol, there were no significant differences in the frequency of nonreassuring fetal status or cesarean delivery.

■ Oxytocin

As discussed, in most instances, preinduction cervical ripening and labor induction are simply a continuum. Thus, “ripening” will also stimulate labor. If not, induction or augmentation may be continued with solutions of oxytocin given by infusion pump. Synthetic oxytocin is one of the most frequently used medications in the United States. It was the first polypeptide hormone synthesized, an achievement for which the 1955 Nobel Prize in chemistry was awarded (du Vigneaud, 1953). Oxytocin may be used for labor induction or for augmentation. With oxytocin use, the American College of Obstetricians and Gynecologists (2013b) recommends fetal heart rate and contraction monitoring similar to that for any high-risk pregnancy. Contractions can be monitored either by palpation or by electronic means (Chap. 24, p. 497).

Intravenous Oxytocin Administration

The goal of induction or augmentation is to effect uterine activity sufficient to produce cervical change and fetal descent, while avoiding development of a nonreassuring fetal status. In general, oxytocin should be discontinued if the number of contractions persists with a frequency of more than five in a 10-minute period or more than seven in a 15-minute

period or with a persistent nonreassuring fetal heart rate pattern. Oxytocin discontinuation nearly always rapidly decreases contraction frequency. When oxytocin is stopped, its concentration in plasma rapidly falls because the half-life is approximately 3 to 5 minutes. Seitchik and coworkers (1984) found that the uterus contracts within 3 to 5 minutes of beginning an oxytocin infusion and that a plasma steady state is reached in 40 minutes. Response is highly variable and depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks' gestation and increases rapidly at term (Chap. 24, p. 498).

Oxytocin Dosage. A 1-mL ampule containing 10 units usually is diluted into 1000 mL of a crystalloid solution and administered by infusion pump. A typical infusate consists of 10 or 20 units, which is 10,000 or 20,000 mU or one or two 1-mL vials, mixed into 1000 mL of lactated Ringer solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site.

Oxytocin is generally very successful when used to stimulate labor. A Cochrane metaanalysis of 12 trials involving 12,819 women comparing oxytocin with expectant management reported that fewer women—8 versus 54 percent—failed to deliver vaginally within 24 hours when oxytocin was used (Alfirevic, 2009). This metaanalysis studied different oxytocin dosing regimens. A smaller metaanalysis of four trials involving 660 women and comparing high-dose and low-dose oxytocin regimens reported that high-dose regimens were associated with reduced length of labor and cesarean delivery rate and with a concomitant increased spontaneous vaginal delivery rate (Mori, 2011).

Oxytocin Regimens

As a result of numerous studies, several regimens for labor stimulation are now recommended by the American College of Obstetricians and Gynecologists (2013a). These and others are shown in [Table 26-3](#). Initially, only variations of low-dose protocols were used in the United States. Then O'Driscoll and colleagues (1984) described their Dublin protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Subsequent comparative trials during the 1990s studied high-dose—4 to 6 mU/min—versus conventional low-dose—0.5 to 1.5 mU/min—regimens, both for labor induction and for augmentation.

From Parkland Hospital, Satin and associates (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Increases at 20-minute intervals were provided as needed. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery

TABLE 26-3. Various Low- and High-Dose Oxytocin Regimens Used for Labor Induction

Regimen	Starting Dose (mU/min)	Incremental Increase (mU/min)	Interval (min)
Low-dose	0.5–1.5	1	15–40
	2	4, 8, 12, 16, 20, 25, 30	15
High-dose	4	4	15
	4.5	4.5	15–30
	6	6 ^a	20–40 ^b

^aWith uterine tachysystole and after oxytocin infusion is discontinued, it is restarted at the previous dose and increased at 3 mU/min incremental doses.
^bUterine tachysystole is more common with shorter intervals.
Data from Merrill, 1999; Satin, 1992, 1994; Xenakis, 1995.

time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and decreased rates of intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine tachysystole is managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage is increased at 3 mU/min when appropriate, instead of the usual 6-mU/min increase used for women without tachysystole. No adverse neonatal effects were observed.

Xenakis and coworkers (1995) reported benefits using an incremental oxytocin regimen starting at 4 mU/min. In a comparative study of 1307 women by Merrill and Zlatnik (1999), 816 women were randomized for labor induction and 816 for augmentation with incremental oxytocin given at either 1.5 or 4.5 mU/min. Women randomized to the 4.5 mU/min dosage had significantly decreased mean durations of induction-to-second-stage labor and induction-to-delivery. Nulliparas randomized to the 4.5 mU/min dosage had a significantly lower cesarean delivery rate for dystocia compared with those given 1.5 mU/min dosage—5.9 versus 11.9 percent.

Thus, benefits favor higher-dose regimens of 4.5 to 6 mU/min compared with lower dosages of 0.5 to 1.5 mU/min. In 1990 at Parkland Hospital, routine use of the 6-mU/min oxytocin beginning and incremental dosage was incorporated and continues through today. In other labor units, a 2-mU/min beginning and incremental oxytocin regimen is preferred and administered. With either regimen, these dosages are employed for either labor induction or augmentation.

Interval between Incremental Dosing

Intervals to increase oxytocin doses vary from 15 to 40 minutes as shown in Table 26-3. Satin and colleagues (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significantly reduced cesarean delivery rate for dystocia compared with that for the 40-minute interval regimen—8 versus 12

percent. As perhaps expected, uterine tachysystole was significantly more frequent with the 20-minute escalation regimen.

Other investigators reported even more frequent incremental increases. Frigoletto (1995) and Xenakis (1995) and their coworkers gave oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5 mU/min, with increases every 30 minutes. López-Zeno and associates (1992) began at 6 mU/min with increases every 15 minutes. Thus, there are several acceptable oxytocin protocols that at least appear dissimilar. But a comparison of protocols from two institutions indicates that this is not so:

1. The Parkland Hospital protocol calls for a starting dose of oxytocin at 6 mU/min and with 6-mU/min increases every 40 minutes, but it employs flexible dosing based on uterine tachysystole.
2. The University of Alabama at Birmingham Hospital protocol begins oxytocin at 2 mU/min and increases it as needed every 15 minutes to 4, 8, 12, 16, 20, 25, and 30 mU/min.

Thus, although the regimens at first appear disparate, if there is no uterine activity, either regimen is delivering 12 mU/min by 45 minutes into the infusion.

Maximal Dosage

The *maximal* effective dose of oxytocin to achieve adequate contractions in all women is different. Wen and colleagues (2001) studied 1151 consecutive nulliparas and found that the likelihood of progression to vaginal delivery decreased at and beyond an oxytocin dosage of 36 mU/min. Still, at a dosage of 72 mU/min, half of the nulliparas were delivered vaginally. Thus, if contractions are not adequate—less than 200 Montevideo units—and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks.

Risks versus Benefits

Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women (Chap. 41, p. 790). Flannelly and associates (1993) reported no uterine ruptures, with or without oxytocin, in 27,829 nulliparas. There were eight instances of overt uterine rupture during labor in 48,718 parous women. Only one of these was associated with oxytocin use.

Oxytocin has amino-acid homology similar to arginine vasopressin. Because of this, it has significant antidiuretic action, and when infused at doses of 20 mU/min or more, renal free water clearance decreases markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, *water intoxication* can lead to convulsions, coma, and even death. In general, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the flow rate of a more dilute solution. Consideration also should be given to use of crystalloids—either normal saline or lactated Ringer solution.

Uterine Contraction Pressures

Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units. As described in Chapter 24

(p. 498), the latter are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window. The pressures generated by each contraction are then summed. Caldeyro-Barcia (1950) and Seitchik (1984) with their coworkers found that the mean or median spontaneous uterine contraction pattern resulting in a progression to a vaginal delivery was between 140 and 150 Montevideo units.

In the management of active-phase arrest, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hawth and colleagues (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest. With it, more than 90 percent of women achieved an average of at least 200 to 225 Montevideo units. Hawth and associates (1991) later reported that nearly all women in whom active-phase arrest persisted despite oxytocin generated more than 200 Montevideo units. Importantly, despite no labor progression, there were no adverse maternal or perinatal effects in those undergoing cesarean delivery. There are no data regarding safety and efficacy of contraction patterns in women with a prior cesarean delivery, with twins, or with an overdistended uterus.

Active-Phase Arrest

First-stage arrest of labor is defined by the American College of Obstetricians and Gynecologists (2013a) as a completed latent phase along with contractions exceeding 200 Montevideo units for more than 2 hours without cervical change. Some investigators have attempted to define a more accurate duration for active-phase arrest (Spong, 2012). Arulkumaran and coworkers (1987) extended the 2-hour limit to 4 hours and reported a 1.3-percent cesarean delivery rate in women who continued to have adequate contractions and progressive cervical dilatation of at least 1 cm/hr. In women without progressive cervical dilatation who were allowed another 4 hours of labor, half required cesarean delivery.

Rouse and colleagues (1999) prospectively managed 542 women at term with active-phase arrest and no other complications. Their protocol was to achieve a sustained pattern of at least 200 Montevideo units for a *minimum* of 4 hours. This time frame was extended to 6 hours if activity of 200 Montevideo units or greater could not be sustained. Almost 92 percent of these women were delivered vaginally. As discussed in Chapter 23 (p. 459), these and other studies support the practice of allowing an active-phase arrest of 4 hours (Rouse, 2001; Solheim, 2009).

Zhang and coworkers (2002) analyzed labor duration from 4 cm to complete dilatation in 1329 nulliparas at term. They found that before dilatation of 7 cm was reached, lack of progress for more than 2 hours was not uncommon in those who delivered vaginally. Alexander and associates (2002) reported that epidural analgesia prolonged active labor by 1 hour compared with duration of the active phase as defined by Friedman (1955). Consideration of these changes in the management of labor, especially in nulliparas, may safely reduce the cesarean delivery rate.

As data have accrued, investigators have increasingly questioned the thresholds for labor arrest disorders established by Friedman and others in the 1960s. In particular, investigators with the *Consortium on Safe Labor* reported that half of cases of

dystocia after labor induction occurred before 6 cm of cervical dilation (Boyle, 2013; Zhang, 2010c). Even for women with spontaneous labor, these researchers found that active-phase labor was more likely to occur at 6 cm, and after slow progress between 4 and 6 cm (Zhang, 2010a). Additionally, they reported that a 2-hour threshold for diagnosing arrest disorders may be too brief when cervical dilation is < 6 cm (Zhang, 2010b). It was also shown that the duration of first-stage labor was more than 2 hours longer than had been reported using data from the Collaborative Perinatal Project (Laughon, 2012b).

Amniotomy for Induction and Augmentation

A common indication for artificial rupture of the membranes—*surgical amniotomy*—includes the need for direct monitoring of the fetal heart rate or uterine contractions or both. During amniotomy, to minimize cord prolapse risk, dislodgement of the fetal head is avoided. For this, fundal or suprapubic pressure or both may be helpful. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amniotic fluid can sometimes be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. In many of these, however, membranes tear and fluid is lost rapidly. Because of the risk of cord prolapse or rarely abruption, the fetal heart rate is assessed before and immediately after amniotomy.

Elective Amniotomy

Membrane rupture with the intention of accelerating labor is often performed. In the investigations presented in Table 26-4, amniotomy at approximately 5-cm dilation accelerated spontaneous labor by 1 to 1½ hours. Importantly, neither the need for oxytocin stimulation nor the overall cesarean delivery rate was increased. Although mild and moderate cord compression patterns were increased following amniotomy, cesarean delivery rates for fetal distress were not increased. Most importantly, there were no adverse perinatal effects.

Amniotomy Induction

Artificial rupture of the membranes—sometimes called *surgical induction*—can be used to induce labor, and it always implies a commitment to delivery. The main disadvantage of amniotomy used alone for labor induction is the unpredictable and occasionally long interval until labor onset. That said, in a randomized trial, Bakos and Bäckström (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomized 209 women undergoing oxytocin induction to either early amniotomy at 1 to 2 cm or late amniotomy at 5 cm. Early amniotomy was associated with a significant 4-hour reduction in labor duration. With early amniotomy, however, there was an increased incidence of chorioamnionitis.

Amniotomy Augmentation

It is common practice to perform amniotomy when labor is abnormally slow. Rouse and associates (1994) found that amniotomy

TABLE 26-4. Randomized Clinical Trials of Elective Amniotomy in Early Spontaneous Labor at Term

Study	Number	Effects of Amniotomy					
		Mean Dilatation at Amniotomy	Mean Shortening of Labor	Need for Oxytocin	Cesarean Delivery Rate	Abnormal Tracing	Neonatal Effects
Fraser (1993)	925	< 5 cm	125 min	None	None ^a	None	None
Garite (1993)	459	5.5 cm	81 min	Decreased	None	Increased ^b	None
UK Amniotomy Group (1994)	1463	5.1 cm	60 min	None	None	NA	None

^aNo effect on overall rate; cesarean delivery for fetal distress significantly increased.

^bIncreased mild and moderate umbilical cord compression patterns.

NA = not assessed.

with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. Although amniotomy did not alter the delivery route, one drawback was that it significantly increased the incidence of chorioamnionitis. The American College of Obstetricians and Gynecologists (2013a) recommends the use of amniotomy to enhance progress in active labor, but cautions that this may increase the risks of infection and maternal fever.

■ Membrane Stripping for Labor Induction

Labor induction by membrane “stripping” is a frequent practice. Several studies have suggested that membrane stripping is safe and decreases the incidence of postterm pregnancy without consistently increasing the incidence of ruptured membranes, infection, or bleeding. Authors of a metaanalysis of 22 trials including 2797 women reported that membrane stripping reduced the number of women remaining undelivered after 41 weeks without increasing the infection risk. They concluded that eight women would need to undergo membrane stripping to avoid one labor induction. Downsides are discomfort and associated bleeding (Boulvain, 2005).

ACTIVE MANAGEMENT OF LABOR

This term describes a codified approach to the management of labor, which is discussed in detail in Chapter 22 (p. 452).

SPECIAL POPULATIONS 545

THIRD STAGE OF LABOR 546

“FOURTH STAGE” OF LABOR 548

EPISIOTOMY 550

The natural culmination of second-stage labor is controlled vaginal delivery of a healthy neonate with minimal trauma to the mother. Vaginal delivery is the preferred route of delivery for most fetuses, although certain clinical settings may favor cesarean delivery. Spontaneous vaginal delivery is typical, however, maternal or fetal complications may warrant operative vaginal delivery as described in Chapter 29. Last, a mal-presenting fetus or multifetal gestation in many cases may be delivered vaginally but requires special techniques. These are described in Chapters 28—Breech Delivery and 45—Multifetal Pregnancy.

ROUTE OF DELIVERY

In general, spontaneous vaginal vertex delivery poses the lowest risk of most maternal and fetal comorbidity. Compared with cesarean delivery, spontaneous vaginal delivery has lower

associated rates of maternal infection, hemorrhage, anesthesia complications, and peripartum hysterectomy, among others. In contrast, for women undergoing spontaneous vaginal delivery compared with cesarean delivery, pelvic floor disorders may be increased (Handa, 2011; Rortveit, 2003). Longitudinal studies, however, suggest that initial pelvic floor protection advantages gained from cesarean delivery are lost as women age (Dolan, 2010; Glazener, 2013; Rortveit, 2001). During their State-of-the-Science Conference, the National Institutes of Health panel (2006) summarized that stress urinary incontinence rates after elective cesarean delivery are lower than those following vaginal delivery. However, the duration of this protection is unclear, particularly in older and multiparous populations. This same conference considered the evidence implicating vaginal delivery in other pelvic floor disorders to be weak and not favoring either delivery route.

PREPARATION FOR DELIVERY

The end of second-stage labor is heralded as the perineum begins to distend, the overlying skin becomes stretched, and the fetal scalp is seen through the separating labia. Increased perineal pressure from the fetal head creates reflexive bearing-down efforts, which are encouraged when appropriate. At this time, preparations are made for delivery. Some considerations that arise during labor and which are also discussed in Chapter 22 (p. 451) are reiterated. For example, the bladder is palpated, and if it is distended, catheterization may be necessary. Continued attention is also given to fetal heart rate monitoring. As one example, a nuchal cord often tightens with descent and may lead to deepening variable decelerations. Antibiotic prophylaxis against infective endocarditis is not recommended for vaginal delivery in most women with cardiac conditions. Exceptions are in women with cyanotic heart disease or prosthetic valves or both. For these women, prophylaxis as outlined in Table 49-10 (p. 991) is indicated

30 to 60 minutes before the anticipated procedure (American College of Obstetricians and Gynecologists, 2011).

During second-stage labor, pushing positions may vary. But for delivery, dorsal lithotomy position is the most widely used and often the most satisfactory. For better exposure, leg holders or stirrups are used. Corton and associates (2012) found no increased rates of perineal lacerations with stirrup use compared to without their use. With positioning, legs are not separated too widely or placed one higher than the other. Within the leg holder, the popliteal region should rest comfortably in the proximal portion and the heel in the distal portion. The legs are not strapped into the stirrups, thereby allowing quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop (p. 541). Legs may cramp during the second stage, in part, because of pressure by the fetal head on pelvic nerves. Cramping may be relieved by repositioning the affected leg or by brief massage.

Preparation for delivery includes vulvar and perineal cleansing. If desired, sterile drapes may be placed in such a way that only the immediate area around the vulva is exposed. In the past, scrubbing, gowning, gloving, and donning protective mask and eyewear was done to protect the laboring woman from infectious agents. Although these considerations remain valid, infectious disease exposure concerns today must also be extended to health-care providers.

OCCIPUT ANTERIOR POSITION

By the time of perineal distention, the position of the presenting occiput is usually known. In some cases, however, molding and caput formation have precluded accurate identification. At this time, careful assessment is again performed as described in Chapter 22 (p. 438). In most cases, presentation is directly occiput anterior or is rotated slightly oblique. But, in perhaps 5 percent, persistent occiput posterior is identified. Rarely, the vertex will be presenting in the occiput transverse position when the head bulges the perineum.

Delivery of the Head

With each contraction, the vulvovaginal opening is dilated by the fetal head to gradually form an ovoid and finally, an almost circular opening (Fig. 27-1). This encirclement of the largest head diameter by the vulvar ring is termed *crowning*. Unless an episiotomy has been made as described later, the perineum thins and especially in nulliparous women, may undergo spontaneous laceration. The anus becomes greatly stretched, and the anterior wall of the rectum may be easily seen through it.

There once was considerable controversy concerning routine episiotomy use. It is now clear that episiotomy increases the risk of a tear into the external anal sphincter, the rectum, or both. Conversely, anterior tears involving the urethra and labia are more common in women in whom an episiotomy is avoided. Most, including us, advocate individualization and do not routinely perform episiotomy.

To limit spontaneous vaginal laceration, some perform intrapartum perineal massage to widen the introitus for head passage. With this, the perineum is grasped in the midline by

FIGURE 27-1 Delivery of the head. The occiput is being kept close to the symphysis by moderate pressure on the fetal chin at the tip of the maternal coccyx.

both hands using the thumb and opposing fingers. Outward and lateral stretch against the perineum is then repeatedly applied. Evidence for this technique is limited and mixed regarding efficacy for perineal protection when applied either antepartum or intrapartum (Geranmayeh, 2012; Meidan, 2008; Stamp, 2001).

When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, a gloved hand may be used to support the perineum (Fig. 27-2). The other hand is used to guide and control the fetal head to avoid expulsive delivery. Slow delivery of the head may decrease

FIGURE 27-2 Delivery of the head. The mouth appears over the perineum.

FIGURE 27-3 Modified Ritgen maneuver. Moderate upward pressure is applied to the fetal chin by the posterior hand covered with a sterile towel, while the suboccipital region of the fetal head is held against the symphysis.

FIGURE 27-4 The umbilical cord, if identified around the neck, is readily slipped over the head.

lacerations (Laine, 2008). Alternatively, if expulsive efforts are inadequate or expeditious delivery is needed, the modified *Ritgen maneuver* may be employed. With this, gloved fingers beneath a draped towel exert forward pressure on the fetal chin through the perineum just in front of the coccyx. Concurrently, the other hand presses superiorly against the occiput (Fig. 27-3). Originally described in 1855, the Ritgen maneuver allows controlled fetal head delivery (Cunningham, 2008). It also favors neck extension so that the head passes through the introitus and over the perineum with its smallest diameters. Comparing the Ritgen maneuver with simple perineal support in 1623 women, Jönsson and colleagues (2008) found a similar incidence of third- and fourth-degree tears—5.5 percent with the maneuver and 4.4 percent with simple support. Last, some espouse a “hands-poised” method, in which the attendant does not touch the perineum during delivery of the head (Mayerhofer, 2002; McCandlish, 1998). Compared with traditional perineal support, this expectant method does not appear to offer greater third-degree laceration protection (Aasheim, 2011).

■ Delivery of the Shoulders

Following delivery of the fetal head, a finger should be passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops (Fig. 27-4). A nuchal cord is found in approximately 25 percent of deliveries and ordinarily causes no harm. If an umbilical cord coil is felt, it should be slipped over the head if loose enough. If applied too tightly, the loop should be cut between two clamps. Such tight nuchal cords complicate approximately 6 percent of all deliveries but are not associated with worse neonatal outcome than those without a cord loop (Henry, 2013).

Following its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. The occiput promptly turns toward one of the maternal thighs, and the head assumes a transverse position (Fig. 27-5). This external rotation indicates that the bisacromial diameter, which is the transverse diameter of the thorax, has rotated into the anteroposterior diameter of the pelvis.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, extraction aids controlled delivery. The sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder appears under the pubic arch. Next, by an upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert brachial plexus injury.

The rest of the body almost always follows the shoulders without difficulty. With prolonged delay, however, its birth may be hastened by moderate traction on the head and moderate pressure on the uterine fundus. Hooking the fingers in the axillae is avoided. This can injure upper extremity nerves and produce a transient or possibly permanent paralysis. Traction, furthermore, should be exerted only in the direction of the long axis of the neonate. If applied obliquely, it causes neck bending and excessive brachial plexus stretching. Immediately after delivery of the newborn, there is usually a gush of amniotic fluid, often blood-tinged but not grossly bloody.

Previously, immediate nasopharyngeal bulb suctioning of the newborn was routine to remove secretions. It was found, however, that suctioning of the nasopharynx may lead to neonatal bradycardia (Gungor, 2006). The American Heart Association neonatal resuscitation recommendations currently

FIGURE 27-5 Delivery of the shoulders. **A.** Gentle downward traction to effect descent of the anterior shoulder. **B.** Delivery of the anterior shoulder completed. Gentle upward traction to deliver the posterior shoulder.

eschew most suctioning immediately following birth—even with meconium present. This includes bulb syringe aspiration. Suctioning should be reserved for neonates who have obvious obstruction to spontaneous breathing or who require positive-pressure ventilation (Kattwinkel, 2010). Similarly, if meconium is present and the newborn is depressed, then intubation and tracheal suctioning is recommended (American College of Obstetricians and Gynecologists, 2013b). These aspects are discussed in further detail in Chapter 33 (p. 638).

■ Clamping the Cord

The umbilical cord is cut between two clamps placed 6 to 8 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from its insertion into the fetal abdomen. A plastic clamp that is safe, efficient, and fairly inexpensive, such as the Double Grip Umbilical Clamp (Hollister), is used at Parkland Hospital.

For term neonates, the timing of umbilical cord clamping remains debatable. A delay in umbilical cord clamping for up to 60 seconds may increase total body iron stores, expand blood volume, and decrease anemia incidence in the neonate (Andersson, 2011; Yao, 1974). This may be particularly valuable in populations in which iron deficiency is prevalent

(Abalos, 2009). Conversely, and as discussed in Chapter 33 (p. 643), higher hemoglobin concentration increases risks for hyperbilirubinemia and extended hospitalization for neonatal phototherapy (McDonald, 2008). Delayed cord clamping may also hinder timely and needed neonatal resuscitation. Fortunately, in general, delayed umbilical cord clamping compared with early clamping does not worsen Apgar scores, umbilical cord pH, or respiratory distress caused by polycythemia. Regarding maternal outcomes, rates of postpartum hemorrhage are similar between early and delayed clamping groups (Andersson, 2013). Fewer data are available regarding cord “milking,” in which the operator pushes blood through the cord toward the newborn. This maneuver appears safe and may be advantageous if rapid cord clamping is clinically indicated (Upadhyay, 2013).

For the preterm neonate, delayed cord clamping has several benefits. These include higher red cell volume, decreased need for blood transfusion, better circulatory stability, and lower rates of intraventricular hemorrhage and of necrotizing enterocolitis (Rabe, 2012; Raju, 2013; Sommers, 2012).

The American College of Obstetricians and Gynecologists (2012c) has concluded that there is insufficient evidence to support or refute benefits from delayed umbilical cord clamping for term neonates in resource-rich settings. For preterm newborns, however, evidence supports delaying umbilical cord clamping to 30 to 60 seconds after birth. This opinion is also endorsed by the American Academy of Pediatrics (2013). Our policy is to clamp the cord after assessing the need to clear the airway, all of which usually requires approximately 30 seconds. The newborn is not elevated above the introitus at vaginal delivery or much above the maternal abdominal wall at the time of cesarean delivery.

PERSISTENT OCCIPUT POSTERIOR POSITION

Approximately 2 to 10 percent of singleton term cephalic fetuses deliver in an occiput posterior (OP) position (Cheng, 2010). As shown in Figure 27-6, many fetuses delivering OP were occiput anterior (OA) in early labor and reflect malrotation during labor. Predisposing risks include epidural analgesia, nulliparity, greater fetal weight, and prior OP position delivery (Cheng, 2006a; Gardberg, 2004; Lieberman, 2005).

■ Morbidity

Women with a persistent OP position have higher associated rates of prolonged second-stage labor, cesarean delivery, and operative vaginal delivery. For women who deliver vaginally, rates of blood loss and of third- and fourth-degree laceration, so-called higher-order vaginal lacerations, are increased (Senécal, 2005).

Infants delivered from an OP position have many more complications than those born positioned OA. Cheng and coworkers (2006b) compared outcomes of 2591 women undergoing delivery with a persistent OP position with those of 28,801 women whose newborns were delivered OA. Virtually every possible delivery complication was found more frequently with persistent OP position. Only 46 percent of these women

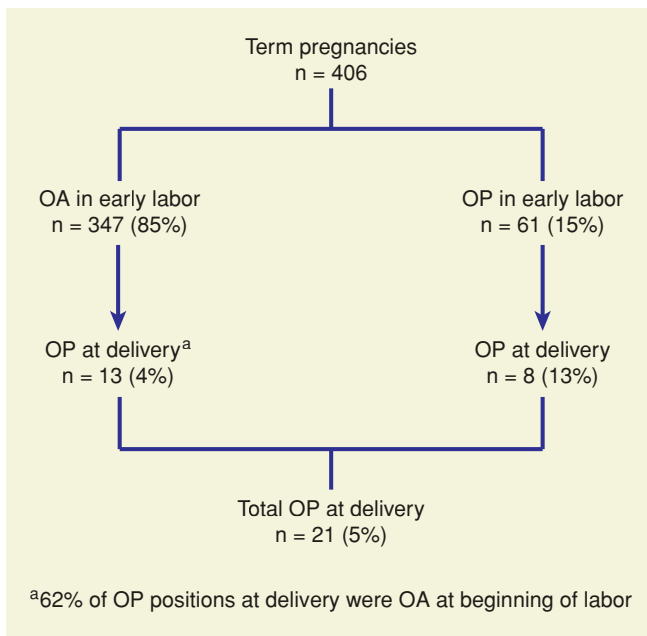

FIGURE 27-6 Occiput posterior (OP) presentation in early labor compared with presentation at delivery. Sonography was used to determine position of the fetal head in early labor. OA = occiput anterior. (Data from Gardberg, 1998.)

delivered spontaneously, and the remainder accounted for 9 percent of cesarean deliveries performed. These investigators also found that an OP position at delivery was associated with increased adverse short-term neonatal outcomes that included acidemic umbilical cord gases, birth trauma, Apgar scores < 7, and intensive care nursery admission, among others. Similar results were reported by Ponkey (2003) and Fitzpatrick (2001) and their associates.

Methods to prevent persistent OP position and its associated morbidity have been investigated. First, digital examination for identification of fetal head position can be inaccurate, and sonography can be used to increase accuracy (Dupuis, 2005; Souka, 2003; Zahalka, 2005). Such information may provide an explanation for prolonged second-stage labor or may identify suitable candidates for manual rotation. In contrast, varying maternal position either before or during labor does not appear to lower rates of persistent OP position (Desbriere, 2013; Kariminia, 2004).

■ Delivery of Persistent Occiput Posterior Position

Delivery of a fetus with an OP position may be completed by spontaneous or operative vaginal delivery. First, if the pelvic outlet is roomy and the vaginal outlet and perineum are somewhat relaxed from prior deliveries, rapid spontaneous OP delivery will often take place. Conversely, if the vaginal outlet is resistant to stretch and the perineum is firm, second-stage labor may be appreciably prolonged. During each expulsive effort, the head is driven against the perineum to a much greater degree than when the head position is OA. This leads to greater rates of higher-order perineal lacerations (Groutz, 2011; Melamed, 2013).

In some cases, spontaneous vaginal delivery from an OP position does not appear feasible or expedited delivery is needed. Here, manual rotation with spontaneous delivery from an OA position may be preferred. This technique is described fully in Chapter 29 (p. 580). Successful rotation rates range from 47 to 90 percent. And, as would be expected, lower rates of cesarean delivery, vaginal laceration, and maternal blood loss follow rotation to OA position and vaginal delivery (Le Ray, 2005; Sen, 2013; Shaffer, 2006, 2011). Disadvantageously, manual rotation is linked with higher cervical laceration rates. Thus, careful inspection of the cervix following rotation is prudent.

For exigent delivery, forceps or vacuum device can be applied to a persistent OP position. This is often performed in conjunction with an episiotomy. Also, if the head is engaged, the cervix fully dilated, and the pelvis adequate, forceps rotation may be attempted. These circumstances most likely prevail when expulsive efforts of the mother during the second stage are ineffective. Both these operative vaginal techniques are detailed in Chapter 29 (p. 582).

Infrequently, protrusion of fetal scalp through the introitus is the consequence of marked elongation of the fetal head from molding combined with formation of a large caput succedaneum. In some cases, the head may not even be engaged—that is, the biparietal diameter may not have passed through the pelvic inlet. In these, labor is characteristically long and descent of the head is slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate.

At Parkland Hospital, spontaneous delivery or manual rotation is preferred for management of persistent OP position. In other cases, either manual rotation to OA position followed by forceps delivery or forceps delivery from the OP position is used. If neither can be completed with relative ease, cesarean delivery is performed.

OCIPUT TRANSVERSE POSITION

In the absence of a pelvic architecture abnormality or asynclitism, the occiput transverse position is usually transitory. Thus, unless contractions are hypotonic, the head usually spontaneously rotates to an OA position. If hypotonic uterine contractions are suspected and cephalopelvic disproportion is absent, then an oxytocin infusion can be used to stimulate labor.

If rotation ceases because of poor expulsive forces, vaginal delivery usually can be accomplished readily in a number of ways. The easiest is manual rotation of the occiput either anteriorly to OA or less commonly, posteriorly to OP. If either is successful, Le Ray and coworkers (2007) reported a 4-percent cesarean delivery rate compared with a 60-percent rate in women in whom manual rotation was not successful. Some recommend rotation with Kielland forceps for the persistent occiput transverse position as outlined in Chapter 29 (p. 582). These forceps are used to rotate the occiput to the anterior position, and delivery is accomplished with the same forceps or by substitution with either Simpson or Tucker–McLane forceps.

In some cases, there may be an underlying cause leading to the persistent occiput transverse position that is not easily overcome. For example, a platypeloid pelvis is flattened anteroposteriorly and an android pelvis is heart shaped. With these, there may be inadequate space for occipital rotation to either an OA or OP position (Fig. 2-20, p. 34). Because of these concerns, undue force should be avoided if forceps delivery is attempted.

SHOULDER DYSTOCIA

Following complete emergence of the fetal head during vaginal delivery, the remainder of the body may not rapidly follow. The anterior fetal shoulder can become wedged behind the symphysis pubis and fail to deliver using normally exerted downward traction and maternal pushing. Because the umbilical cord is compressed within the birth canal, such dystocia is an emergency. Several maneuvers, in addition to downward traction on the fetal head, may be performed to free the shoulder. This requires a team approach, in which effective communication and leadership are critical.

Consensus regarding a specific definition of shoulder dystocia is lacking. Some investigators focus on whether maneuvers to free the shoulder are needed, whereas others use the head-to-body delivery time interval as defining (Beall, 1998). Spong and coworkers (1995) reported that the mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. These investigators proposed that a head-to-body delivery time > 60 seconds be used to define shoulder dystocia. Currently, however, the diagnosis continues to rely on the clinical perception that the normal downward traction needed for fetal shoulder delivery is ineffective.

Because of these differing definitions, the incidence of shoulder dystocia varies. Current reports cite an incidence between 0.6 percent and 1.4 percent (American College of Obstetricians and Gynecologists, 2012b). There is evidence that the incidence has increased in recent decades, likely due to increasing fetal birthweight (MacKenzie, 2007). Alternatively, this increase may be due to more attention given to appropriate documentation of dystocia (Nocon, 1993).

Maternal and Neonatal Consequences

In general, shoulder dystocia poses greater risk to the fetus than the mother. Postpartum hemorrhage, usually from uterine atony but also from vaginal lacerations, is the main maternal risk (Jangö, 2012; Rahman, 2009). In contrast, significant neonatal neuromusculoskeletal injury and even mortality are concerns. MacKenzie and associates (2007) reviewed 514 cases of shoulder dystocia and found that 11 percent were associated with serious neonatal trauma. Brachial plexus injury was diagnosed in 8 percent, and 2 percent suffered a clavicle, humeral, or rib fracture. Seven percent showed evidence of acidosis at delivery, and 1.5 percent required cardiac resuscitation or developed hypoxic ischemic encephalopathy. Mehta and colleagues (2007) found a similar number of injuries in a study of 205 shoulder dystocia cases, in which 17 percent had injury.

Again, most involved the brachial plexus. These specific injuries are described more fully in Chapter 33 (p. 648). Of predictors, increasing fetal weight, maternal body mass index, and second-stage duration and a prior shoulder dystocia appear to raise the neonatal injury risk with shoulder dystocia (Bingham, 2010; Mehta, 2006).

Prediction and Prevention

There has been considerable evolution in obstetrical thinking regarding the preventability of shoulder dystocia. Although there are clearly several risk factors associated with this complication, identification of individual instances before the fact has proved to be impossible. The American College of Obstetricians and Gynecologists (2012b) reviewed studies and concluded that:

1. Most cases of shoulder dystocia cannot be accurately predicted or prevented.
2. Elective induction of labor or elective cesarean delivery for all women suspected of having a macrosomic fetus is not appropriate.
3. Planned cesarean delivery may be considered for the non-diabetic woman with a fetus whose estimated fetal weight is > 5000 g or for the diabetic woman whose fetus is estimated to weigh > 4500 g.

Birthweight

Commonly cited maternal characteristics associated with increased fetal birthweight are obesity, postterm pregnancy, multiparity, diabetes, and gestational diabetes. There is universal agreement that increasing birthweight is associated with an increasing incidence of shoulder dystocia. In one study of nearly 2 million vaginal deliveries, Overland and coworkers (2012) noted that in 75 percent of shoulder dystocia cases, newborns weighed > 4000 g. That said, the concept that cesarean delivery is indicated for large fetuses, even those estimated to weigh 4500 g, should be tempered. Rouse and Owen (1999) concluded that a prophylactic cesarean delivery policy for macrosomic fetuses would require more than 1000 cesarean deliveries with attendant morbidity as well as millions of dollars to avert a single permanent brachial plexus injury.

Intrapartum Factors

Some labor characteristics have been associated with an increased shoulder dystocia risk and include prolonged second-stage labor, operative vaginal delivery, and prior shoulder dystocia (Mehta, 2004; Moragianni, 2012; Overland, 2009). Of these, the risk of recurrent shoulder dystocia ranges from 1 to 13 percent (Bingham, 2010; Moore, 2008; Ouzounian, 2013). For many women with prior shoulder dystocia, a trial of labor may be reasonable. The American College of Obstetricians and Gynecologists (2012b) recommends that estimated fetal weight, gestational age, maternal glucose intolerance, and severity of prior neonatal injury be evaluated and risks and benefits of cesarean delivery discussed with any woman with a history of shoulder dystocia. After discussion, either mode of delivery is appropriate.

Management

Because shoulder dystocia cannot be accurately predicted, clinicians should be well versed in its management principles. Because of ongoing cord compression with this dystocia, one goal is to reduce the head-to-body delivery time. This is balanced against the second goal, which is avoidance of fetal and maternal injury from aggressive manipulations. Accordingly, an initial gentle attempt at traction, assisted by maternal expulsive efforts, is recommended. Adequate analgesia is certainly ideal. Some clinicians advocate performing a large episiotomy to provide room for manipulations. Of note, Paris (2011) and Gurewitsch (2004) and their colleagues reported no change in the brachial plexus injury rate for groups in which episiotomy was not performed during shoulder dystocia management.

After gentle traction, various techniques can be used to free the anterior shoulder from its impacted position behind the symphysis pubis. Of these, moderate *suprapubic pressure* can be applied by an assistant, while downward traction is applied to the fetal head. Pressure is applied with the heel of the hand to

the anterior shoulder wedged above and behind the symphysis. The anterior shoulder is thus either depressed or rotated, or both, so the shoulders occupy the oblique plane of the pelvis and the anterior shoulder can be freed.

The *McRoberts maneuver* was described by Gonik and associates (1983) and named for William A. McRoberts, Jr., who popularized its use at the University of Texas at Houston. The maneuver consists of removing the legs from the stirrups and sharply flexing them up onto the abdomen (Fig. 27-7). Gherman and associates (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. They found that the procedure caused straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. Although this does not increase pelvic dimensions, pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and coworkers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder.

FIGURE 27-7 The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up onto the abdomen. The assistant is also providing suprapubic pressure simultaneously (arrow).

FIGURE 27-8 Delivery of the posterior shoulder for relief of shoulder dystocia. **A.** The operator's hand is introduced into the vagina along the fetal posterior humerus. **B.** The arm is splinted and swept across the chest, keeping the arm flexed at the elbow. **C.** The fetal hand is grasped and the arm extended along the side of the face. The posterior arm is delivered from the vagina.

FIGURE 27-9 Woods maneuver. The hand is placed behind the posterior shoulder of the fetus. The shoulder is then rotated progressively 180 degrees in a corkscrew manner so that the impacted anterior shoulder is released.

Another maneuver, *delivery of the posterior shoulder*, consists of carefully sweeping the posterior arm of the fetus across its chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder (Fig. 27-8).

Woods (1943) reported that by progressively rotating the posterior shoulder 180 degrees in a corkscrew fashion, the impacted anterior shoulder could be released. This is frequently referred to as the *Woods corkscrew maneuver* (Fig. 27-9). Rubin (1964) recommended two maneuvers. First, the fetal shoulders are rocked from side to side by applying force to the maternal abdomen. If this is not successful, the pelvic hand reaches the most easily accessible fetal shoulder, which is then pushed toward the anterior surface of the chest. This maneuver most often abducts both shoulders, which in turn produces a smaller shoulder-to-shoulder diameter. This permits displacement of the anterior shoulder from behind the symphysis (Fig. 27-10).

Importantly, progression from one maneuver to the next should be organized and methodical. As noted, the urgency to relieve the dystocia should be balanced against potentially injurious traction forces and manipulations. Lerner and coworkers (2011) in their evaluation of 127 shoulder dystocia cases reported that all neonates without sequelae from shoulder dystocia were born by 4 minutes. Conversely, most depressed neonates—57 percent—had head-to-body delivery intervals > 4 minutes. The percentage of depressed neonates rose sharply after 3 minutes.

Deliberate *fracture of the anterior clavicle* by using the thumb to press it toward and against the pubic ramus can be attempted to free the shoulder impaction. In practice, however, deliberate fracture of a large neonate clavicle is difficult. If successful, the fracture will heal rapidly and is usually trivial compared with brachial nerve injury, asphyxia, or death.

FIGURE 27-10 The second Rubin maneuver. **A.** The shoulder-to-shoulder diameter is aligned vertically. **B.** The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus (*arrow*). Most often, this results in abduction of both shoulders, which reduces the shoulder-to-shoulder diameter and frees the impacted anterior shoulder.

Hibbard (1982) recommended that pressure be applied to the fetal jaw and neck in the direction of the maternal rectum, with strong fundal pressure applied by an assistant as the anterior shoulder is freed. Strong fundal pressure, however, applied at the wrong time may result in even further impaction of the anterior shoulder. Gross and associates (1987) reported that fundal pressure in the absence of other maneuvers “resulted in a 77-percent complication rate and was strongly associated with (fetal) orthopedic and neurologic damage.”

Sandberg (1985) reported the *Zavanelli maneuver* for cephalic replacement into the pelvis followed by cesarean delivery. The first part of the maneuver consists of returning the head to the occiput anterior or posterior position. Terbutaline, 0.25 mg, is given subcutaneously to produce uterine relaxation. The operator flexes the head and slowly pushes it back into the vagina. Cesarean delivery is then performed. Sandberg (1999) reviewed 103 reported cases in which the Zavanelli maneuver was used. It was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Despite successful replacement, fetal injuries were common but may have resulted from the multiple manipulations used before the Zavanelli maneuver (Sandberg, 2007). Six stillbirths, eight neonatal deaths, and 10 neonates who suffered brain damage were described. Uterine rupture also was reported.

Symphysiotomy, in which the intervening symphyseal cartilage and much of its ligamentous support is cut to widen the symphysis pubis, is described in Chapter 28 (p. 567). It has been used successfully for shoulder dystocia (Hartfield, 1986). Goodwin and colleagues (1997) reported three cases in which symphysiotomy was performed after the Zavanelli maneuver had failed. All three neonates died, and maternal morbidity was significant due to urinary tract injury. *Cleidotomy* consists of cutting the clavicle with scissors or other sharp instruments and is usually done for a dead fetus (Schramm, 1983).

Hernandez and Wendel (1990) suggested use of a *shoulder dystocia drill* to better organize emergency management:

1. Call for help—mobilize assistants and anesthesia and pediatric personnel. Initially, a gentle attempt at traction is made. Drain the bladder if it is distended.
2. A generous episiotomy may be desired to afford room posteriorly.
3. Suprapubic pressure is used initially by most practitioners because it has the advantage of simplicity. Only one assistant is needed to provide suprapubic pressure, while normal downward traction is applied to the fetal head.
4. The McRoberts maneuver requires two assistants. Each assistant grasps a leg and sharply flexes the maternal thigh against the abdomen.

These maneuvers will resolve most cases of shoulder dystocia.

If the above listed steps fail, the following steps may be attempted, and any of the maneuvers may be repeated:

5. Delivery of the posterior arm is attempted. With a fully extended arm, however, this is usually difficult to accomplish.
6. Woods screw maneuver is applied.
7. Rubin maneuver is attempted.

Other techniques generally should be reserved for cases in which all other maneuvers have failed. These include intentional fracture of the anterior clavicle and the Zavanelli maneuver. The American College of Obstetricians and Gynecologists (2012b) has concluded that no one maneuver is superior to another in releasing an impacted shoulder or reducing the chance of injury. Performance of the McRoberts maneuver, however, was deemed a reasonable initial approach. The College (2012a) also has created a Patient Safety Checklist to guide the documentation process with shoulder dystocia.

Shoulder dystocia training and protocols using simulation-based education and drills has evidence-based support. These tools improve performance and retention of drill steps (Buerkle, 2012; Crofts, 2008; Grobman, 2011). Their use has translated into improved neonatal outcome in some, but not all, investigations (Draycott, 2008; Inglis, 2011; Walsh, 2011).

SPECIAL POPULATIONS

Typical vaginal delivery may be challenging in women with perineal limitations or with a large anomalous fetus. Delivery in women with prior pelvic reconstructive surgeries and in those with scarring from female genital mutilation is described here. The special needs of women with congenital vaginal septa, giant condyloma, Crohn disease, or connective-tissue disorders are discussed in chapters covering those topics.

Female Genital Mutilation

Inaccurately called female circumcision, mutilation refers to medically unnecessary vulvar and perineal modification. In the United States it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years. That said, forms of female genital mutilation are practiced in countries throughout Africa, the Middle East, and Asia. As many as 130 million women worldwide have undergone one of these procedures, and approximately 230,000 live in the United States (Nour, 2006). Cultural sensitivity is imperative, because many women may be offended by the suggestion that they have been assaulted or mutilated (American College of Obstetricians and Gynecologists, 2007).

The World Health Organization (1997) classifies genital mutilations into four types (Table 27-1). Complications include infertility, dysmenorrhea, diminished sexual quality of life, and propensity for vulvovaginal infection (Almroth, 2005; Andersson, 2012; Nour, 2006). In general, women with significant symptoms following type III procedures are candidates for corrective surgery. Specifically, division of midline scar tissue to reopen the vulva is termed defibulation or deinfibulation.

Female genital mutilation has been associated with some adverse maternal and neonatal complications. The World Health

FIGURE 27-11 Process of defibulation. Although not shown here, lidocaine is first infiltrated along the planned incision. As protection, two fingers of one hand are insinuated behind the shelf created by fused labia but in front of the urethra and crowning head. The shelf is then incised in the midline. After delivery, the raw edges are sutured with rapidly absorbable material to secure hemostasis. (From Rouzi, 2012, with permission.)

Organization (2006) estimated that these procedures increased perinatal morbidity rates by 10 to 20 per 1000. Small increased risks for prolonged labor, cesarean delivery, postpartum hemorrhage, and early neonatal death are found by some but not all (Chibber, 2011; Rouzi, 2012; Wuest, 2009). Importantly, the psychiatric consequences can be profound.

For those women who do not desire defibulation until they become pregnant, the procedure can be done at mid-pregnancy using spinal analgesia (Nour, 2006). Or, as shown in Figure 27-11, another option is to wait until delivery. In women not undergoing defibulation, anal sphincter tear rates with vaginal delivery may be increased (Berggren, 2013; Wuest, 2009). In our experiences, intrapartum defibulation in many cases allows successful vaginal delivery without major complications.

TABLE 27-1. World Health Organization Classification of Female Genital Mutilation

Type I	Prepuce excision with or without clitoral excision
Type II	Clitoral excision with or without partial or total labia minora excision
Type III	Partial or complete labial minora and/or majora excision with or without clitoridectomy and then fusion of the wound, termed infibulation.
Type IV	Unclassified and includes pricking, piercing, incision, stretching, and introduction of corrosive substances into the vagina

Adapted from the World Health Organization, 1997.

Prior Pelvic Reconstructive Surgery

These surgeries are performed with increasing frequency in reproductive-aged women, and thus pregnancy following these procedures is not uncommon. Logically, there are concerns for symptom recurrence following vaginal delivery, and high-quality data to aid evidenced-based decisions are limited. For women with prior stress urinary incontinence surgery, slightly greater protection against postpartum incontinence is gained by elective cesarean delivery (Pollard, 2012; Pradhan, 2013). Stated another way, most women with prior anti-incontinence surgery can be delivered vaginally without symptom recurrence. Also, cesarean delivery is not always protective.

Obviously, symptom recurrence and the need for additional vaginal surgery should be weighed against the surgical risk of cesarean delivery (Groenen, 2008). In those with prior surgeries for anal incontinence or pelvic organ prolapse, only scant information regarding outcomes is available. Such cases require individualization.

Anomalous Fetuses

Rarely, delivery can be obstructed by extreme macrocephaly secondary to hydrocephaly or by massive fetal abdomen enlargement from a greatly distended bladder, ascites, or large kidneys or liver. With milder forms of hydrocephaly, if the biparietal diameter is < 10 cm or if the head circumference is < 36 cm, then vaginal delivery may be permitted (Anteby, 2003).

In rare cases in which neonatal death has occurred or is certain due to associated anomalies, vaginal delivery may be reasonable, but the head or abdomen must be reduced in size for delivery. Removal of fluid by cephalocentesis or paracentesis with sonographic guidance can be performed intrapartum. For hydrocephalic fetuses that are breech, cephalocentesis can be accomplished suprapubically when the aftercoming head enters the pelvis. For those that require cesarean delivery, fluid removal before hysterotomy circumvents extending a low transverse or lengthening a vertical incision.

THIRD STAGE OF LABOR

Delivery of the Placenta

Third-stage labor begins immediately after fetal birth and ends with placental delivery. Goals include delivery of an intact placenta and avoidance of uterine inversion or postpartum hemorrhage. The latter two are grave intrapartum complications and constitute emergencies, as described in Chapter 41 (p. 783).

Immediately after newborn birth, uterine fundal size and consistency are examined. If the uterus remains firm and there is no unusual bleeding, watchful waiting until the placenta separates is the usual practice. Massage is not employed, but the fundus is frequently palpated to ensure that it does not become atonic and filled with blood from placental separation. To prevent uterine inversion, umbilical cord traction must not be used to pull the placenta from the uterus. Moreover, placental expression is not forced before placental separation. Signs of separation include a sudden gush of blood into the vagina, a globular and firmer fundus, a lengthening of the umbilical cord as the placenta descends into the vagina, and a rise of the uterus into the abdomen. With the last, the placenta, having separated, passes down into the lower uterine segment and vagina. Here, its bulk pushes the uterus upward.

These signs sometimes appear within 1 minute after newborn delivery and usually within 5 minutes. Once the placenta has detached from the uterine wall, it should be determined that the uterus is firmly contracted. The mother

FIGURE 27-12 Expression of placenta. Note that the hand is *not* trying to push the fundus of the uterus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is elevated by the hand on the abdomen while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina.

may be asked to bear down, and the intraabdominal pressure often expels the placenta into the vagina. These efforts may fail or may not be possible because of analgesia. After ensuring that the uterus is contracted firmly, pressure is exerted by a hand wrapped around the fundus to propel the detached placenta into the vagina (Fig. 27-12). The umbilical cord is kept slightly taut but is not pulled. Concurrently, the heel of the hand exerts downward pressure between the symphysis pubis and the uterine fundus. This also aids inversion prevention. Once the placenta passes through the introitus, pressure on the uterus is relieved. The placenta is then gently lifted away (Fig. 27-13). Care is taken to prevent placental membranes from being torn off and left behind. If the membranes begin to tear, they are grasped with a clamp and removed by gentle teasing (Fig. 27-14).

Manual Removal of Placenta

Occasionally, the placenta will not separate promptly. This is especially common with preterm delivery (Dombrowski, 1995). If there is brisk bleeding and the placenta cannot be delivered by the above technique, manual removal of the placenta is indicated, using the safeguards described in Chapter 41 (p. 784). It is unclear how much time should elapse in the absence of bleeding before the placenta is manually removed (Deneux-Tharaux, 2009). If labor analgesia is still intact, some obstetricians practice routine manual removal of any placenta that has not separated spontaneously by the time they have completed

FIGURE 27-13 The placenta is removed from the vagina by lifting the cord.

delivery of the newborn and care of the cord. The benefits of this practice, however, have not been proven, and most obstetricians await spontaneous placental detachment unless bleeding is excessive. When manual removal is performed, some administer a single dose of intravenous antibiotics similar to that used for cesarean infection prophylaxis (Chap. 30, p. 590). The American College of Obstetricians and Gynecologists (2011) has concluded that there are no data to either support or refute this practice.

FIGURE 27-14 Membranes that were somewhat adhered to the uterine lining are separated by gentle traction with a ring forceps.

Management of the Third Stage

Practices within the third stage of labor may be broadly considered as either physiological or active management. Physiological or expectant management involves waiting for placental separation signs and allowing the placenta to deliver either spontaneously or aided by nipple stimulation or gravity (World Health Organization, 2012). In contrast, active management of third-stage labor consists of early cord clamping, controlled cord traction during placental delivery, and immediate administration of prophylactic uterotonics. The goal of this triad is to limit postpartum hemorrhage (Begley, 2011; Jangsten, 2011; Prendiville, 1988). In addition, uterine massage following placental delivery is recommended by many but not all to prevent postpartum hemorrhage. We support this with the caveat that evidence for this practice is not strong (Abdel-Aleem, 2010). As noted earlier (p. 539), immediate cord clamping does not increase postpartum hemorrhage rates and thus is a less important component of this trio. Similarly, cord traction may also be less critical (Gülmezoglu, 2012).

Therefore, uterotonics appear to be the most important factor to decrease postpartum blood loss. Choices include oxytocin (Pitocin), misoprostol (Cytotec), carboprost (Hemabate), and the ergots, namely ergonovine (Ergotrate) and methylergonovine (Methergine). In addition, a combination agent of oxytocin and ergonovine (Syntometrine) is used outside the United States. Also in other countries, carbetocin (Duratocin), a long-acting oxytocin analogue, is available and effective for hemorrhage prevention during cesarean delivery (Attilakos, 2010; Su, 2012). Of these, the World Health Organization (2012) recommends oxytocin as a first-line agent. Ergot-based drugs and misoprostol are alternatives in settings that lack oxytocin.

Uterotonics may be given before or after placental expulsion without increasing rates of postpartum hemorrhage, placental retention, or third-stage labor length (Soltani, 2010). If they are given before delivery of the placenta, however, they may entrap an undiagnosed, undelivered second twin. Thus, abdominal palpation should confirm no additional fetuses.

High-Dose Oxytocin

Synthetic oxytocin is identical to that produced by the posterior pituitary. Its action is noted at approximately 1 minute, and it has a mean half-life of 3 to 5 minutes. When given as a bolus, oxytocin can cause profound hypotension. Secher and coworkers (1978) reported that an intravenous bolus of 10 units of oxytocin caused a marked transient fall in blood pressure with an abrupt increase in cardiac output. Svanström and associates (2008) confirmed those findings in 10 healthy women following cesarean delivery. Mean pulse rate increased 28 bpm, mean arterial pressure decreased 33 mm Hg, and electrocardiogram changes of myocardial ischemia as well as chest pain and subjective discomfort were noted. These hemodynamic changes could be dangerous for women hypovolemic from hemorrhage or those with cardiac disease. Thus, oxytocin should not be given

intravenously as a large bolus. Rather, it should be given as a dilute solution by continuous intravenous infusion or as an intramuscular injection.

Water intoxication can result from the antidiuretic action of high-dose oxytocin if administered in a large volume of electrolyte-free dextrose solution (Whalley, 1963). In a case report, Schwartz and Jones (1978) described convulsions in both a mother and her newborn following administration of 6.5 liters of 5-percent dextrose solution and 36 units of oxytocin before delivery. The cord plasma sodium concentration was 114 mEq/L. Accordingly, if oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than increasing the infusion flow rate (Chap. 26, p. 530).

Despite the routine use of oxytocin, no standard prophylactic dose has been established for its use following either vaginal or cesarean delivery. In an analysis of studies that compared oxytocin dosage, investigators found higher infusion doses to be more effective than lower doses or protracted fixed-dose administration (Roach, 2013; Tita, 2012). Our standard practice, if an intravenous infusion is established, is to add 20 units (2 mL) of oxytocin per liter of infusate. This solution is administered after delivery of the placenta at a rate of 10 to 20 mL/min (200 to 400 mU/min) for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer from the recovery suite to the postpartum unit. The infusion is usually then discontinued. For women without intravenous access, 10 units of intramuscular oxytocin are provided.

Ergonovine and Methylergonovine

These ergot alkaloids have similar activity levels in myometrium, and only methylergonovine is currently manufactured in the United States. These agents require very specific storage conditions, as they deteriorate rapidly with exposure to light, heat, and humidity.

Whether given intramuscularly or orally, both are powerful stimulants of myometrial contraction, exerting an effect that may persist for hours. In pregnant women, an intramuscular or oral dose of 0.2 mg results in tetanic uterine contractions. Effects develop within a few minutes after intramuscular or oral administration. Moreover, the response is sustained with little tendency toward relaxation. *Ergots are dangerous for the fetus and mother when given before delivery.* Moreover, cases of serious injury and death have been reported when methylergonovine was administered accidentally to newborns in the labor and delivery room instead of vitamin K, hepatitis B vaccine, or naloxone (Aeby, 2003; American Regent, 2012a; Bangh, 2005). The Food and Drug Administration (2012) has added a warning to the package insert recommending a 12-hour delay between the last methylergonovine dose and breast feeding. Despite this, no adverse effects attributable to this drug in breast milk have been reported (Briggs, 2011).

In addition to neonatal concerns, parenteral administration of ergot alkaloids, especially by the intravenous route, may induce transient maternal hypertension. Other reported

side effects include nausea, vomiting, tinnitus, headache, and painful uterine contractions. Hypertension is more likely to be severe in women with gestational hypertension. These drugs are contraindicated in patients with hypertension, cardiac disease or occlusive vascular disorders, severe hepatic or renal disease, and sepsis (Novartis, 2012; Sanders-Bush, 2011). Moreover, this drug is not routinely given intravenously to avoid inducing sudden hypertensive and cerebrovascular accidents. If considered a lifesaving measure, however, intravenous methylergonovine should be given slowly during no less than 60 seconds with careful monitoring of blood pressure (American Regent, 2012b).

Ergot alkaloid agents do not provide superior protection against postpartum hemorrhage compared with oxytocin. Moreover, safety and tolerability are greater with oxytocin (Liabsuetrakul, 2007). For these reasons, ergot alkaloid agents are considered second-line for third-stage labor prevention of hemorrhage.

Misoprostol

This prostaglandin E₁ analogue has proved inferior to oxytocin for postpartum hemorrhage prevention (Tunçalp, 2012). Although oxytocin is preferred, in resource-poor settings that lack oxytocin, misoprostol is suitable for hemorrhage prophylaxis and is given as a single oral 600- μ g dose (Mobeen, 2011; World Health Organization, 2012). Side effects include shivering in 30 percent and fever in 5 percent. Unlike some other prostaglandins, nausea or diarrhea is infrequent (Derman, 2006; Lumbiganon, 1999; Walraven, 2005).

"FOURTH STAGE" OF LABOR

The hour immediately following delivery of the placenta is critical, and it has been designated by some as the fourth stage of labor. During this time, lacerations are repaired. Although uterotonics are administered, postpartum hemorrhage as the result of uterine atony is most likely at this time. Hematomas may expand. Consequently, uterine tone and the perineum should be frequently evaluated. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that maternal blood pressure and pulse be recorded immediately after delivery and every 15 minutes for the first 2 hours. The placenta, membranes, and umbilical cord should be examined for completeness and for anomalies, as described in Chapter 6 (p. 117).

Birth Canal Lacerations

Lower genital tract lacerations may involve the cervix, vagina, or perineum. Those of the cervix and vagina are described in Chapter 41 (p. 788). Perineal tears may follow any vaginal delivery and are classified by their depth. Complete definitions and visual examples are given in [Figure 27-15](#). As noted, third- and fourth-degree lacerations are considered higher-order lacerations. Short-term, these are associated with greater blood loss, puerperal pain, and wound disruption or infection risk.

FIGURE 27-15 Classification of perineal lacerations. **A.** First-degree lacerations involve the fourchette, perineal skin, and vaginal mucous membrane but not the underlying fascia and muscle. These included periurethral lacerations, which may bleed profusely. **B.** Second-degree lacerations involve, in addition, the fascia and muscles of the perineal body but not the anal sphincter. These tears may be midline, but often extend upward on one or both sides of the vagina, forming an irregular triangle. **C.** Third-degree lacerations extend farther to involve the external anal sphincter. **D.** Fourth-degree lacerations extend completely through the rectal mucosa to expose its lumen and thus involves disruption of both the external and internal anal sphincters. (Used with permission from Drs. Shayzreen Roshanravan and Marlene Corton.)

Long-term, they are linked with higher rates of anal incontinence and dyspareunia. The incidence of higher-order lacerations varies from 0.25 to 6 percent (Garrett, 2014; Groutz, 2011; Melamed, 2013; Stock, 2013). Risk factors for these more complex lacerations include midline episiotomy, nulliparity, longer second-stage labor, precipitous delivery, persistent occiput posterior position, operative vaginal delivery, Asian race, and increasing fetal birthweight (Landy, 2011; Melamed, 2013). Epidural analgesia was found to be protective (Jango, 2014).

Morbidity rates rise as laceration severity increases. Stock and coworkers (2013) reported that approximately 7 percent of

909 higher-order lacerations had complications. Williams and Chames (2006) found that mediolateral episiotomy was the most powerful predictor of wound disruption. Goldaber and associates (1993) found that 21 of 390 or 5.4 percent of women with fourth-degree lacerations experienced significant morbidity. There were 1.8 percent dehiscences, 2.8 percent infections plus a dehiscence, and 0.8 percent with isolated infections.

The repair of perineal lacerations is virtually the same as that of episiotomy incisions, albeit sometimes less satisfactory because of tear irregularities. Thus, laceration repair technique is discussed with episiotomy repair.

FIGURE 27-16 Midline episiotomy. Two fingers are insinuated between the perineum and fetal head, and the episiotomy is then cut vertically downward.

■ Episiotomy

The word episiotomy derives from the Greek *episton*—pubic region—plus *-tomy*—to cut. In a strict sense, episiotomy is incision of the pudendum—the external genital organs. Perineotomy is incision of the perineum. In common parlance, however, the term episiotomy often is used synonymously with perineotomy, a practice that we follow here. The incision may be made in the midline, creating a median or midline episiotomy (Fig. 27-16). It may also begin off the midline and directed laterally and downward away from the rectum, termed a mediolateral episiotomy.

Episiotomy Indications and Consequences

Although episiotomy is still a common obstetrical procedure, its use has decreased remarkably over the past 30 years. Oliphant and coworkers (2010) used the National Hospital Discharge Survey to analyze episiotomy rates between 1979 and 2006 in the United States. They noted a 75-percent decline in the episiotomy age-adjusted rate. Through the 1970s, however, it was common practice to cut an episiotomy for almost all women having their first delivery. The reasons for its popularity included substitution of a straight surgical incision, which was easier to repair, for the ragged laceration that otherwise might result. The long-held beliefs that postoperative pain is less and healing improved with an episiotomy compared with a tear, however, appeared to be incorrect (Larsson, 1991).

Another commonly cited but unproven benefit of routine episiotomy was that it prevented pelvic floor disorders. A number of observational studies and randomized trials, however, showed that routine episiotomy is associated with an *increased* incidence of anal sphincter and rectal tears (Angioli, 2000; Nager, 2001; Rodriguez, 2008).

Caroli and Mignini (2009) reviewed the Cochrane Pregnancy and Childbirth Group trials registry. There were lower rates of posterior perineal trauma, surgical repair, and healing complications in women managed with a restrictive use of episiotomy. Alternatively, the incidence of anterior perineal trauma was lower in the group managed with routine use of episiotomy.

With these findings came the realization that episiotomy did not protect the perineal body but contributed to anal sphincter incontinence by increasing the risk of higher-order lacerations. Signorello and associates (2000) reported that fecal and flatal incontinence was increased four- to sixfold in women with an episiotomy compared with a group of women delivered with an intact perineum. Even compared with spontaneous lacerations, episiotomy tripled the risk of fecal incontinence and doubled it for flatal incontinence. Episiotomy without extension did not lower this risk. Despite repair of a third-degree extension, 30 to 40 percent of women have long-term anal incontinence (Gjessing, 1998; Poen, 1998). Finally, Alperin and associates (2008) reported that episiotomy performed for the first delivery conferred a fivefold risk for second-degree or higher-order laceration with the second delivery.

The American College of Obstetricians and Gynecologists (2013a) has concluded that restricted use of episiotomy is preferred to routine use. We are of the view that the procedure should be applied selectively for appropriate indications. Thus, episiotomy should be *considered* for indications such as shoulder dystocia, breech delivery, macrosomic fetuses, operative vaginal deliveries, persistent occiput posterior positions, and other instances in which failure to perform an episiotomy will result in significant perineal rupture. The final rule is that there is no substitute for surgical judgment and common sense.

Episiotomy Type and Timing

Before episiotomy, analgesia may be provided by existing labor epidural analgesia, by bilateral pudendal nerve blockade, or by infiltration of 1-percent lidocaine. If performed unnecessarily early, bleeding from the episiotomy may be considerable during the interval between incision and delivery. If it is performed too late, lacerations will not be prevented. Typically, episiotomy is completed when the head is visible during a contraction to a diameter of approximately 4 cm, that is, crowning. When used in conjunction with forceps delivery, most perform an episiotomy after application of the blades (Chap. 29, p. 580).

Technique

For midline episiotomy, fingers are insinuated between the crowning head and the perineum. The scissors are positioned at 6 o'clock on the vaginal opening and directed posteriorly (see Fig. 27-16). The incision length varies from 2 to 3 cm depending on perineal length and degree of tissue thinning. The incision is customized for specific delivery needs but should stop well before reaching the external anal sphincter. With mediolateral

TABLE 27-2. Midline versus Mediolateral Episiotomy

Characteristic	Type of Episiotomy	
	Midline	Mediolateral
Surgical repair	Easy	More difficult
Faulty healing	Rare	More common
Postoperative pain	Minimal	Common
Anatomical results	Excellent	Occasionally faulty
Blood loss	Less	More
Dyspareunia	Rare	Occasional
Extensions	Common	Uncommon

episiotomy, scissors are positioned at 7 o'clock or at 5 o'clock, and the incision is extended 3 to 4 cm toward the ipsilateral ischial tuberosity.

Differences between the two types of episiotomies are summarized in [Table 27-2](#). Except for the important issue of third- and fourth-degree extensions, midline episiotomy is superior. Anthony and colleagues (1994) presented data from the Dutch National Obstetric Database of more than 43,000 deliveries. They found a more than fourfold decrease in severe perineal lacerations following mediolateral episiotomy compared with rates after midline incision. Proper selection of cases can minimize this one disadvantage. For example, if episiotomy is required during

operative vaginal delivery, several studies have reported a protective effect from mediolateral episiotomy against higher-order perineal lacerations (de Leeuw, 2008; de Vogel, 2012; Hirsch, 2008).

Repair of Episiotomy or Perineal Laceration

Typically, episiotomy repair is deferred until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that episiotomy repair is not interrupted or disrupted by the obvious necessity of delivering the placenta, especially if manual removal must be performed that may disrupt a newly repaired episiotomy. The major disadvantage is continuing blood loss until the repair is completed. Direct pressure from an applied gauze sponge will help to limit this loss.

For suitable repair, an understanding of perineal support and anatomy is necessary and is discussed in Chapter 2 (p. 21). Adequate analgesia is imperative, and Sanders and coworkers (2002) emphasized that women without regional analgesia can experience high levels of pain during perineal suturing. Again, local lidocaine can be used solely or as a supplement to bilateral pudendal nerve blockade. In those with epidural analgesia, additional dosing may be necessary.

There are many ways to repair an episiotomy incision, but hemostasis and anatomical restoration without excessive suturing are essential. A technique that commonly is employed for midline repair is shown in [Figure 27-17](#). Some

**A****B**

FIGURE 27-17 Repair of midline episiotomy. **A.** Disruption of the hymenal ring and bulbocavernosus and superficial transverse perineal muscles are seen within the diamond-shaped episiotomy incision. **B.** An anchor stitch is placed above the wound apex to begin a running closure. Absorbable 2-0 or 3-0 suture is used for continuous closure of the vaginal mucosa and submucosa with interlocking stitches. (*continued*)

FIGURE 27-17 (Continued) **C.** After closing the vaginal incision and reapproximating the cut margins of the hymenal ring, the needle and suture are positioned to close the perineal incision. **D.** A continuous closure with absorbable 2-0 or 3-0 suture is used to close the fascia and muscles of the incised perineum. This aids restoration of the perineal body for long-term support. **E.** The continuous suture is then carried upward as a subcuticular stitch. The final knot is tied proximal to the hymenal ring.

FIGURE 27-18 Mediolateral episiotomy repair. The vaginal mucosa is shown as already closed using 2-0 absorbable suture in a running interlocking stitch similar to that for midline repair. As illustrated, perineal reapproximation begins with reunion of bulbocavernosus and transverse perineal muscles. These will assist reestablishment of perineal body support. Distal to these muscles, abundant fat in the ischioanal fossa is incorporated in the same running closure. A second layer atop this first perineal layer may be required to adequately close dead space. The skin is then closed with a subcuticular stitch as used for midline closure.

studies have found similar postoperative pain scores using either continuous or interrupted closure (Kindberg, 2008; Valenzuela, 2009). Others note less pain with continuous suturing (Kettle, 2012). Moreover, continuous suturing is faster and uses less suture material. Mornar and Perlow (2008) have shown that blunt needles are suitable and likely decrease the incidence of needlestick injuries. The suture material commonly used is 2-0 chromic catgut. Sutures made of polyglycolic acid derivatives are also frequently used. A decrease in postsurgical pain is cited as the major advantage of synthetic materials. Closures with these materials, however, occasionally require suture removal from the repair site because of pain or dyspareunia. According to Kettle and associates (2002), this disadvantage may be reduced using a rapidly absorbed polyglactin 910 (Vicryl Rapide).

Repair of a mediolateral episiotomy is similar to a midline repair. The technique is shown in [Figure 27-18](#).

Fourth-Degree Laceration Repair

Two methods are used to repair a laceration involving the anal sphincter and rectal mucosa. The first is the end-to-end technique, which we prefer, and the second is the overlapping technique.

The *end-to-end technique* is shown in [Figure 27-19](#). In all techniques that have been described, it is essential to approximate the torn edges of the rectal mucosa with sutures placed in the rectal muscularis approximately 0.5 cm apart. One suitable choice is 2-0 or 3-0 chromic gut. This muscular layer then is covered by reapproximation of the internal anal sphincter. Finally, the cut ends of the external anal sphincter are isolated, approximated, and sutured together end-to-end with three or four interrupted stitches. The remainder of the repair is the same as for a midline episiotomy.

The *overlapping technique* is an alternative method to approximate the external anal sphincter. Data based on randomized controlled trials do not support that this method yields superior anatomical or functional results compared with those of the traditional end-to-end method (Farrell, 2012; Fitzpatrick, 2000).

We, as well as others, recommend perioperative antimicrobial prophylaxis for the reduction of infectious morbidity associated with higher-order perineal injury repair (Goldaber, 1993; Stock, 2013). A single dose of a second-generation cephalosporin is suitable, or clindamycin for penicillin-allergic women. Although such prophylaxis has some evidence-based support, the American College of Obstetricians and Gynecologists (2011) has concluded that this practice has not been extensively studied (Duggal, 2008; Stock, 2013). Postoperatively, stool softeners should be prescribed for a week, and enemas and suppositories should be avoided.

Unfortunately, normal function is not always ensured even with correct and complete surgical repair. Some women may experience continuing fecal incontinence caused by injury to the innervation of the pelvic floor musculature (Roberts, 1990).

Postepisiotomy Pain

Pudendal nerve blockade can aid relief of perineal pain postoperatively (Aissaoui, 2008). Locally applied ice packs help reduce swelling and allay discomfort. Topical application of 5-percent lidocaine ointment was not effective in relieving episiotomy or perineal laceration discomfort in one randomized trial (Minassian, 2002). Analgesics such as codeine give considerable relief. Because pain may be a signal of a large vulvar, paravaginal, or ischiorectal fossa hematoma or perineal cellulitis, these sites should be examined carefully if pain is severe or persistent. Management of these complications is discussed in Chapters 37 and 41 (p. 689 and p. 790). In addition to pain, urinary retention may complicate episiotomy recovery (Mulder, 2012). Its management is described in Chapter 36 (p. 676).

For those with second-degree or greater lacerations, intercourse is usually proscribed until after the first puerperal visit at 4 to 6 weeks. Signorello and coworkers (2001) surveyed 615 women 6 months postpartum and reported that those delivered with an intact perineum reported better sexual function compared with those who had perineal trauma. In another

FIGURE 27-19 Layered repair of a fourth-degree perineal laceration. **A.** Approximation of the anorectal mucosa and submucosa in a running or interrupted fashion using fine absorbable suture such as 3-0 or 4-0 chromic or Vicryl. During this suturing, the superior extent of the anterior anal laceration is identified, and the sutures are placed through the submucosa of the anorectum approximately 0.5 cm apart down to the anal verge. **B.** A second layer is placed through the rectal muscularis using 3-0 Vicryl suture in a running or interrupted fashion. This “reinforcing layer” should incorporate the torn ends of the internal anal sphincter, which is identified as the thickening of the circular smooth muscle layer at the distal 2 to 3 cm of the anal canal. It can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter (EAS). In many cases, the internal sphincter retracts laterally and must be sought and retrieved for repair. (*continued*)

FIGURE 27-19 (Continued) C. In overview, with traditional end-to-end approximation of the EAS, a suture is placed through the EAS muscle, and four to six simple interrupted 2-0 or 3-0 Vicryl sutures are placed at the 3, 6, 9, and 12 o'clock positions through the connective tissue capsule of the sphincter. The sutures through the inferior and posterior portions of the sphincter should be placed first to aid this part of the repair. To begin this portion of the closure, the disrupted ends of the striated EAS muscle and capsule are identified and grasped with Allis clamps. Suture is placed through the posterior wall of the EAS capsule. **D.** Sutures through the EAS (blue suture) and inferior capsule wall. **E.** Sutures to reapproximate the anterior and superior walls of the EAS capsule. The remainder of the repair is similar to that described for a midline episiotomy in Figure 27-17.

follow-up of 2490 women, Rådestad and associates (2008) reported delayed intercourse at 3 and 6 months, but not at 1 year, in women with and without perineal trauma.

INTERNAL PODALIC VERSION 571

Near term, the fetus typically turns spontaneously to a cephalic presentation as the increasing bulk of the buttocks seeks the more spacious fundus. However, if the fetal buttocks or legs enter the pelvis before the head, the presentation is breech. This fetal lie is more common remote from term as each fetal pole is of similar bulk earlier in pregnancy (Fig. 28-1). That said, breech presentation persists at term in 3 to 4 percent of singleton deliveries. The annual rate of breech presentation at delivery in nearly 270,000 singleton newborns at Parkland Hospital has varied from only 3.3 to 3.9 percent during the past 30 years.

Current obstetrical thinking regarding vaginal delivery of the breech fetus has been tremendously influenced by results

reported from the Term Breech Trial Collaborative Group (Hannah, 2000). This trial included 1041 women randomly assigned to planned cesarean and 1042 to planned vaginal delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Planned cesarean delivery was associated with a lower risk of perinatal mortality compared with planned vaginal delivery—3 per 1000 versus 13 per 1000. Cesarean delivery was also associated with a lower risk of “serious” neonatal morbidity—1.4 versus 3.8 percent.

The reaction to these findings by the American College of Obstetricians and Gynecologists (2001) resulted in an abrupt decline in the rate of attempted vaginal breech deliveries. Since those times, however, a more moderate plan was reached for management of breech delivery.

Critics of the Term Breech Trial emphasized that most of the outcomes included in the “serious” neonatal morbidity composite did not actually portend long-term disability. Moreover, as data from countries with low perinatal mortality rates became available, they showed infrequent perinatal deaths, and rates did not differ significantly between mode-of-delivery groups. Also, only nulliparas were included in the Term Breech Trial, and fewer than 10 percent underwent radiological pelvimetry. And last, the 2-year outcomes for children born during the original multicenter trial showed that planned cesarean delivery was not associated with a reduction in the rate of death or developmental delay (Whyte, 2004). Some of the large studies reporting the safety and risks of vaginal delivery for the term breech singleton are discussed further on page 561.

These findings prompted the American College of Obstetricians and Gynecologists (2012b) to modify its stance on breech presentation, and it currently recommends that “the decision regarding the mode of delivery should depend on the experience of the health care provider” and that “planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines.” This has been echoed by

FIGURE 28-1 Prevalence of breech presentation by gestational age at delivery in 58,842 singleton pregnancies at the University of Alabama at Birmingham Hospitals 1991 to 2006. (Data courtesy of Dr. John Hauth and Ms. Sue Cliver.)

other obstetrical organizations (Carbonne, 2001; Kotaska, 2009; Royal College of Obstetricians and Gynaecologists, 2009).

CLASSIFICATION OF BREECH PRESENTATIONS

The varying relations between the lower extremities and buttocks of breech fetuses form the categories of frank, complete,

and incomplete breech presentations. With a frank breech presentation, the lower extremities are flexed at the hips and extended at the knees, and thus the feet lie in close proximity to the head (Fig. 28-2). A complete breech differs in that one or both knees are flexed (Fig. 28-3). With incomplete breech presentation, one or both hips are not flexed, and one or both feet or knees lie below the breech, such that a foot or knee is lowermost in the birth canal (Fig. 28-4). A footling breech is an incomplete breech with one or both feet below the breech.

In perhaps 5 percent of term breech fetuses, the head may be in extreme hyperextension. These presentations have been referred to as the *stargazer fetus*, and in Britain as the *flying foetus*. With such hyperextension, vaginal delivery may result in injury to the cervical spinal cord. Thus, if present after labor has begun, this is an indication for cesarean delivery (Svenningsen, 1985).

DIAGNOSIS

Risk Factors

Understanding the clinical settings that predispose to breech presentation can aid early recognition. Other than early gestational age, risk factors include abnormal amniotic fluid

FIGURE 28-2 Frank breech presentation.

FIGURE 28-3 Complete breech presentation.

FIGURE 28-4 Incomplete breech presentation.

volume, multifetal gestation, hydrocephaly, anencephaly, uterine anomalies, placenta previa, fundal placental implantation, pelvic tumors, high parity with uterine relaxation, and prior breech delivery. Specifically, following one breech delivery, the recurrence rate for a second pregnancy with breech presentation was nearly 10 percent, and that for a subsequent third pregnancy was 27 percent (Ford, 2010). Prior cesarean delivery has also been described by some to increase twofold the incidence of breech presentation (Kalogiannidis, 2010; Vendittelli, 2008). Last, smoking may be a modifiable cause of this presentation (Rayl, 1996; Witkop, 2008).

■ Examination

Leopold maneuvers to ascertain fetal presentation are discussed in Chapter 22 (p. 438). With the first maneuver, the hard, round, ballotable fetal head may be found to occupy the fundus. The second maneuver indicates the back to be on one side of the abdomen and the small parts on the other. With the third maneuver, if not engaged, the breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the firm breech to be beneath the symphysis. The accuracy of this palpation varies (Lydon-Rochelle, 1993; Nassar, 2006). Thus, with suspected breech presentation—or any presentation other than cephalic—sonographic evaluation is indicated.

With a frank breech during vaginal examination, no feet are appreciated, but the fetal ischial tuberosities, sacrum, and anus are usually palpable. After further fetal descent, the external genitalia may also be distinguished. Especially when labor is prolonged, the fetal buttocks may become markedly swollen, rendering differentiation of a face and breech difficult. In some

cases, the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the firmer, less yielding jaws are felt through the mouth. The finger, upon removal from the anus, may be stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line. With a complete breech, the feet may be felt alongside the buttocks. In footling presentations, one or both feet are inferior to the buttocks.

The fetal sacrum and its spinous processes are palpated also to establish position. As with cephalic presentations described in Chapter 22 (p. 434), fetal positions are designated as left sacrum anterior (LSA), right sacrum anterior (RSA), left sacrum posterior (LSP), right sacrum posterior (RSP), or sacrum transverse (ST) to reflect the relations of the fetal sacrum to the maternal pelvis.

ROUTE OF DELIVERY

Multiple factors aid determination of the best delivery route for a given mother-fetus pair. These include fetal characteristics, pelvic dimensions, coexistent pregnancy complications, operator experience, patient preference, and hospital capabilities.

■ Term and Preterm Breech Fetus

Although sharing the similarity of presentation, preterm breech fetuses have distinct risks related to immaturity compared with their term breech counterparts. Accordingly, separation of term and preterm breech fetuses for discussion allows a more accurate evaluation of information.

Term Breech Fetus

Data regarding superior perinatal outcomes for planned cesarean delivery of a singleton term breech are conflicting. As described earlier (p. 558), the Term Breech Trial reported lower neonatal morbidity and mortality rates with planned cesarean delivery for breech presentation. Additional data favoring cesarean delivery comes from the World Health Organization (Lumbiganon, 2010). From their evaluation of more than 100,000 deliveries from nine participating Asian countries, they reported improved perinatal outcomes associated with planned cesarean compared with planned vaginal delivery of the term breech fetus. Other studies have evaluated neonatal outcome with cesarean delivery and also found lowered neonatal morbidity and mortality rates (Hartnack Tharin, 2011; Mailath-Pokorny, 2009; Rietberg, 2005; Swedish Collaborative Breech Study Group, 2005).

In contrast, the *Presentation et Mode d'Accouchement*—which translates as presentation and mode of delivery (PREMODA)—study showed no differences in corrected neonatal mortality rates and neonatal outcomes according to delivery mode (Goffinet, 2006). This French prospective observational study involved more than 8000 women with term breech singletons. Strict criteria were used to select 2526 of these for planned vaginal delivery, and 71 percent of that group were delivered vaginally. Similarly, data from the Lille Breech Study Group in France showed no

excessive morbidity in term breech singletons delivered vaginally provided strict fetal biometric and maternal pelvimetry parameters were applied (Michel, 2011). Other smaller studies also support these findings as long as guidelines are part of the selection process (Alarab, 2004; Albrechtsen, 1997; Giuliani, 2002; Toivonen, 2012). Long-term evidence in support of vaginal breech delivery comes from Eide and associates (2005). These researchers analyzed intelligence testing scores of more than 8000 men delivered breech and found no differences in intellectual performance in those delivered vaginally or by cesarean.

Despite evidence on both sides of the debate, at least in this country, rates of planned vaginal delivery attempts continue to decline (Hehir, 2012). And as predicted, the number of skilled operators able to safely select and vaginally deliver breech fetuses continues to dwindle (Chinnock, 2007). Moreover, obvious medicolegal concerns makes physician training in such deliveries difficult. In response, some institutions have developed birth simulators to improve resident competence in vaginal breech delivery (Deering, 2006; Maslovitz, 2007).

Preterm Breech Fetus

Although there are no randomized studies regarding delivery of the preterm breech fetus, planned cesarean delivery appears to confer a survival advantage. Reddy and associates (2012) reported data from an National Institutes of Health retrospective multicenter cohort study involving 208,695 deliveries between 24 and 32 weeks' gestation. For breech fetuses within these gestational ages, attempting vaginal delivery yielded a low completion rate, and those completed were associated with higher neonatal mortality rates compared with planned cesarean delivery. Other studies have reported similar findings (Demirci, 2012; Lee, 1998; Muhuri, 2006). There are, however, a few smaller studies that describe no improved survival rate in fetuses at earlier gestational ages—24 to 29 weeks—delivered by planned cesarean (Kayem, 2008; Stohl, 2011).

There are limited data regarding any preferable delivery route for preterm breech fetuses between 32 and 37 weeks. In these cases, fetal weight rather than gestational age is likely most important. The Maternal Fetal Medicine Committee of the Society of Obstetricians and Gynaecologists of Canada (SOGC) recommend that vaginal breech delivery is reasonable when the estimated fetal weight is > 2500 g (Kotaska, 2009).

Delivery Complications

Maternal Morbidity and Mortality

Increased rates of maternal and perinatal morbidity can be anticipated with breech presentations. For the mother, with either cesarean or vaginal delivery, genital tract laceration can be problematic. With cesarean delivery, added stretching of the lower uterine segment by forceps or by a poorly molded fetal head can extend hysterotomy incisions. With vaginal delivery, especially with a thinned lower uterine segment, delivery of the aftercoming head through an incompletely dilated cervix or application of forceps may cause vaginal wall or cervical lacerations. Manipulations may also extend an episiotomy, create deep perineal tears, and increase infection risks. Anesthesia sufficient to induce appreciable uterine relaxation during vaginal delivery

may cause uterine atony and in turn, postpartum hemorrhage. Death is a rare complication, but rates appear higher in those with planned cesarean delivery for breech presentation—a case fatality rate of 0.47 maternal deaths per 1000 births (Schutte, 2007). Last, as described in Chapter 30 (p. 588), the risks associated with vaginal breech delivery are balanced against general cesarean delivery risks, which include those associated with vaginal birth after cesarean (VBAC) or those with repeated cesarean hysterotomy.

Perinatal Morbidity and Mortality

Preterm delivery is a common association, and there is an increased rate of congenital anomalies. In addition, birth trauma, although uncommon, can contribute to death of the breech fetus. Importantly, these are seen both with vaginal as well as cesarean delivery. Some of the more common injuries are fractures of the humerus, clavicle, and femur (Canpolat, 2010; Matsubara, 2008). In some cases, traction may separate scapular, humeral, or femoral epiphyses.

Rare traumatic injuries may involve bony or soft tissues. Neonatal perineal tears have been reported from fetal scalp electrodes (Freud, 1993). Upper extremity paralysis—Erb or Duchenne—may follow brachial plexus stretching (Al-Qattan, 2010). When the fetus is extracted through a contracted pelvis, spoon-shaped depressions or actual fractures of the skull may result. The spinal cord may be injured or vertebra fractured if great force is employed (Vialle, 2007). Hematomas of the sternocleidomastoid muscles occasionally develop after delivery, although they usually disappear spontaneously. Last, testicular injury may follow breech delivery (Mathews, 1999). These are discussed in further detail in Chapter 33 (p. 645).

Compared with cephalic presentation, umbilical cord prolapse is more frequent with breech fetuses. Huang and coworkers (2012) analyzed 40 cases of prolapse and reported that half were associated with malpresentation or vaginal delivery of a second twin.

Some perinatal outcomes may be inherent to the breech position rather than delivery. For example, development of hip dysplasia is more common in breech compared with cephalic presentation and is unaffected by delivery mode (de Hundt, 2012; Fox, 2010; Ortiz-Neira, 2012).

Imaging Techniques

In many fetuses—especially those that are preterm—the breech is smaller than the aftercoming head. Moreover, unlike cephalic presentations, the head of a breech-presenting fetus does not undergo appreciable molding during labor. Thus, to avoid head entrapment following delivery of the breech, pelvic dimensions should be assessed before vaginal delivery. In addition, fetal size, type of breech, and degree of neck flexion or extension should be identified. To evaluate these, several imaging techniques can be used.

Sonography

In most cases, sonographic fetal evaluation will have been performed as part of prenatal care. If not, gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly

ascertained with sonography. This will identify many fetuses not suitable for vaginal delivery and will help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous fetus with no chance of survival.

Head flexion can usually also be determined sonographically, and for vaginal delivery, the fetal head should not be extended (Fontenot, 1997; Rojansky, 1994). If imaging is uncertain, then simple two-view radiography of the abdomen is useful to define head inclination. The sonographic accuracy of fetal weight estimation does not appear limited by breech presentation (McNamara, 2012). Although variable, many protocols use fetal weights < 2500 g and > 3800 to 4000 g or evidence of growth restriction as exclusion criteria for planned vaginal delivery (Azria, 2012; Kotaska, 2009). Similarly, a biparietal diameter (BPD) > 90 to 100 mm is often considered exclusionary (Giuliani, 2002; Roman, 2008).

Pelvimetry

This assessment of the bony pelvis before vaginal delivery may be completed with one-view computed tomography (CT), magnetic resonance imaging, or plain film radiographs. Although there are no comparative data among these modalities for pelvimetry, computed tomography is favored due to its accuracy, low radiation dose, and widespread availability (Thomas, 1998). At Parkland Hospital, we use CT pelvimetry when possible to assess the critical dimensions of the pelvis (Chap. 2, p. 32). Although variable, some suggest specific measurements to permit a planned vaginal delivery: inlet anteroposterior diameter ≥ 105 mm; inlet transverse diameter ≥ 120 mm; and midpelvic interspinous diameter ≥ 100 mm (Azria, 2012; Vendittelli, 2006). Others use maternal-fetal biometry correlation. Appropriate values include: the sum of the inlet obstetrical conjugate minus the fetal BPD is ≥ 15 mm; the inlet transverse diameter minus the BPD is ≥ 25 mm; and the midpelvis interspinous diameter minus the BPD is ≥ 0 mm (Michel, 2011).

Decision-Making Summary

As outlined by the American College of Obstetricians and Gynecologists (2012b), risks versus benefits are weighed and discussed with the patient. If possible, this is preferably done before admission. A diligent search is made for any other complications, actual or anticipated, that might warrant cesarean delivery. Common circumstances are listed in Table 28-1. For a favorable outcome with any breech delivery, at the very minimum, the birth canal must be sufficiently large to allow passage of the fetus without trauma. The cervix must be fully dilated, and if not, then a cesarean delivery nearly always is the more appropriate method of delivery if suspected fetal compromise develops.

MANAGEMENT OF LABOR AND DELIVERY

Methods of Vaginal Delivery

There are important fundamental differences between labor and delivery in cephalic and breech presentations. With a cephalic presentation, once the head is delivered, the rest of the

TABLE 28-1. Factors Favoring Cesarean Delivery of the Breech Fetus

Lack of operator experience
Patient request for cesarean delivery
Large fetus: > 3800 to 4000 g
Apparently healthy and viable preterm fetus either with active labor or with indicated delivery
Severe fetal-growth restriction
Fetal anomaly incompatible with vaginal delivery
Prior perinatal death or neonatal birth trauma
Incomplete or footling breech presentation
Hyperextended head
Pelvic contraction or unfavorable pelvic shape determined clinically or with pelvimetry
Prior cesarean delivery

body typically follows without difficulty. With a breech, however, successively larger and less compressible parts are born. Spontaneous complete expulsion of the fetus that presents as a breech, as subsequently described, is seldom accomplished successfully. Therefore, as a rule, vaginal delivery requires skilled participation for a favorable outcome.

There are three general methods of breech delivery through the vagina:

- 1. Spontaneous breech delivery. The fetus is expelled entirely spontaneously without any traction or manipulation other than support of the newborn.
- 2. Partial breech extraction. The fetus is delivered spontaneously as far as the umbilicus, but the remainder of the body is extracted or delivered with operator traction and assisted maneuvers, with or without maternal expulsive efforts.
- 3. Total breech extraction. The entire body of the fetus is extracted by the obstetrician.

Labor Induction and Augmentation

Induction or augmentation of labor in women with a breech presentation is controversial, and data are limited. Marzouk and associates (2011) found similar perinatal neonatal outcomes with spontaneous labor or with cervical preparation and induced labor. In many studies, improved rates of successful vaginal delivery and neonatal outcome are associated with orderly labor progression. Thus, some protocols avoid augmentation, whereas others recommend it only for hypotonic contractions (Alarab, 2004; Kotaska, 2009). In women with a viable fetus, at Parkland Hospital, we attempt amniotomy induction but prefer cesarean delivery instead of oxytocin induction or augmentation.

Management of Labor

On arrival, rapid assessment should be made to establish the status of the membranes, labor, and fetal condition. Surveillance of fetal heart rate and uterine contractions begins at admission, and immediate recruitment of necessary staff should include:

(1) an obstetrician skilled in the art of breech extraction, (2) an associate to assist with the delivery, (3) anesthesia personnel who can ensure adequate analgesia or anesthesia when needed, and (4) an individual trained in newborn resuscitation.

For the mother, an intravenous catheter is inserted, and crystalloid infusion begun. Emergency induction of anesthesia or maternal resuscitation following hemorrhage from lacerations or from uterine atony are but two of many reasons that may require immediate intravenous access.

Assessment of cervical dilatation and effacement and the station of the presenting part is essential for planning the route of delivery. If labor is too far advanced, there may not be sufficient time to obtain pelvimetry. This alone, however, should not force the decision for cesarean delivery. Commonly, satisfactory progress in labor is the best indicator of pelvic adequacy (Biswas, 1993; Nwosu, 1993). Sonographic fetal biometry and assessment of head flexion are completed. And if not performed as part of earlier prenatal care, fetal anatomy is evaluated. Ultimately, the choice of abdominal or vaginal delivery is based on factors discussed earlier and listed in Table 28-1.

For managing labor and delivery of a breech fetus, additional help is required. One-on-one nursing is ideal during labor because of the risk of cord prolapse or occlusion, and physicians must be readily available for such emergencies. Guidelines for monitoring the high-risk fetus are applied as discussed in Chapter 24 (p. 497). During the first stage of labor, the fetal heart rate is recorded at least every 15 minutes. Most clinicians prefer continuous electronic monitoring. If a nonreassuring fetal heart rate pattern develops, then a decision must be made regarding the necessity of cesarean delivery.

When membranes are ruptured, either spontaneously or artificially, the cord prolapse risk is appreciable and is increased when the fetus is small or when the breech is not frank (Dilbaz, 2006; Erdemoglu, 2010). Therefore, a vaginal examination should be performed following rupture to exclude prolapse, and special attention should be directed to the fetal heart rate for the first 5 to 10 minutes following membrane rupture.

■ Cardinal Movements with Breech Delivery

Engagement and descent of the breech usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet. If the posterior extremity is prolapsed, however, it, rather than the anterior hip, rotates to the symphysis pubis.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the fetal buttocks, thus allowing the infant to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or require aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought

into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed on the thorax, enters the pelvis in one of the oblique diameters and then rotates in such a manner as to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

The breech may engage in the transverse diameter of the pelvis, with the sacrum directed anteriorly or posteriorly. The mechanism of labor in the transverse position differs only in that internal rotation is through an arc of 90 rather than 45 degrees. Infrequently, rotation occurs in such a manner that the back of the fetus is directed posteriorly instead of anteriorly. Such rotation should be prevented if possible. Although the head may be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head, which increases the diameter of the head that must pass through the pelvis.

■ Partial Breech Extraction

With all breech deliveries, unless there is considerable relaxation of the perineum, an episiotomy should be made and is an important adjunct to delivery. Ideally, the breech is allowed to deliver spontaneously to the umbilicus. Delivery is easier, and in turn, morbidity and mortality rates are, at least intuitively, lower. Delivery of the breech draws the umbilicus and attached cord into the pelvis, which stretches and compresses the cord. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly either spontaneously or assisted, as described here.

The posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium (Fig. 28-5). The anterior hip then delivers, followed by external rotation to a sacrum anterior position. The mother should be encouraged to continue to push.

FIGURE 28-5 The hips of the frank breech are delivering over the perineum. The anterior hip usually is delivered first.

FIGURE 28-6 Delivery of the body. The hands are applied, but not above the pelvic girdle. With thumbs over the sacrum, gentle downward traction is accomplished until the scapulas are clearly visible.

As the fetus continues to descend, the legs are sequentially delivered by splinting the medial aspect of each femur with the operator's fingers positioned parallel to each femur, and by exerting pressure laterally to sweep each leg away from the midline.

Following delivery of the legs, the fetal bony pelvis is grasped with both hands, using a cloth towel moistened with warm water. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum, minimizing the chance of fetal abdominal soft tissue injury (Fig. 28-6). Maternal expulsive efforts are used in conjunction with downward traction to effect delivery.

A cardinal rule in successful breech extraction is to employ steady, gentle, downward traction until the lower halves of the scapulas are delivered, making no attempt at delivery of the shoulders and arms until one axilla becomes visible. As the scapulas become visible, the fetal back tends to turn spontaneously toward the side of the mother to which it was originally directed. The appearance of one axilla indicates that the time has arrived for shoulder delivery. It makes little difference which shoulder is delivered first, and there are two methods for their delivery. In the first method, with the scapulas visible, the trunk is rotated in such a way that the anterior shoulder and arm appear at the vulva and can easily be released and delivered first (Fig. 28-7). The body of the fetus is then rotated 180 degrees in the reverse direction to deliver the other shoulder and arm (Fig. 28-8).

The second method is employed if trunk rotation is unsuccessful. With this maneuver, the posterior shoulder is delivered first. For this, the feet are grasped in one hand and drawn upward over the inner thigh of the mother, toward which the ventral surface of the fetus is directed (Fig. 28-9). In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand. Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously.

These rotational and downward traction maneuvers will decrease the persistence of nuchal arms, which can prevent descent and may result in a traumatic delivery. These maneuvers are frequently most easily effected with the operator at the level of the maternal pelvis and with one knee on the floor.

After both shoulders are delivered, the back of the fetus tends to rotate spontaneously in the direction of the symphysis. If upward rotation fails to occur, it is completed by manual rotation of the body. Delivery of the head may then be accomplished.

Unfortunately, the process is not always so simple, and it is sometimes necessary to assist delivery of the arms. There is more space available in the posterior and lateral segments of the normal pelvis than elsewhere. Therefore, in difficult cases, the posterior arm should be freed first. Because the corresponding axilla is already visible, upward traction on the feet is continued, and two fingers of the other hand are passed along the humerus until the elbow is reached (see Fig. 28-9). The fingers are placed parallel to the humerus and used to splint the arm, which is swept downward and delivered through the vulva. To deliver the anterior arm, depression of the fetal body is sometimes all that is required to allow the anterior arm to slip out spontaneously. In other instances, the anterior arm can be swept down over the thorax using two of the operator's fingers as a splint.

In some cases, the body must be held with the thumbs over the scapulas and rotated to bring the undelivered shoulder near the closest sacrosciatic notch. The legs then are carried upward to bring the ventral surface of the fetus to the opposite inner thigh of the mother. Subsequently, the arm can be delivered posteriorly as described previously. If the arms have become extended over the head, their delivery, although more difficult, usually can be accomplished by the maneuvers just described. In so doing, particular care must be taken by the operator to carry his or her fingers up to the elbow and to use them as a splint to prevent fracture of the fetal humerus.

Nuchal Arm

As just mentioned, one or both fetal arms occasionally may be found around the back of the neck—the nuchal arm—and impacted at the pelvic inlet. In this situation, delivery is more difficult. If the nuchal arm cannot be freed in the manner just described, extraction may be aided, especially with a single nuchal arm, by rotating the fetus through a half circle in such a direction that the friction exerted by the birth canal will serve to draw the elbow toward the face (Fig. 28-10). Should rotation of the fetus fail to free the nuchal arm(s), it may be necessary to push the fetus upward in an attempt to release it. If the rotation is still unsuccessful, the nuchal arm often is extracted by hooking a finger(s) over it and forcing the arm over the shoulder, and down the ventral surface for delivery of the arm. In this event, fracture of the humerus or clavicle is common.

Modified Prague Maneuver

Rarely, the back of the fetus fails to rotate to the anterior. In this situation, rotation of the back to the anterior may be achieved

FIGURE 28-7 Clockwise rotation of the fetal pelvis and abdomen 90 degrees brings the sacrum from anterior to left sacrum transverse (LST). Simultaneously, the application of gentle downward traction effects delivery of the scapula (**A**) and arm (**B-D**).

by using stronger traction on the fetal legs or bony pelvis. If the back still remains oriented posteriorly, extraction may be accomplished using the Mauriceau maneuver, described next, and delivering the fetus back down. If this is impossible, the fetus still may be delivered using the modified Prague maneuver, which, as practiced today, consists of two fingers of one hand grasping the shoulders of the back-down fetus from below

while the other hand draws the feet up and over the maternal abdomen (**Fig. 28-11**).

Delivery of the Aftercoming Head

Mauriceau Maneuver. Normally, the fetal head may be extracted with forceps or by one of several maneuvers. With the Mauriceau maneuver, the index and middle finger of one hand

FIGURE 28-8 Counterclockwise rotation from right sacrum anterior (RSA) to right sacrum transverse (RST) along with gentle downward traction effects delivery of the right scapula.

are applied over the maxilla, to flex the head, while the fetal body rests on the palm of the hand and forearm (Fig. 28-12). The operator's forearm is straddled by the fetal legs. Two fingers of the other hand then are hooked over the fetal neck,

FIGURE 28-9 As breech extraction continues, upward traction is employed with the fetus drawn to the mother's left inner thigh, thus effecting delivery of the posterior shoulder. This is followed by delivery of the posterior arm. The fetal body is then depressed and delivery of the anterior shoulder follows.

FIGURE 28-10 Reduction of nuchal arm being accomplished by rotating the fetus through half a circle counterclockwise so that the friction exerted by the birth canal will draw the elbow toward the face.

and grasping the shoulders, downward traction is concurrently applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body then is elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the

FIGURE 28-11 Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

FIGURE 28-12 A. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant. **B.** Pressure on the maxilla is applied simultaneously by the operator as upward and outward traction is exerted.

perineum. With this maneuver, the operator uses both hands simultaneously and in tandem to exert continuous downward gentle traction simultaneously on the fetal neck and on the maxilla. At the same time, appropriate suprapubic pressure is applied by an assistant (see Fig. 28-12).

Forceps to Aftercoming Head. Specialized forceps can also be used to deliver the aftercoming head. Piper forceps, shown in Figure 28-13, or divergent Laufe forceps may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps should not be applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus up and helps keep the arms and cord out of the way as the forceps blades are applied.

Because the forceps blades are directed upward from the level of the perineum, some choose to apply them from a one-knee kneeling position. Piper forceps have a downward arch in the shank to accommodate the fetal body and lack a pelvic curve. This shape permits a direct application of the cephalic curve of the blade along the length of the maternal vagina and fetal parietal bone. The blade to be placed on the maternal left is held in the operator's left hand. The right hand slides between the fetal head and left maternal vaginal sidewall to guide the blade inward and around the parietal bone. The opposite blade mirrors this application. Once in place, the blades are articulated, and the fetal body rests across the shanks. The head is delivered by pulling gently outward and raising the handle simultaneously. This rolls the face over the perineum, while the occiput remains beneath the symphysis until after the brow delivers. Ideally, the head and body move in unison to minimize trauma.

Entrapment of the Aftercoming Head. Occasionally—especially with a small preterm fetus—the incompletely dilated cervix will constrict around the neck and impede delivery of the aftercoming head. At this point, it must be assumed that there is significant and even total cord compression, and thus time management is essential. With gentle traction on the fetal body, the cervix, at times, may be manually slipped over the occiput. If this is not successful, then Dührssen incisions as shown in Figure 28-14 may be necessary. Other alternatives include intravenous nitroglycerin—typically 100 µg—to provide cervical relaxation (Dufour, 1997; Wessen, 1995). There is, however, no compelling evidence of its efficacy for this purpose. General anesthesia with halogenated agents is another option.

As a last resort, replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can be used to rescue an entrapped breech fetus that cannot be delivered vaginally. This maneuver was described for the protruding head with intractable shoulder dystocia and is termed the *Zavanelli maneuver* as described by Sandberg (1988). It was subsequently reported by Steyn and Pieper (1994) to be used to deliver the entrapped aftercoming head in a 2590-g breech fetus. Sandberg (1999) reviewed 11 breech deliveries in which this maneuver was used.

Symphysiotomy is also used to aid delivery of an entrapped aftercoming head. Using local analgesic, this operation surgically divides the intervening symphyseal cartilage and much of its ligamentous support to widen the symphysis pubis up to 2.5 cm (Basak, 2011). Lack of operator training and potentially serious maternal pelvic or urinary tract injury explain its rare use in the United States. That said, if cesarean section is not available or unsafe for the mother, symphysiotomy may be lifesaving for both mother and baby (Hofmeyr, 2012).

Total Breech Extraction

Complete or Incomplete Breech

At times, total extraction of a complete or incomplete breech may be required. A hand is introduced through the vagina, and both fetal feet are grasped. The ankles are held with the second finger lying between them. With gentle traction, the feet are brought through the introitus. If difficulty is experienced in grasping both feet, first one foot should be drawn into the vagina but not through the introitus, and then the other foot is advanced in a similar fashion. Now both feet are grasped and pulled through the vulva simultaneously (Fig. 28-15).

FIGURE 28-13 Piper forceps for delivery of the aftercoming head. **A.** The fetal body is held elevated using a warm towel and the left blade of forceps is applied to the aftercoming head. **B.** The right blade is applied with the body still elevated. **C.** Forceps delivery of the aftercoming head. Note the direction of movement shown by the arrow.

As the legs begin to emerge through the vulva, downward gentle traction is continued. As the legs emerge, successively higher portions are grasped, first the calves and then the thighs. When the breech appears at the vaginal outlet, gentle traction is applied until the hips are delivered. As the buttocks emerge, the back of the fetus usually rotates to the anterior. The thumbs are then placed over the sacrum and the fingers over the hips, and breech extraction is completed, as described for partial breech extraction (p. 564). During cesarean delivery, these maneuvers are also used during delivery of a complete, incomplete, or foaling breech through the hysterotomy incision.

Frank Breech

During complete extraction of a frank breech, moderate traction is exerted by a finger in each groin and aided by a generous episiotomy (Fig. 28-16). Once the breech is pulled through the introitus, the steps described for partial breech extraction are then completed (p. 564). These maneuvers are also used during cesarean delivery of the frank breech through the hysterotomy incision.

If moderate traction does not effect delivery, then vaginal delivery can be accomplished only by breech decomposition. This procedure involves manipulation within the birth canal

FIGURE 28-14 Dührssen incision being cut at 2 o'clock, which is followed by a second incision at 10 o'clock. Infrequently, an additional incision is required at 6 o'clock. The incisions are so placed as to minimize bleeding from the laterally located cervical branches of the uterine artery. After delivery, the incisions are repaired as described in Chapter 41 (p. 790).

to convert the frank breech into a footling breech. It is accomplished more readily if the membranes have ruptured only recently, and it becomes extremely difficult if there is minimal amniotic fluid. In such cases, the uterus may have become tightly contracted around the fetus. Pharmacological relaxation by general anesthesia, intravenous magnesium sulfate, or a beta-mimetic agent such as terbutaline, 250 µg subcutaneously, may be required.

FIGURE 28-15 Complete breech extraction begins with traction on the feet and ankles.

A

B

FIGURE 28-16 **A.** Extraction of frank breech using fingers in groins. **B.** Once the hips are delivered, each hip and knee is flexed to deliver them from the vagina.

Breech decomposition is accomplished by the maneuver attributed to Pinard (1889). It aids in bringing the fetal feet within reach of the operator. As shown in [Figure 28-17](#), two fingers are carried up along one extremity to the knee to push it away from the midline. Spontaneous flexion usually follows,

FIGURE 28-17 Frank breech decomposition using the Pinard maneuver. Two fingers are inserted along one extremity to the knee, which is then pushed away from the midline after spontaneous flexion. Traction is used to deliver a foot into the vagina.

and the foot of the fetus is felt to impinge on the back of the hand. The fetal foot then may be grasped and brought down.

ANALGESIA AND ANESTHESIA

Continuous epidural analgesia, as described in Chapter 25 (p. 509), is advocated by some as ideal for women in labor with a breech presentation. This may increase the need for labor augmentation and may prolong second-stage labor (Chadha, 1992; Confino, 1985). These potential disadvantages must be weighed against the advantages of better pain relief and increased pelvic relaxation should extensive manipulation be required. Analgesia must be sufficient for episiotomy, for breech extraction, and for Piper forceps application. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it must be induced quickly.

Anesthesia for breech decomposition and extraction must provide sufficient relaxation to allow intrauterine manipulations. Although successful decomposition has been accomplished using epidural or spinal analgesia, increased uterine tone may render the operation more difficult. Under such conditions, general anesthesia with a halogenated agent may be required.

VERSION

With this procedure, fetal presentation is altered by physical manipulation, either substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. According to whether the head or breech is made the presenting part, the operation is designated cephalic or podalic version, respectively. With external version, the manipulations are performed exclusively through the abdominal wall. With internal version, they are accomplished inside the uterine cavity.

External Cephalic Version

For breech fetuses near term, the American College of Obstetricians and Gynecologists (2012a,b) recommends that version should be offered and attempted whenever possible. Its success rate ranges from 35 to 86 percent, with an average of 58 percent. For women with a transverse lie, the overall success rate is significantly higher.

Indications

In general, external version is attempted before labor in a woman who has reached 36 weeks' gestation with a breech fetus. Before this time, a breech presentation still has a high likelihood of correcting spontaneously. And, if performed too early, time may allow a return back to breech (Bogner, 2012). Last, if version causes a need for immediate delivery, complications of iatrogenic preterm delivery generally are not severe.

Version is contraindicated if vaginal delivery is not an option. Examples include placenta previa or nonreassuring fetal status. Other contraindications include rupture of membranes, known uterine malformation, multifetal gestation, and recent uterine bleeding. As discussed in Chapter 31 (p. 616), prior

uterine incision is a relative contraindication. In a few small studies, external version was not associated with uterine rupture (Abenheim, 2009; Sela, 2009). At Parkland Hospital, external version is not attempted in these women, but larger studies are needed.

Several factors can improve the chances of a successful version attempt. These include multiparity, abundant amniotic fluid, unengaged presenting part, fetal size 2500 to 3000 g, posterior placenta, and nonobese patient (Buhimschi, 2011; de Hundt, 2012; Kok, 2008, 2009, 2011).

Complications

Patient counseling includes projected success rates, conversion back to breech, and risks of the procedure itself. Risks include placental abruption, uterine rupture, fetomaternal hemorrhage, alloimmunization, preterm labor, fetal compromise, and even death. Most worrisome is the report by Stine and coworkers (1985) of a maternal death due to amniotic fluid embolism. That said, fetal deaths are rare, serious complication rates are typically very low, and emergent cesarean rates are 0.5 percent or less (Collaris, 2004; Collins, 2007; Grootsholten, 2008).

Importantly, even after successful version, several reports suggest that the cesarean delivery rate does not completely revert to the baseline for vertex presentations. Specifically, dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common in these fetuses despite successful version (Chan, 2004; Vézina, 2004).

Technique

External cephalic version should be carried out in an area that has ready access to a facility equipped to perform an emergency cesarean delivery (American College of Obstetricians and Gynecologists, 2012a). Sonographic examination is performed to confirm nonvertex presentation, document amniotic fluid volume adequacy, exclude obvious fetal anomalies if not done previously, and identify placental location. External monitoring is performed to assess fetal heart rate reactivity. Anti-D immune globulin is given to Rh-D negative women.

A forward roll of the fetus usually is attempted first. Each hand grasps one fetal pole, and the fetal buttocks are elevated from the maternal pelvis and displaced laterally (Fig. 28-18). The buttocks are then gently guided toward the fundus, while the head is directed toward the pelvis. If the forward roll is unsuccessful, then a backward flip is attempted. Version attempts are discontinued for excessive discomfort, persistently abnormal fetal heart rate, or after multiple failed attempts. Failure is not always absolute. Ben-Meir and colleagues (2007) reported a spontaneous version rate of 7 percent among 226 failed versions—2 percent among nulliparas and 13 percent among parous women.

If version is successful, the nonstress test is repeated until a normal test result is obtained. If version is completed before 39 weeks' gestation, then awaiting spontaneous labor and fetal maturity is preferred.

Tocolysis

Existing evidence may support the use of tocolytic agents during external version attempts (American College of Obstetricians

FIGURE 28-18 External cephalic version. With an attempted forward roll, clockwise pressure is exerted against the fetal poles.

and Gynecologists, 2012a). Agents investigated include betamimetics, such as terbutaline, ritodrine, or salbutamol; calcium-channel blockers, such as nifedipine; and nitric oxide donors, such as nitroglycerin. Most randomized investigations have evaluated betamimetics. In one such trial, Fernandez and coworkers (1996) reported that the success rate with subcutaneous terbutaline—52 percent—was significantly higher than without—27 percent. Other studies of betamimetics support their efficacy, although not universally (Marquette, 1996; Robertson, 1987; Vani, 2009). There is less evidence to support the use of nifedipine and nitroglycerin (Cluver, 2012; Wilcox, 2011). Our policy at Parkland Hospital is to administer 250 µg of terbutaline subcutaneously to most women before attempted version. When maternal tachycardia—a known side effect of terbutaline—is noted, then the version attempt is begun.

Conduction Analgesia

Epidural analgesia has been reported to increase version success rates (Mancuso, 2000; Schorr, 1997). But Sullivan and associates (2009) noted no improvement with combined spinal-epidural analgesia. In two small randomized trials, Weiniger and associates (2007, 2010) reported that spinal analgesia increased version success rate. In the trials by Dugoff (1999) and Delisle (2003) and their colleagues, spinal analgesia was not of benefit. According to the American College of Obstetricians and Gynecologists (2012a), there is not enough consistent evidence to recommend conduction analgesia routinely for external version.

With the exception of rare severe complications, Collaris and Oei (2004) concluded that external cephalic version is safe. One caveat was that complications were more common

when conduction analgesia was used. Use of nitrous oxide or conduction analgesia was associated with twice as many abnormal fetal heart rate tracings. Moreover, vaginal bleeding and procedure-related emergency cesarean deliveries were increased tenfold. These reviewers concluded that diminished pain in these women likely encouraged overzealous application of force during the version attempts. In another small study, however, Suen and associates (2012) showed that the force applied during version under spinal analgesia was actually less.

Other Methods

There are some unconventional interventions that have been used to help effect version. Moxibustion is a traditional Chinese medicine technique that burns a cigarette-shaped stick of ground *Artemisia vulgaris*—which is also known as mugwort or in Japanese as *moxa*. At the BL 67 acupuncture point, the stick is directly placed against the skin or indirectly heats an acupuncture needle at the site to increase fetal movement and promote spontaneous breech version. It is performed usually between 33 and 36 weeks' gestation to permit a trial of external cephalic version if not successful. Results from randomized controlled studies are conflicting. However, a Cochrane Database review found some evidence to support moxibustion use when combined with acupuncture (Cardini, 1998, 2005; Coyle, 2012; Guittier, 2009; Neri, 2004).

Internal Podalic Version

This maneuver is used only for delivery of a second twin. With the membranes preferably still intact, a hand is inserted into the uterine cavity to turn the fetus manually. The operator seizes one or both feet and draws them through the fully dilated cervix, while using the other hand transabdominally to push the upper portion of the fetal body in the opposite direction as shown in Chapter 45 (p. 918). This is then followed by breech extraction.

CHAPTER 29

Operative Vaginal Delivery

INDICATIONS 574

CLASSIFICATION AND PREREQUISITES 574

MATERNAL MORBIDITY 575

PERINATAL MORBIDITY 576

TRIAL OF OPERATIVE VAGINAL DELIVERY 577

TRAINING 577

FORCEPS DELIVERY 578

VACUUM EXTRACTION 583

Operative deliveries are vaginal deliveries accomplished with the use of a vacuum device or forceps. Once either is applied to the fetal head, outward traction generates forces that augment maternal pushing to deliver the fetus vaginally. The most important function of both devices is traction. In addition, however, forceps may also be used for rotation, particularly from occiput transverse and posterior positions.

The precise frequency of operative vaginal delivery in the United States is unknown. According to the birth certificate data from the National Vital Statistics Report, forceps- or vacuum-assisted vaginal delivery was used for 3.6 percent of births in the United States in 2010. According to Yeomans (2010), the vacuum-to-forceps delivery ratio is 4:1. [Figure 29-1](#) depicts the decline in the rates of this type of delivery since 1990. In general, operative vaginal delivery attempts are successful. In the United States in 2006, only 0.4 percent of forceps trials and 0.8 percent of vacuum extraction attempts failed to result in vaginal delivery (Osterman, 2009).

INDICATIONS

If it is technically feasible and can be safely accomplished, termination of second-stage labor by operative vaginal delivery is

indicated in any condition threatening the mother or fetus that is likely to be relieved by delivery. Some fetal indications for operative vaginal delivery include nonreassuring fetal heart rate pattern and premature placental separation. In the past, forceps delivery was believed to be somewhat protective of the fragile preterm infant head. Subsequent studies, however, reported no significant differences in outcomes for neonates who weighed 500 to 1500 g between those delivered spontaneously and those delivered by outlet forceps (Fairweather, 1981; Schwartz, 1983).

Some maternal indications include heart disease, pulmonary injury or compromise, intrapartum infection, and certain neurological conditions. The most common are exhaustion and prolonged second-stage labor. For nulliparas, the latter is defined as > 3 hours with or > 2 hours without regional analgesia (American College of Obstetricians and Gynecologists, 2012). In parous women, it is defined as > 2 hours with and > 1 hour without regional analgesia.

Operative vaginal delivery should generally be performed from either a low or outlet station. Additionally, forceps or vacuum delivery generally should not be used *electively* until the criteria for an outlet delivery have been met. In these circumstances, operative vaginal delivery is a simple and safe operation, although with some risk of maternal lower reproductive tract injury (Yancey, 1991). Moreover, there is no evidence that use of prophylactic operative delivery is beneficial in the otherwise normal delivery.

CLASSIFICATION AND PREREQUISITES

The American College of Obstetricians and Gynecologists (2012) classifies operative vaginal deliveries as summarized in [Table 29-1](#). It emphasizes that the two most important discriminators of risk for both mother and infant are station and rotation. Station is measured in centimeters, -5 to 0 to +5. Zero station reflects a line drawn between the

FIGURE 29-1 Decline in operative vaginal delivery rates, 1990–2010. (From Martin, 2012.)

ischial spines. Deliveries are categorized as outlet, low, and midpelvic procedures. High forceps, in which instruments are applied above 0 station, have no place in contemporary obstetrics.

TABLE 29-1. Operative Vaginal Delivery Prerequisites and Classification According to Station and Rotation^a

Procedure	Criteria
Outlet forceps	<ul style="list-style-type: none"> Scalp is visible at the introitus without separating the labia Fetal skull has reached pelvic floor Fetal head is at or on perineum Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position, and Rotation does not exceed 45 degrees
Low forceps (2 types)	Leading point of fetal skull is at station $\geq +2$ cm, and not on the pelvic floor, and: <ol style="list-style-type: none"> Rotation is 45 degrees or less, <i>or</i> Rotation is greater than 45 degrees
Midforceps	Station is between 0 and +2 cm
High	Not included in classification
Prerequisites	
Experienced operator Engaged head Ruptured membranes Vertex presentation ^b Completely dilated cervix Precisely assessed fetal head position Cephalopelvic disproportion not suspected No fetal coagulopathy or bone demineralization disorder	

^aClassification for the vacuum delivery system is the same as for forceps except that vacuum is used for traction but not rotation.

^bForceps, but not vacuum extractor, may be used for delivery of a face presentation with mentum anterior.

Once station and rotation are assessed, there are several prerequisites for operative vaginal delivery (see Table 29-1). In addition and specific to vacuum extraction, fetuses should be at least 34 weeks gestational age, and although infrequently used in the United States, fetal scalp blood sampling should not have been recently performed.

Regional analgesia or general anesthesia is preferable for low forceps or midpelvic procedures, although pudendal blockade may prove adequate for outlet forceps. Before operative vaginal delivery, the bladder should also be emptied to provide additional pelvic space and minimize bladder trauma.

MORBIDITY

In general, a higher station and/or greater degrees of rotation increase the chance of maternal or fetal injury. In the discussion of operative vaginal delivery, morbidity is most properly compared with morbidity from cesarean delivery, and not with that from spontaneous vaginal delivery. This is because the alternative to indicated operative vaginal delivery is cesarean delivery. As examples, postpartum uterine infection and pelvic cellulitis are more frequent, and often more severe, in women following cesarean delivery compared with that following operative vaginal delivery (Robertson, 1990). Moreover, in a study of more than 1 million births, Spiliopoulos and associates (2011) reported cesarean delivery, but not operative vaginal delivery, as a risk for peripartum hysterectomy.

Maternal Morbidity

Lacerations

The very conditions that lead to indications for operative vaginal delivery also increase the need for episiotomy and the likelihood of lacerations (de Leeuw, 2008). That said, operative vaginal delivery is associated with higher rates of third- and fourth-degree lacerations as well as vaginal wall and cervical lacerations (Hamilton, 2011; Hirayama, 2012; Landy, 2011). These appear to occur more frequently with forceps compared with vacuum extraction, and especially if there is a midline episiotomy (Kudish, 2006; O'Mahony, 2010). Hagadorn-Freathy and coworkers (1991) reported a 13-percent rate of third- and fourth-degree episiotomy extensions and vaginal lacerations for outlet forceps, 22 percent for low forceps with less than 45-degree rotation, 44 percent for low forceps with more than 45-degree rotation, and 37 percent for midforceps deliveries.

In an effort to lower rates of third- and fourth-degree lacerations, and coincident with overall efforts to reduce routine episiotomy use, many advocate only indicated episiotomy with operative vaginal delivery. For example, Ecker and colleagues (1997) reported a significant decrease in the episiotomy rate with both forceps—96 to 30 percent—as well as vacuum—89 to 39 percent—deliveries from 1984 to 1994. During this time, there was a decrease in fourth-degree but no change in third-degree lacerations. If episiotomy is required, several studies have reported a protective effect from mediolateral episiotomy against these more extensive perineal lacerations (de Leeuw, 2008; de Vogel, 2012; Hirsch, 2008). But as discussed

in Chapter 27 (p. 551), this is balanced against the additional potential morbidity compared with a midline episiotomy. Early disarticulation of forceps and cessation of maternal pushing during disarticulation can also be protective. Last, these injuries are more common with operative vaginal delivery from an occiput posterior position (Damron, 2004). Thus, manual or forceps rotation from occiput posterior to occiput anterior position and then subsequent operative vaginal delivery may decrease lower-reproductive-tract injury.

Pelvic Floor Disorders

This term encompasses urinary incontinence, anal incontinence, and pelvic organ prolapse. Operative vaginal delivery has been suggested as a possible risk for each of these. Proposed mechanisms include structural compromise and/or pelvic floor denervation secondary to forces exerted during delivery.

Urinary retention and bladder dysfunction are often short-term effects of forceps and vacuum deliveries (Mulder, 2012). Importantly, episiotomy and epidural analgesia, both common associates of operative vaginal delivery, are also identified risks for urinary retention. Symptoms are brief and typically resolve with 24 to 48 hours of passive catheter bladder drainage.

Regarding more sustained urinary dysfunction, parity and specifically vaginal delivery are known risk factors for urinary incontinence (Gyhagen, 2013; Rortveit, 2003). And, a few studies show a greater attributable risk with operative vaginal delivery (Baydock, 2009; Handa, 2011). But, many studies do not support an increased risk compared with vaginal delivery alone (Handa, 2012; Leijonhufvud, 2011; MacArthur, 2006; Thom, 2011).

Evidence linking anal incontinence with operative vaginal delivery is conflicting. Some studies show that anal sphincter disruption caused by higher-order episiotomy, but not delivery mode, is the main etiological factor strongly associated with anal incontinence (Baud, 2011; Bols, 2010; Evers, 2012; Nygaard, 1997). In contrast, others directly link operative vaginal delivery with this complication (MacArthur, 2005; Pretlove, 2008). But, these studies may not be incongruous as operative vaginal delivery, as previously discussed, is associated with increased rates of higher-order episiotomy. Importantly, several studies and reviews have not found cesarean delivery to be protective for anal incontinence (Nelson, 2010).

Last, evidence linking pelvic organ prolapse with operative vaginal delivery also shows mixed results (Gyhagen, 2013; Handa, 2011). Interestingly, Glazener and associates (2013) evaluated women 12 years after delivery by means of a symptom questionnaire and physical examination. Complaints of prolapse *symptoms* were linked to operative vaginal delivery, but true *objective measurement of prolapse* showed a protective effect from this delivery mode compared with vaginal delivery alone.

Perinatal Morbidity

Acute Perinatal Injuries

These are more frequent with operative vaginal deliveries than with cesarean delivery or spontaneous vaginal delivery alone. Although these may be seen with either method, they are more commonly seen with vacuum extraction. Some injuries

include cephalohematoma, subgaleal hemorrhage, retinal hemorrhage, neonatal jaundice secondary to these hemorrhages, shoulder dystocia, clavicular fracture, and scalp lacerations. Cephalohematoma and subgaleal hemorrhage are both extracranial lesions described in Chapter 33 (p. 646).

In 1998, the Food and Drug Administration issued a Public Health Advisory regarding the possible association of vacuum-assisted delivery with serious fetal complications, including death. In response, the American College of Obstetricians and Gynecologists (1998) issued a Committee Opinion recommending the continued use of vacuum-assisted delivery devices when appropriate. At that time, they estimated that there was approximately one adverse event per 45,455 vacuum extractions per year.

In contrast, forceps-assisted vaginal delivery has higher rates of facial nerve injury, brachial plexus injury, depressed skull fracture, and corneal abrasion (Demissie, 2004; Dupuis, 2005; American College of Obstetricians and Gynecologists, 2012). And while some studies have associated vacuum extraction with higher rates of intracranial hemorrhage, others show similar rates with either of the two methods (Towner, 1999; Wen, 2001; Werner, 2011).

As a group, if operative vaginal delivery is compared with cesarean delivery, rates of extracranial hematoma, skull fracture, facial nerve or brachial plexus injury, retinal hemorrhage, and facial or scalp laceration are lower with cesarean delivery, and shoulder dystocia is eliminated. Importantly, however, fetal acidemia rates are not increased with operative vaginal delivery (Contag, 2010; Walsh, 2013). Intracranial hemorrhage rates are similar among infants delivered by vacuum extraction, forceps, or cesarean delivery during labor (Towner, 1999). But, these rates are higher than among those delivered spontaneously or by cesarean delivery before labor. These authors suggest that the common risk factor for intracranial hemorrhage is abnormal labor. Werner and associates (2011), in their evaluation of more than 150,000 singleton deliveries, reported that forceps-assisted delivery was associated with fewer total neurological complications compared with vacuum-assisted or cesarean delivery. However, as a subset, subdural hemorrhage was significantly more frequent in both operative vaginal delivery cohorts compared with infants in the cesarean delivery group.

Reports of neonatal morbidity rates compared between midforceps and cesarean delivery are conflicting. In the study by Towner and colleagues (1999), similar risks were reported for intracranial hemorrhage. Bashore and associates (1990) observed comparable Apgar scores, cord blood acid-base values, neonatal intensive care unit admission, and birth trauma between these two. In another study, however, Robertson and coworkers (1990) reported significantly higher rates of these adverse outcomes in the midforceps group. And Hagadorn-Freathy and colleagues (1991) reported an increased risk for facial nerve palsy—9 percent—with midforceps delivery.

Mechanisms of Acute Injury

In general, with operative vaginal delivery, the types of fetal injury can usually be explained by the forces exerted. In cases of cephalohematoma or subgaleal hemorrhage, suction and perhaps rotation during vacuum extraction may lead to a primary vessel laceration (Fig. 33-1, p. 647). Intracranial hemorrhage may result from skull fracture and vessel laceration or from

vessel laceration alone due to exerted forces. With facial nerve palsy, one of the forceps blades may compress the nerve against the facial bones (Duval, 2009; Falco, 1990). The higher rates of shoulder dystocia seen with vacuum extraction may result from the angle of traction. With the vacuum, this angle creates vector forces that actually pull the anterior shoulder into the symphysis pubis (Caughey, 2005). To explain brachial plexus injury, Towner and Ciotti (2007) proposed that as the fetal head descends down the birth canal, the shoulders may stay above the pelvic inlet. Thus, similar to shoulder dystocia at the symphysis, this “shoulder dystocia at the pelvic inlet” is overcome by traction forces but with concomitant stretch on the brachial plexus.

Long-Term Infant Morbidity

Evidence regarding long-term neurodevelopmental outcomes in children delivered by operative vaginal delivery is reassuring. Seidman and colleagues (1991) evaluated more than 52,000 Israeli Defense Forces draftees at age 17 years and found that regardless of delivery mode, there were similar rates of physical or cognitive impairments. Wesley and associates (1992) noted similar intelligence scores among 5-year-olds following spontaneous, forceps, or vacuum deliveries. Murphy and coworkers (2004) found no association between forceps delivery and epilepsy in a cohort of 21,441 adults. In their epidemiological review, O’Callaghan and colleagues (2011) found no association between cerebral palsy and operative vaginal delivery. A prospective study by Bahl and associates (2007) included children of 264 women who underwent operative delivery. Their incidence of neurodevelopmental morbidity was similar in those undergoing successful forceps delivery, failed forceps with cesarean delivery, or cesarean delivery without forceps.

Data regarding midforceps deliveries are for the most part reassuring. Broman and coworkers (1975) reported that infants delivered by midforceps had slightly higher intelligence scores at age 4 years compared with those of children delivered spontaneously. Using the same database, however, Friedman and associates (1977, 1984) analyzed intelligence assessments at or after age 7 years. They concluded that children delivered by midforceps had lower mean intelligence quotients compared with children delivered by outlet forceps. In yet another report from this same database, Dierker and colleagues (1986) compared long-term outcomes of children delivered by midforceps with those of children delivered by cesarean after dystocia. The strength of this study is the appropriateness of the control group. These investigators reported that delivery by midforceps was not associated with neurodevelopmental disability. Last, Nilsen (1984) evaluated 18-year-old men and found that those delivered by Kielland forceps had higher intelligence scores than those delivered spontaneously, by vacuum extraction, or by cesarean. As discussed on page 582, Burke and coworkers (2012) reported 144 cases of attempted Kielland forceps rotation and described minimal morbidity.

TRIAL OF OPERATIVE VAGINAL DELIVERY

If an attempt to perform an operative vaginal delivery is expected to be difficult, then it should be considered a trial. Delivery is conducted preferably in an operating room equipped and

staffed for immediate cesarean delivery. If forceps cannot be satisfactorily applied, then the procedure is stopped and either vacuum extraction or cesarean delivery is performed. With the former, if there is no descent with traction, the trial should be abandoned and cesarean delivery performed.

With such caveats, cesarean delivery after an attempt at operative vaginal delivery was not associated with adverse neonatal outcomes if there was a reassuring fetal heart rate tracing (Alexander, 2009). A similar study evaluated 122 women who had a trial of midcavity forceps or vacuum extraction in a setting with full preparations for cesarean delivery (Lowe, 1987). Investigators found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean but without such a trial. Conversely, in 61 women who had “unexpected” vacuum or forceps failure in which there was no prior preparation for immediate cesarean delivery, neonatal morbidity was higher.

Factors associated with operative delivery failure are persistent occiput posterior position, absence of regional or general anesthesia, and birthweight > 4000 g (Ben-Haroush, 2007). In general, to avert morbidity with failed forceps or vacuum delivery, the American College of Obstetricians and Gynecologists (2012) cautions that these trials should be attempted only if the clinical assessment is highly suggestive of a successful outcome. We also emphasize proper training.

Sequential instrumentation most frequently involves an attempt at vacuum extraction followed by one with forceps. This most likely stems from the higher completion rate with forceps compared with vacuum extraction noted earlier (p. 574). There is no evidence to justify this practice, as it significantly increases risks for fetal trauma (Dupuis, 2005; Murphy, 2001; Gardella, 2001). Because of these adverse outcomes, the American College of Obstetricians and Gynecologists (2012) recommends against the sequential use of instruments unless there is a “compelling and justifiable reason.”

TRAINING

As the rate of operative vaginal delivery has declined, so have opportunities for training. Fifteen years ago, Hankins and colleagues (1999) reported that fewer than half of residency directors expected proficiency with midforceps delivery. From the data shown in Figure 29-1, we, and others, would expect that number to be much lower today (Miller, 2014). In many programs, training in even low and outlet forceps procedures has reached critically low levels. For residents completing training in 2012, the Accreditation Council for Graduate Medical Education (2012) lists a median of only six forceps deliveries, and that for vacuum deliveries was 16.

Because traditional hands-on training has evolved, residency programs should have readily available skilled operators to teach these procedures by simulation as well as through actual cases (Spong, 2012). And, the effectiveness of simulation training has been reported (Bahl, 2009; Dupuis, 2006, 2009; Leslie, 2005). In one program, there were lowered rates of maternal and neonatal morbidity associated with operative vaginal delivery after the implementation of a formal education

FIGURE 29-2 Elliot forceps. **A.** Note the ample pelvic curve in the blades. **B.** The cephalic curve, which accommodates the fetal head, is evident in the articulated blades. The fenestrated blade and the overlapping shank in front of the English-style lock characterize these forceps.

program that included a manikin and pelvic model (Cheong, 2004). In another, assignment of a labor and delivery attending with the specific goal to increase forceps delivery education led to a 59-percent increase in forceps-assisted vaginal delivery rates.

FORCEPS DELIVERY

Forceps Design

These instruments consist basically of two crossing branches. Each branch has four components: blade, shank, lock, and handle. Each blade has two curves: the outward cephalic curve conforms to the round fetal head, and the upward pelvic curve corresponds more or less to the axis of the birth canal. Some varieties have an opening within or a depression along the blade surface and are termed *fenestrated* or

pseudofenestrated, respectively (Fig. 29-2). These blade modifications permit a firmer grasp of the fetal head, but at the expense of increased blade thickness, which may increase vaginal trauma. In general, Simpson or Elliot forceps, with their fenestrated blades, are used to deliver a fetus with a molded head, as is common in nulliparous women. The Tucker-McLane forceps have thin smooth blades and are often used for a fetus with a rounded head, which is more characteristic in multiparas (Fig. 29-3). In most situations, however, any of these are appropriate.

The blades are connected to the handles by shanks. The common method of articulation, the English lock, consists of a socket located on the shank at the junction with the handle, into which fits a socket similarly located on the opposite shank (see Fig. 29-3). A sliding lock is used in some forceps, such as Kielland forceps (Fig. 29-4).

Forceps Blade Application and Delivery

Forceps blades grasp the head and are applied according to fetal head position. If the head is in an occiput anterior position, two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and then into the vagina beside the fetal head. The handle of the left branch is grasped between the thumb and two fingers of the left hand (Fig. 29-5). The blade tip is then gently passed into the vagina between the fetal head and the palmar surface of the fingers of the right hand (Fig. 29-6). For application of the right blade, two or more fingers of the left hand are introduced into the right posterior portion of the vagina to serve as a guide for the right blade. This blade is held in the right hand and introduced into the vagina as described for the left blade. After positioning, the branches are articulated (Fig. 29-7). If the head is positioned in a left occiput anterior or right occiput anterior position, then the lower of the two blades is typically placed first.

The blades are constructed so that their cephalic curve is closely adapted to the sides of the fetal head. The biparietal

FIGURE 29-4 Kielland forceps. The characteristic features are minimal pelvic curvature (**A**), sliding lock (**B**), and light weight.

FIGURE 29-5 The left handle of the forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and the fingers of the operator's right hand.

diameter of the fetal head corresponds to the greatest distance between appropriately applied blades. Consequently, the fetal head is perfectly grasped only when the long axis of the blades corresponds to the occipitomenal diameter. These diameters are depicted in Figure 7-12 (p. 140). As a result, most of the blade lies over the face. If the fetus is in an occiput anterior

FIGURE 29-7 The vertex is now occiput anterior, and the forceps are symmetrically placed and articulated.

position, then the concave arch of the blades is directed toward the sagittal suture. If the fetus is in an occiput posterior position, then the concave arch is directed toward the fetal face.

For the occiput anterior position, appropriately applied blades are equidistant from the sagittal suture, and each blade is equidistant from its adjacent lambdoidal suture. In the occiput posterior position, the blades are equidistant from the midline of the face and brow. Also for occiput posterior position, blades are symmetrically placed relative to the sagittal suture and each coronal suture. Applied in this way, the forceps should not slip, and traction may be applied most advantageously. With most forceps, if one blade is applied over the brow and the other over the occiput, the instrument cannot be locked, or if locked, the blades will slip off when traction is applied (**Fig. 29-8**). For these reasons, the forceps must be applied directly to the sides of the fetal head along the occipitomenal diameter.

FIGURE 29-6 A. Continued insertion of the left blade. The right hand, not shown here, guides the blade during placement. Note the arc of the handles as they rotate to be applied to the mother's left. **B.** First blade in place. An assistant's hand can hold this handle in place as the second blade is applied.

FIGURE 29-8 Incorrect application of forceps. **A.** One blade over the occiput and the other over the brow. Forceps cannot be locked. **B.** With incorrect placement, blades tend to slip off with traction.

If necessary, rotation to occiput anterior is performed before traction is applied (Fig. 29-9). When it is certain that the blades are placed satisfactorily, then gentle, intermittent, horizontal traction is exerted concurrent with maternal efforts until the perineum begins to bulge (Fig. 29-10). With traction, as the vulva is distended by the occiput, an episiotomy may be performed if indicated. Additional horizontal traction is applied, and the handles are gradually elevated, eventually pointing almost directly upward as the parietal bones emerge (Figs. 29-11 and 29-12). As the handles are raised, the head is extended. During the birth of the head, spontaneous delivery should be simulated as closely as possible.

FIGURE 29-9 Forceps have been locked. Vertex is rotated from left occiput anterior to occiput anterior (arrow).

The force produced by the forceps on the fetal skull is a complex function of both traction and compression by the forceps, as well as friction produced by maternal tissues. It is impossible to ascertain the amount of force exerted by forceps for an individual patient. Traction should therefore be intermittent, and the head should be allowed to recede between contractions, as in spontaneous labor. Except when urgently indicated, as in severe fetal bradycardia, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction. Maternal pushing will augment these efforts.

After the vulva has been well distended by the head, the delivery may be completed in several ways. Some clinicians keep the forceps in place to control the advance of the head. If done, however, the thickness of the blades adds to vulvar distention, thus increasing the likelihood of laceration or necessitating a large episiotomy. To prevent this, the forceps may be removed, and delivery is then completed by maternal pushing (Fig. 29-13). Importantly, if blades are disarticulated and removed too early, the head may recede and lead to a prolonged delivery. Pushing in some cases may be aided by addition of the modified Ritgen maneuver.

Delivery of Occiput Posterior Positions

Prompt delivery may at times become necessary when the small occipital fontanel is directed toward one of the sacroiliac synchondroses, that is, in right occiput or left occiput posterior positions. When delivery is required in either instance, the head is often imperfectly flexed. In some cases, when the hand is

FIGURE 29-10 Occiput anterior. Delivery by low forceps. The direction of gentle traction for delivery of the head is indicated (arrow).

FIGURE 29-11 Upward arching traction (arrow) is used as the head is delivered.

FIGURE 29-12 Upward traction is continued as the head is delivered.

introduced into the vagina to locate the posterior ear, the occiput rotates spontaneously toward the anterior, indicating that manual rotation of the fetal head might easily be accomplished.

With manual rotation, an open hand is inserted into the vagina. The palm straddles the sagittal suture of the fetal head. The operator's fingers wrap around one side of the fetal face and thumb extends along the other side. If the occiput is in a right posterior position, rotation is clockwise to bring it to a right occiput anterior or to a straight occiput anterior position. With left occiput posterior position, rotation is counterclockwise. If resistance is met during rotation, the head may be slightly elevated but should not be disengaged, as this risks cord prolapse. After the occiput has reached the anterior position, labor may be allowed to continue, or forceps can be applied. Le Ray and colleagues (2007, 2013) reported a success rate of greater than 90 percent with manual rotation.

Manual rotations are most easily completed in multiparas. If manual rotation cannot be easily accomplished, application of forceps blades to the head in the posterior position and delivery from the

FIGURE 29-13 Forceps may be disarticulated as the head is delivered. Modified Ritgen maneuver may be used to complete delivery of the head.

FIGURE 29-14 Outlet forceps delivery from an occiput posterior position. The head should be flexed after the bregma passes under the symphysis.

occiput posterior position may be the safest procedure (Fig. 29-14). In many cases, the cause of the persistent occiput posterior position and of the difficulty in accomplishing rotation is an anthropoid pelvis. This architecture opposes rotation and predisposes to posterior delivery (Fig. 2-20, p. 34).

With forceps delivery from an occiput posterior position, horizontal traction should be applied until the base of the nose is under the symphysis. The handles should then be slowly elevated until the occiput gradually emerges over the anterior margin of the perineum. Then, the forceps are directed in a downward motion, and the nose, mouth, and chin successively emerge from the vulva.

Occiput posterior delivery causes greater distention of the vulva, and a large episiotomy may be needed. Pearl and associates (1993) reviewed 564 occiput posterior deliveries and compared them with 1068 occiput anterior deliveries as controls. The occiput posterior group had a higher incidence of severe perineal lacerations and extensive episiotomy compared with the occiput anterior group. From The Netherlands, de Leeuw and associates (2008) studied more than 28,500 operative vaginal deliveries and reported similar findings. Consequences of these perineal tears are discussed in Chapter 27 (p. 536). Also, infants delivered from the occiput posterior position had a higher incidence of Erb and facial nerve palsies, 1 and 2 percent, respectively, than did those delivered from the occiput anterior position. As expected, rotations to occiput anterior ultimately decrease perineal delivery trauma (Bradley, 2013).

For rotations from the occiput posterior position, Tucker-McLane, Simpson, or Kielland forceps may be used. The oblique occiput may be rotated 45 degrees to the posterior position, or 135 degrees to the anterior position. If rotation is performed with Tucker-McLane or Simpson forceps, the head must be flexed, but this is not necessary with Kielland forceps because they have a less pronounced pelvic curve. In rotating the occiput anteriorly with Tucker-McLane or Simpson forceps, the pelvic curvature, originally directed upward, is, at the completion of rotation, inverted and directed posteriorly. Attempted delivery with the instrument in this position is likely to cause vaginal sulcus tears and sidewall lacerations. To avoid such trauma, it

is essential to remove and reapply the instrument as previously described for occiput anterior delivery.

■ Rotation from Occiput Transverse Positions

When the occiput is obliquely anterior, it gradually rotates spontaneously to the symphysis pubis as traction is exerted. When it is directly transverse, however, a rotary motion of the forceps is required. When the occiput is directed toward the patient's left, rotation counterclockwise from the left side toward the midline is required. For right occiput transverse positions, clockwise rotation is required.

With experienced operators, high success rates with minimal maternal morbidity can be achieved (Burke, 2012; Stock, 2013). Either standard forceps, such as Simpson, or specialized forceps, such as Kielland, are employed. The latter have a sliding lock and almost no pelvic curve (see Fig. 29-4). On each handle is a small knob that indicates the direction of the occiput. The station of the fetal head must be accurately ascertained to be at, or preferably below, the level of the ischial spines, especially in the presence of extreme molding.

Kielland described two methods of applying the anterior blade. The first is the wandering or gliding method in which the anterior blade is introduced at the side of the pelvis over the brow or face. The blade is then arched around the brow or face to an anterior position, with the handle of the blade held close to the opposite maternal buttock throughout the maneuver. The second blade is introduced posteriorly and the branches are locked.

The second is the classic application in which the anterior blade is introduced first with its cephalic curve directed upward, curving under the symphysis. After it has been advanced far enough toward the upper vagina, it is turned on its axis through 180 degrees to adapt the cephalic curvature to the head. For a more detailed description of Kielland forceps procedures, see the second edition of *Operative Obstetrics* (Gilstrap, 2002).

Application of forceps to an occiput transverse positioned fetus in these women with a platypeloid pelvis should not be attempted until the fetal head has reached or approached the pelvic floor. Regardless of the original position of the head, after rotation, delivery eventually is accomplished by exerting traction downward until the occiput appears at the vulva. After this, the rest of the operation is completed as previously described for occiput anterior delivery.

■ Face Presentation Forceps Delivery

With a mentum anterior face presentation, forceps can be used to effect vaginal delivery. The blades are applied to the sides of the head along the occipitomenal diameter, with the pelvic curve directed toward the neck. Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum. Forceps should not be applied

to the mentum posterior presentation because vaginal delivery is impossible except in very small fetuses.

VACUUM EXTRACTION

Vacuum Extractor Design

With vacuum delivery technique, suction is created within a cup placed on the fetal scalp such that traction on the cup aids fetal expulsion. In the United States, *vacuum extractor* is the preferred term for the devices shown in [Figure 29-15](#), whereas in Europe it is commonly called a *ventouse*—from French, literally, “soft cup.” Theoretical advantages of this tool compared with forceps include simpler requirements for precise positioning on the fetal head and avoidance of space-occupying blades within the vagina, thereby lowering maternal trauma rates.

As noted, vacuum devices contain a cup, shaft, handle, and vacuum generator. Vacuum cups may be metal, hard plastic, or soft plastic and may also differ in their shape, size, and reusability. In the United States, nonmetal cups are generally preferred, and there are two main types. The soft cup is a pliable funnel- or bell-shaped dome, whereas the rigid type has a firm flattened mushroom-shaped cup and circular ridge around the cup rim ([Table 29-2](#)). When compared, rigid mushroom cups generate significantly more traction force (Hofmeyr, 1990; Muise, 1993). With occiput posteriorly positioned heads or with asynclitism, the flatter cup also permits improved placement at the flexion point, which is typically less accessible with these head positions. The trade-off is that the flatter cups have higher scalp laceration rates. Thus, many manufacturers recommend soft bell cups for more straightforward occiput anterior deliveries. Rigid mushroom cups may be preferred for occiput posterior or transverse presentation or for asynclitism.

Several investigators have compared outcomes with various rigid and soft cups. Metal cups provide higher success rates

but greater rates of scalp injuries, including cephalohematomas (O'Mahony, 2010). In another study, Kuit and coworkers (1993) found that the only advantage of the soft cups was a lower incidence of scalp injury. They reported a 14-percent episiotomy extension rate with both rigid and pliable cups. Associated perineal lacerations occurred with 16 percent of rigid cup extractions and 10 percent with the pliable cup. In a review, Vacca (2002) concluded that there were fewer scalp lacerations with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage was similar between soft and rigid cups. Importantly, high-pressure vacuum generates large amounts of force regardless of the cup used (Duchon, 1998).

Aside from the cup, the shaft that connects the cup and handle may be flexible or semiflexible. Tubing-like flexible shafts may be preferred for occiput posterior or asynclitic presentation to permit better seating of the cup (see [Fig. 29-15A](#)). Last, the vacuum generator may be handheld and actuated by the operator or may be held and operated by an assistant.

Technique

An important step in vacuum extraction is proper cup placement over the *flexion point*. This pivot point maximizes traction, minimizes cup detachment, flexes but averts twisting of the fetal head, and delivers the smallest head diameter through the pelvic outlet. This improves success rates, lowers fetal scalp injury rates, and lessens perineal trauma because the smallest fetal head diameter distends the vulva (Baskett, 2008).

FIGURE 29-15 Vacuum delivery systems. **A.** The *Kiwi OmniCup* contains a handheld vacuum-generating pump, which is attached via flexible tubing to a rigid plastic mushroom cup. **B.** The *Mityvac Mystic II MitySoft Bell Cup* has a soft bell cup attached by a semirigid shaft to a handheld pump.

FIGURE 29-16 Drawing demonstrates correct cup placement at the flexion point. Along the sagittal suture, this spot lies 3 cm from the posterior fontanel and 6 cm from the anterior fontanel.

The flexion point is found along the sagittal suture, approximately 3 cm in front of the posterior fontanel and approximately 6 cm from the anterior fontanel. Because cup diameters range from 5 to 6 cm, when properly placed, the cup rim lies 3 cm from the anterior fontanel (**Fig. 29-16**). Placement of the cup more anteriorly on the fetal cranium—near the anterior fontanel—should be avoided as it leads to cervical spine extension during traction unless the fetus is small. Such placement also delivers a wider fetal head diameter through the vaginal opening. Last, asymmetrical placement relative to the sagittal suture may worsen asynclitism. For elective use, cup placement in occiput anterior positions is seldom difficult. In contrast, when the indication for delivery is failure to descend caused by occipital malposition—with or without asynclitism or deflexion—cup positioning can be difficult.

During cup placement, maternal soft tissue entrapment predisposes the mother to lacerations and virtually ensures cup dislodgement. Thus, the entire cup circumference should be palpated both before and after the vacuum has been created as well as prior to traction to exclude such entrapment. Gradual vacuum creation is advocated by some and is generated by increasing the suction in increments of 0.2 kg/cm² every 2 minutes until a total negative pressure of 0.8 kg/cm² is reached (**Table 29-3**). That said, other studies have shown that

FIGURE 29-17 Cup placed before application of traction.

negative pressure can be increased to 0.8 kg/cm² in < 2 minutes without a significant difference in efficacy or in maternal and fetal outcomes (Suwannachat, 2011, 2012).

Once suction is created, the instrument handle is grasped, and traction is initiated (**Fig. 29-17**). Effort should be intermittent and coordinated with maternal expulsive efforts. Similar to forceps delivery, traction is usually directed initially downward, then progressively extended upward as the head emerges. Manual torque to the cup is avoided as it may cause cup displacement or cephalohematomas and with metal cups, “cookie-cutter”-type scalp lacerations. Thus, occiput anterior oblique positions are corrected not by rotation, but solely by downward outward traction. During pulls, the operator should place the nondominant hand within the vagina, with the thumb on the extractor cup and one or more fingers on the fetal scalp. So positioned, descent of the presenting part can be judged and the traction angle can be adjusted with head descent. In addition, the relationship of the cup edge to the scalp can be assessed to help detect cup separation.

Between contractions, some physicians will lower the suction levels to decrease rates of scalp injury, whereas others will maintain suction in cases of nonreassuring fetal heart tones to aid rapid delivery. No differences in maternal or fetal outcome could be demonstrated if the level of vacuum was decreased between contractions or if an effort was made to prevent fetal loss of station (Bofill, 1997). Once the head is extracted, the vacuum pressure is relieved, the cup removed, and the usual techniques to complete vaginal delivery are followed.

Vacuum extraction should be considered a trial. Without early and clear evidence of descent toward delivery, an alternative delivery approach should be considered. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup “pop-offs” that can be tolerated, or optimal

TABLE 29-3. Vacuum Pressure Conversions

total duration of the procedure. Some manufacturers have recommendations regarding these in their instructional literature (Clinical Innovations, LLC, 2013; CooperSurgical, 2011).

During a vacuum extraction trial, cup dislodgement due to technical failure or less than optimal placement should not be equated with dislodgement under ideal conditions of exact cup placement and optimal vacuum maintenance. These cases may merit either additional attempts at placement or alternatively, a trial of forceps (Ezenagu, 1999; Williams, 1991). The least desirable cases are those in which traction without progress or multiple disengagements occur following correct cup application and appropriate traction. As with forceps procedures, there should be a willingness to abandon attempts at vacuum extraction if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2012).

PERIPARTUM HYSTERECTOMY TECHNIQUE	600
PERIPARTUM MANAGEMENT	604

Cesarean delivery defines the birth of a fetus via laparotomy and then hysterotomy. The origin of *caesarean* is uncertain and was reviewed in the 23rd edition of *Williams Obstetrics* (Cunningham, 2010). There are two general types of cesarean delivery—*primary* refers to a first-time hysterotomy and *secondary* denotes a uterus with one or more prior hysterotomy incisions. Neither definition includes removal of the fetus from the abdominal cavity in the case of uterine rupture or with abdominal pregnancy. Rarely, hysterotomy is performed in a woman who has just died or in whom death is expected soon—post-mortem or perimortem cesarean delivery (Chap. 47, p. 956).

In some instances, and most often because of emergent complications such as intractable hemorrhage, abdominal hysterectomy is indicated following delivery. When performed at the time of cesarean delivery, the operation is termed *cesarean hysterectomy*. If done within a short time after delivery, it is termed *postpartum hysterectomy*. *Peripartum hysterectomy* is a broader term that combines these two. In most cases, hysterectomy is total, but supracervical hysterectomy is also an option. The adnexa are not typically removed.

CESAREAN DELIVERY IN THE UNITED STATES

From 1970 to 2010, the cesarean delivery rate in the United States rose from 4.5 percent of all deliveries to 32.8 percent. In 2010, this rate actually declined from a peak of 32.9 percent in 2009 (Martin, 2012). The other, albeit brief, decline was between 1989 and 1996 (Fig. 31-1, p. 610). This more profound decrease was largely due to a significantly increased rate of *vaginal birth after cesarean (VBAC)* and to a closely mirrored decrease in the primary rate. These trends were short lived, and in 2007, the primary cesarean delivery rate was above 30 percent, whereas VBAC rates had dropped to 8 percent (MacDorman, 2011).

The reasons for the continued increase in the cesarean rates are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among *nulliparas*, who are at increased risk for cesarean delivery.
2. The average *maternal age* is rising, and older women, especially nulliparas, are at increased risk of cesarean delivery.
3. The use of *electronic fetal monitoring* is widespread. This technique is associated with an increased cesarean delivery rate compared with intermittent fetal heart rate auscultation (Chap. 24, p. 496). Cesarean delivery performed primarily for “fetal distress” comprises only a minority of all such procedures. In many more cases, concern for an abnormal or “nonreassuring” fetal heart rate tracing lowers the threshold for cesarean delivery.
4. Most fetuses presenting as *breech* are now delivered by cesarean. As discussed in Chapter 28 (p. 561), concern for fetal injury, as well as the infrequency with which a breech presentation meets criteria for a labor trial, almost guarantee that most will be delivered by cesarean.
5. The frequency of *forceps* and *vacuum deliveries* has decreased (Chap. 29, p. 574).

6. Rates of *labor induction* continue to rise, and induced labor, especially among nulliparas, increases the cesarean delivery rate (Chap. 26, p. 523).
7. The prevalence of *obesity* has risen dramatically, and obesity increases the cesarean delivery risk (Chap. 48, p. 965).
8. Rates of cesarean delivery for women with preeclampsia have increased, whereas labor induction rates for these patients have declined.
9. *Vaginal birth after cesarean—VBAC*—has decreased from a high of 28 percent in 1996 to 8 percent in 2007 (Chap. 31, p. 610).
10. Elective cesarean deliveries are increasingly being performed for a variety of indications including concern for *pelvic floor injury* associated with vaginal birth, medically indicated *preterm birth*, reduction of *fetal injury risk*, and for *maternal request*.
11. *Malpractice litigation* related to fetal injury during spontaneous or operative vaginal delivery continues to contribute significantly to the present cesarean delivery rate.

CESAREAN DELIVERY INDICATIONS AND RISKS

Some indications for performing cesarean delivery are shown in [Table 30-1](#). More than 85 percent of these operations are performed for four reasons—prior cesarean delivery, dystocia, fetal jeopardy, or abnormal fetal presentation.

■ Maternal Mortality and Morbidity

To provide accurate informed consent, understanding both maternal and neonatal risks and benefits with surgery is essential. As a broad overview, cesarean delivery has higher maternal surgical risks for the current and subsequent pregnancies. This is balanced against lower rates of perineal injury and short-term pelvic floor disorders, described in Chapter 27 (p. 536). For the neonate, cesarean delivery offers lower rates of birth trauma and stillbirth. Conversely, rates of initial respiratory difficulties are greater with cesarean delivery.

For the mother, death attributable solely to cesarean delivery is rare in the United States. Even so, numerous studies attest to increased mortality risks. Clark and colleagues (2008), in a review of nearly 1.5 million pregnancies, found maternal mortality rates of 2.2 per 100,000 cesarean deliveries compared with 0.2 per 100,000 vaginal births. In a metaanalysis of 203 studies, Guise and coworkers (2010) reported a maternal mortality rate of 13 per 100,000 with elective repeat cesarean delivery compared with 4 per 100,000 women undergoing a trial of labor during VBAC attempt.

Similar to mortality rates, the frequency of some maternal complications is increased with all cesarean compared with vaginal deliveries ([Table 30-2](#)). Villar and associates (2007) reported that maternal morbidity rates increased twofold with cesarean compared with vaginal delivery. Principal among these are infection, hemorrhage, and thromboembolism. In addition, anesthetic complications, which also rarely include death, have a greater incidence with cesarean compared with vaginal delivery (Cheesman, 2009; Hawkins, 2011). Adjacent organs may be injured. The bladder laceration rate is 1 to 3

TABLE 30-1. Some Indications for Cesarean Delivery

Maternal

Prior cesarean delivery
Abnormal placentation
Maternal request
Prior classical hysterotomy
Unknown uterine scar type
Uterine incision dehiscence
Prior full-thickness myomectomy
Genital tract obstructive mass
Invasive cervical cancer
Prior trachelectomy
Permanent cerclage
Prior pelvic reconstructive surgery
Pelvic deformity
HSV or HIV infection
Cardiac or pulmonary disease
Cerebral aneurysm or arteriovenous malformation
Pathology requiring concurrent intraabdominal surgery
Peripartum cesarean delivery

Maternal-Fetal

Cephalopelvic disproportion
Failed operative vaginal delivery
Placenta previa or placental abruption

Fetal

Nonreassuring fetal status
Malpresentation
Macrosomia
Congenital anomaly
Abnormal umbilical cord Doppler study
Thrombocytopenia
Prior neonatal birth trauma

HIV = human immunodeficiency virus; HSV = herpes simplex virus.

per 1000 cesarean deliveries, whereas that for ureteral injury approximates 0.3 per 1000 cases (Güngördük, 2010; Phipps, 2005; Rajasekar, 1997). Bowel damage occurs in approximately 1 in 1000 cesarean deliveries (Silver, 2006).

Women expressing a desire for elective primary cesarean delivery may be counseled that surgery offers decreased risks for hemorrhage and chorioamnionitis compared with planned primary vaginal birth. But this is again balanced against higher maternal rates of thromboembolism, hysterectomy, and rehospitalization for infection or wound complications; longer initial hospital stays; and greater rates of uterine rupture or abnormal placental implantation in subsequent pregnancies (Declercq, 2007; Geller, 2010; Liu, 2007).

Women who undergo a cesarean delivery are much more likely to be delivered by a repeat operation in subsequent pregnancies. For women undergoing subsequent cesarean, the maternal risks just described are even greater (Cahill, 2006; Marshall, 2011; Silver, 2006).

As an advantage, there is evidence that cesarean delivery is associated with lower rates of urinary incontinence and pelvic

TABLE 30-2. Complications Associated with Low-Risk Planned Cesarean Delivery^a Compared with Planned Vaginal Delivery among Healthy Women in Canada, 1991–2005

Complication	Type of Planned Delivery ^b	
	Cesarean n = 46,766	Vaginal n = 2,292,420
Overall morbidity	1279 (2.73)	20,639 (0.9)
Hysterectomy	39 (0.09)	254 (0.01)
Transfusion	11 (0.02)	1500 (0.07)
Anesthetic complications	247 (0.53)	4793 (0.21)
Hypovolemic shock	3 (0.01)	435 (0.02) ^c
Cardiac arrest	89 (0.19)	887 (0.04)
Venous thromboembolism	28 (0.06)	623 (0.03)
Puerperal infection	281 (0.60)	4833 (0.21)
Wound disruption	41 (0.09)	1151 (0.05)
Wound hematoma	607 (1.3)	6263 (0.27)
In-hospital deaths	0	41 (0.002)

^aHealthy women with a singleton gestation and no previous cesarean delivery who underwent cesarean delivery for breech presentation were used as a surrogate for a low-risk planned cesarean delivery group.

^bData are shown as number (%).

^cNonsignificant comparison. For all other comparisons $p < 0.05$.

Modified from Liu, 2007.

organ prolapse (Glazener, 2013; Gyhagen, 2013; Handa, 2011; Leijonhufvud, 2011; Rortveit, 2003). This protective advantage may persist to some degree over time, but cesarean delivery is not wholly protective (Dolan, 2010; MacArthur, 2011; Rortveit, 2001). Finally, cesarean delivery is not protective long-term for fecal incontinence (MacArthur, 2011, 2013; Nelson, 2010).

Neonatal Morbidity

Cesarean delivery is associated with less risk of fetal trauma. And this in many instances influences the choice of cesarean delivery despite the associated maternal risks. Alexander and colleagues (2006) found that fetal injury complicated 1 percent of cesarean deliveries. Skin laceration was most common, but others included cephalohematoma, clavicular fracture, brachial plexopathy, skull fracture, and facial nerve palsy. Cesarean deliveries following a failed operative vaginal delivery attempt had the highest injury rate, whereas the lowest rate—0.5 percent—occurred in the elective cesarean delivery group. That said, Worley and colleagues (2009) found that approximately a third of pregnant women who were delivered at Parkland Hospital entered spontaneous labor at term, and 96 percent of these delivered vaginally without adverse neonatal outcomes.

Although physical injury risks are lower, cesarean delivery per se may have no bearing on the neurodevelopmental prognosis of the infant. Scheller and Nelson (1994) in a report from the National Institutes of Health and Lien and associates (1995) presented data specifically refuting any association

between cesarean delivery and lower rates of either cerebral palsy or seizures. Moreover, as discussed in Chapter 33 (p. 638), the incidences of neonatal seizures or cerebral palsy have not diminished as the rate of cesarean delivery has increased (Miller, 2008; Miller, 2013).

Patient Choice in Cesarean Delivery

As women have taken a more active role in their obstetrical care, some request elective cesarean delivery. Data regarding the true incidence of *cesarean delivery on maternal request (CDMR)* are limited, however, estimates are a 1- to 7-percent rate in the United States in 2003 (Gossman, 2006; Menacker, 2006).

Reasons for requested cesarean delivery include reduced risk of fetal injury, avoidance of the uncertainty and pain of labor, protection of pelvic floor support, and convenience. Thus, the debate surrounding CDMR includes its medical rationale from both a maternal and fetal-neonatal standpoint, the concept of informed free choice by the woman, and the autonomy of the physician in offering this choice.

To address this, the National Institutes of Health (2006) held a State-of-the-Science Conference on Cesarean Delivery on Maternal Request. A panel of experts critically reviewed available literature to form recommendations based on identified risks and benefits. It is noteworthy that most of the maternal and neonatal outcomes examined had insufficient data to permit such recommendations. Indeed, one of the main conclusions of the conference was that more high-quality research is needed to fully evaluate the issues. The American College of Obstetricians and Gynecologists (2013) concluded that data comparing planned cesarean and planned vaginal delivery were minimal and thus should be interpreted cautiously.

The panel was able to draw a few conclusions from existing information. Cesarean delivery on maternal request should not be performed before 39 weeks' gestation unless there is evidence of fetal lung maturity. It should be avoided in women desiring several children because of the risk of placental implantation abnormalities and cesarean hysterectomy. Finally, it should not be motivated by the unavailability of effective pain management.

PATIENT PREPARATION

Delivery Availability

There is no nationally recognized standard of care that codifies an acceptable time interval to begin performance of a cesarean delivery. Previously, a 30-minute decision-to-incision interval was recommended. In most instances, however, operative delivery is not necessary within this 30-minute time frame. Bloom and coworkers (2001) reported for the Maternal-Fetal Medicine Units Network that 69 percent of 7450 cesareans performed in labor commenced more than 30 minutes after the decision to operate. In a second study, Bloom and colleagues (2006) evaluated cesarean deliveries performed for emergency indications. They reported that failure to achieve a cesarean delivery decision-to-incision time of less than 30 minutes was not associated with a negative neonatal outcome. On the other hand, when faced with an acute, catastrophic deterioration in

fetal condition, cesarean delivery usually is indicated as rapidly as possible, and thus purposeful delays are inappropriate. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that facilities giving obstetrical care should have the ability to initiate cesarean delivery in a time frame that best incorporates maternal and fetal risks and benefits.

■ Informed Consent

Obtaining informed consent is a process and not merely a medical record document (American College of Obstetricians and Gynecologists, 2012a). This conversation between a clinician and patient should enhance a woman's awareness of her diagnosis and contain a discussion of medical and surgical care alternatives, procedure goals and limitations, and surgical risks. For women with a prior cesarean delivery, the option of a trial of labor should be included for suitable candidates. Also, in those desiring permanent sterilization, consenting for tubal ligation, as described in Chapter 39 (p. 720), can be completed at this time.

■ Timing of Scheduled Cesarean Delivery

Adverse neonatal sequelae from neonatal immaturity with elective delivery before 39 completed weeks are appreciable (Clark, 2009; Tita, 2009a). To avoid these, assurance of fetal maturity before scheduled elective surgery is essential as outlined by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) and discussed in Chapter 31 (p. 615). To assist with this and other components of cesarean delivery planning, the American College of Obstetricians and Gynecologists (2011a,c) has created Patient Safety Checklists to be completed before the planned surgery.

■ Perioperative Care

If cesarean delivery is scheduled, a sedative may be given at bedtime the night before surgery. In general, no other sedatives, narcotics, or tranquilizers are administered until after the fetus is born. Oral intake is stopped at least 8 hours before the procedure. The woman scheduled for repeat cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrical and anesthesia teams. Recently performed hematocrit and indirect Coombs test are reviewed, and if the latter is positive, then availability of compatible blood must be ensured.

As discussed in Chapter 25 (p. 509), regional analgesia is preferred for cesarean delivery. An antacid is given shortly before regional analgesia or induction with general anesthesia. One example is Bicitra, 30 mL orally in a single dose. This minimizes the lung injury risk from gastric acid aspiration. Once the woman is supine, a wedge beneath the right hip creates a left lateral tilt to aid venous return and avoid hypotension. According to the American College of Obstetricians and Gynecologists (2010), there are insufficient data to determine the value of fetal monitoring before scheduled cesarean delivery in women without risk factors. That said, fetal heart sounds should be documented in the operating room prior to surgery.

For further preparation, if hair obscures the operative field it should be removed the day of surgery by clipping. This is

associated with fewer surgical site infections compared with shaving (Tanner, 2011). An indwelling bladder catheter is typically placed at Parkland Hospital to collapse the bladder away from the hysterotomy incision, to avert urinary retention secondary to regional analgesia, and to allow accurate postoperative urine measurement. Small studies support the nonuse of catheterization in hemodynamically stable women to minimize urinary infections (Li, 2011; Nasr, 2009).

The risk of thromboembolism is increased with pregnancy and almost doubled in those undergoing cesarean delivery (James, 2006). For this reason, for all women not already receiving thromboprophylaxis, the American College of Obstetricians and Gynecologists (2011d) recommends initiation of pneumatic compression hose before cesarean delivery. These are usually discontinued once the woman ambulates. In contrast, we favor the recommendations of American College of Chest Physicians for early ambulation for women without risk factors who are undergoing cesarean delivery (Bates, 2012). For women already receiving prophylaxis or those with increasing risk factors, prophylaxis is escalated as discussed in Chapter 52 and shown in Table 52-8 (p. 1046).

Some women scheduled for cesarean delivery have concurrent comorbidity that requires specific management in anticipation of surgery. Among others, these include insulin-requiring or gestational diabetes, coagulopathy or thrombophilia, chronic corticosteroid use, and significant reactive airway disease. Preparations for surgery in these women are discussed in the respective chapters covering these topics.

■ Infection Prevention

Febrile morbidity is frequent after cesarean delivery. Numerous good-quality trials have proved that a single dose of an antimicrobial agent given at the time of cesarean delivery significantly decreases infection morbidity. Although more obvious for women undergoing unscheduled cesarean delivery, this practice also significantly lowers the postoperative infection rate in women undergoing elective surgery (American College of Obstetricians and Gynecologists, 2011b). Depending on drug allergies, most recommend a single intravenous dose of a β -lactam antimicrobial—either a cephalosporin or extended-spectrum penicillin derivative. A 1-g dose of cefazolin is an efficacious and cost-effective choice. For obese women, a 2-g dose usually provides adequate coverage, although Pevzner and associates (2011) showed this dose may be inadequate for those with body mass index > 40. In women with significant penicillin or cephalosporin allergy, a single 600-mg intravenous dose of clindamycin combined with a weight-based dose of aminoglycoside is an alternative. A 900-mg clindamycin dose is used for obese patients.

Antimicrobial administration before surgical incision has been shown to lower postoperative infection rates without adverse neonatal effects compared with drug administration after umbilical cord clamping (Sullivan, 2007; Tita, 2009b; Witt, 2011). For this reason, the American College of Obstetricians and Gynecologists (2011b) recommends that prophylaxis be administered within the 60 minutes prior to the start of planned cesarean delivery. For emergent delivery, prophylaxis should be given as soon as feasible.

Preoperative preparation of the abdominal wall skin is effective to prevent wound infection. Either chlorhexidine or povidone-iodine solutions can be used. In addition, to prevent postoperative metritis following cesarean delivery, preoperative vaginal cleansing with a povidone-iodine scrub has been evaluated in small randomized trials (Haas, 2013). Some show benefit, whereas others do not (Reid, 2001; Starr, 2005; Yildirim, 2012). Vaginal cleansing is not a part of preoperative preparation at Parkland Hospital.

Antibiotic prophylaxis against infective endocarditis is not recommended for most with cardiac conditions—exceptions are women with cyanotic heart disease, prosthetic valves, or both (American College of Obstetricians and Gynecologists, 2011b). Regimens selected for routine cesarean infection prophylaxis will also serve as appropriate endocarditis coverage (Chap. 49, p. 991).

■ Surgical Safety

The Joint Commission (2013) established a protocol to prevent surgical errors that encompasses three components: (1) preprocedure verification of all relevant documents, (2) marking the operative site, and (3) completion of a “time out” before procedure initiation. The “time out” requires attention of the entire team to confirm that the patient, site, and procedure are correct. Important discussions also include introduction of the patient-care team members, verification of prophylactic antibiotics, estimation of procedure length, and communication of anticipated complications. Additionally, requests for special instrumentation should be addressed preoperatively to prevent potential patient compromise and intraoperative delays.

An instrument, sponge, and needle count before and after surgery and vaginal delivery is crucial to surgical safety. If counts are not reconciled following abdominal or vaginal examination, then radiographic imaging for retained foreign objects is obtained (American College of Obstetricians and Gynecologists, 2012b).

TECHNIQUE FOR CESAREAN DELIVERY

With minor variations, surgical performance of cesarean delivery is comparable worldwide. Most steps are founded on evidence-based data, and these have been reviewed by Dahlke (2013) and Hofmeyr (2009) and their associates. As with all surgery, a clear understanding of relevant anatomy is essential, and this is described and illustrated in Chapter 2 (p. 16).

■ Abdominal Incision

In obstetrics, usually a midline vertical or a suprapubic transverse incision is chosen for laparotomy. Transverse abdominal entry is by either Pfannenstiel or Maylard incisions. Of these, the Pfannenstiel incision is selected most frequently for cesarean delivery. Transverse incisions follow Langer lines of skin tension, and superior cosmetic results compared with vertical incisions can be achieved. Additionally, decreased rates of postoperative pain, fascial wound dehiscence, and incisional hernia compared with vertical entry are benefits. Use of the Pfannenstiel incision, however, is often discouraged for cases in

which a large operating space is essential or in which access to the upper abdomen may be needed. Because of the layers created during incision of the internal and external oblique aponeuroses with transverse incisions, purulent fluid can collect between these. Therefore, cases with high infection risks may favor a midline incision. Last, neurovascular structures, which include the ilioinguinal and iliohypogastric nerves and superficial and inferior epigastric vessels, are often encountered with transverse incisions. Logically, bleeding, wound hematoma, and neurological disruption may more frequently complicate these incisions compared with vertical incision. With repeat cesarean delivery, reentry through a Pfannenstiel incision usually is more time consuming and difficult because of scarring.

The Maylard incision differs mainly from the Pfannenstiel in that the bellies of the rectus abdominis muscles are transected horizontally to widen the operating space. It is technically more difficult due to its required isolation and ligation of the inferior epigastric arteries, which lie lateral to these muscle bellies.

Vertical infraumbilical incisions provide quick entry to shorten incision-to-delivery time (Wylie, 2010). Moreover, this incision has minimal blood loss, superior access to the upper abdomen, generous operating room, and the flexibility for easy wound extension if greater space or access is needed. No important neurovascular structures traverse this incision, and aponeuroses at the linea alba are fused. Main disadvantages are poorer cosmetic results, higher fascial dehiscence or incisional hernia rates, and greater postoperative pain. For morbidly obese patients, a vertical incision that extends up and around the umbilicus may be preferable to avoid cutting through a large pannus (Fig. 48-7, p. 968).

Transverse Incisions

With the Pfannenstiel incision, the skin and subcutaneous tissue are incised using a low, transverse, slightly curvilinear incision. This is made at the level of the pubic hairline, which is typically 3 cm above the superior border of the symphysis pubis. The incision is extended somewhat beyond the lateral borders of the rectus abdominis muscles. It should be of adequate width to accommodate delivery—12 to 15 cm is typical.

Sharp dissection is continued through the subcutaneous layer to the fascia. The superficial epigastric vessels can usually be identified halfway between the skin and fascia, several centimeters from the midline, and coagulated. If lacerated, these may be suture ligated with 3-0 plain gut suture or coagulated with an electrosurgical blade.

The fascia is then incised sharply at the midline. The anterior abdominal fascia is typically composed of two visible layers, the aponeurosis from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transverse abdominis muscles. Ideally, the two layers are individually incised during lateral extension of the fascial incision. The inferior epigastric vessels typically lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transverse abdominis muscles. Thus, although infrequently required, extension of the fascial incision further laterally may cut these vessels. Therefore, if lateral extension is needed, these vessels should be identified and coagulated or ligated to prevent bleeding and vessel retraction.

Once the fascia is incised, the inferior fascial edge is grasped with suitable clamps and elevated by the assistant as the operator separates the fascial sheath from the underlying rectus muscles either bluntly or sharply until the superior border of the symphysis pubis is reached. Any blood vessels coursing between the sheath and muscles are clamped, cut, and ligated, or they are coagulated with an electrosurgery blade. Next, the superior fascial edge is grasped and again, separation of fascia from the rectus muscles is completed. Meticulous hemostasis is imperative to lower rates of infection and bleeding. The fascial separation is carried near enough to the umbilicus to permit an adequate midline longitudinal incision of the peritoneum. The rectus abdominis and pyramidalis muscles are then separated in the midline by sharp and blunt dissection to expose the transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are dissected carefully to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly or by elevating it with two hemostats placed approximately 2 cm apart. The tented fold of peritoneum between the clamps is examined and palpated to ensure that omentum, bowel, or bladder is not adjacent. The peritoneum is then incised. The incision is extended superiorly to the upper pole of the incision and downward to just above the peritoneal reflection over the bladder. Importantly, in women who have had previous intraabdominal surgery, including cesarean delivery, omentum or bowel may be adhered to the undersurface of the peritoneum. Moreover, in women with obstructed labor, the bladder may be pushed cephalad almost to the level of the umbilicus.

Vertical Incision

An infraumbilical midline vertical incision begins 2 to 3 cm above the superior margin of the symphysis and should be of sufficient length to allow fetal delivery without difficulty. Therefore, its length should correspond with the estimated fetal size, and 12 to 15 cm is typical. Sharp or electrosurgical dissection is performed to the level of the anterior rectus sheath. A small opening is made sharply with scalpel in the upper half of the linea alba. Placement here avoids potential cystotomy. Index and middle fingers are placed beneath the fascia, and the fascial incision is extended superiorly and inferiorly with scissors or scalpel. Midline separation of the rectus muscles and pyramidalis muscles and peritoneal entry are then similar to those with the Pfannenstiel incision.

Hysterotomy

Most often, the lower uterine segment is incised transversely as described by Kerr in 1921. Occasionally, a low-segment vertical incision as described by Krönig

in 1912 may be used. The classical incision is a vertical incision into the body of the uterus above the lower uterine segment and reaches the uterine fundus. In practice, however, the classical incision is similar to the low-vertical incision, which is typically extended cephalad only to the extent required for fetal delivery. For most cesarean deliveries, the transverse incision is preferred. Compared with a classical incision, it is easier to repair, is located in the inactive segment and thus least likely to rupture during a subsequent pregnancy, causes less incision-site bleeding, and promotes less bowel or omentum adherence to the myometrial incision.

Low Transverse Cesarean Incision

Before any hysterotomy, the surgeon should palpate the fundus and adnexa to identify degrees of uterine rotation. The uterus may be dextrorotated so that the left round ligament is more anterior and closer to the midline. In such cases, hysterotomy placement is modified to keep the incision centered within the lower segment. This avoids extension into and laceration of the left uterine artery. With thick meconium or infected amniotic fluid, some surgeons prefer to put a moistened laparotomy sponge in each lateral peritoneal gutter to absorb fluid and blood that escape from the opened uterus. A moist sponge may also be used to pack protruding bowel away from the operative field.

The reflection of peritoneum above the upper margin of the bladder and overlying the anterior lower uterine segment—termed the bladder flap—is grasped in the midline with forceps and incised transversely with scissors (Fig. 30-1). Bladder flap creation effectively moves the bladder away from

FIGURE 30-1 The loose vesicouterine serosa above the bladder reflection is grasped with forceps and incised with Metzenbaum scissors.

FIGURE 30-2 The loose serosa above the upper margin of the bladder is elevated and incised laterally.

the planned hysterotomy site and prevents bladder laceration if an unintended inferior hysterotomy extension occurs during fetal delivery.

Following this initial incision, scissors are inserted between the vesicouterine serosa and myometrium of the lower uterine segment. The scissors are pushed laterally from the midline on each side to further open the visceral peritoneum and expose the myometrium. This transverse peritoneal incision extends almost the full length of the lower uterine segment. As the lateral margin on each side is approached, the scissors are directed somewhat more cephalad (Fig. 30-2). The lower edge of peritoneum is elevated, and the bladder is gently separated from the underlying myometrium with blunt or sharp dissection within this vesicouterine space (Fig. 30-3).

In general, this caudad separation of bladder does not exceed 5 cm and usually is less. It is possible, especially with an effaced, dilated cervix, to dissect downward so caudally as to inadvertently expose and then enter the underlying vagina rather than the lower uterine segment. However, in instances in which cesarean hysterectomy is planned or anticipated, extended caudad bladder dissection is recommended to aid total hysterectomy and decrease the risk of cystotomy.

Some surgeons do not create a bladder flap. The main advantage is a shorter skin incision-to-delivery time, however, data supporting this practice are limited (Hohlagschwandtner, 2001; Tuuli, 2012).

The uterus is entered through the lower uterine segment approximately 1 cm below the upper margin of the peritoneal reflection. It is important to place the uterine

incision relatively higher in women with advanced or complete cervical dilatation. Failure to adjust increases the risk of lateral extension of the incision into the uterine arteries. It may also lead to incision of the cervix or vagina rather than the lower uterine segment. Such incisions into the cervix can create significant postoperative distortion of cervical anatomy. Correct placement uses the vesicouterine serosal reflection as a guide.

Uterine Incision. The uterus can be incised by a variety of techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline (Fig. 30-4). This must be done carefully to avoid fetal laceration. Careful blunt entry using hemostats or fingertip to split the muscle may be helpful. Once the uterus is opened, the incision can be extended by simply spreading the incision, using lateral and slightly upward pressure applied with each index finger (Fig. 30-5). Alternatively, if the lower uterine segment is thick, then cutting laterally and then slightly upward with bandage scissors will extend the incision. Importantly, when scissors are used, the index and midline fingers of the nondominant hand should be insinuated beneath the myometrium and above fetal parts to prevent fetal laceration. Comparing blunt and sharp extensions of the initial uterine incision, sharp extension is associated with an increased estimated blood loss, but postoperative hematocrit changes, need for transfusion, and infection rates are not different (Xu, 2013).

The uterine incision should be made large enough to allow delivery of the head and trunk of the fetus without either tearing into or having to cut into the uterine vessels that course along the lateral uterine margins. If the placenta is encountered in the incision line, it must be either detached or incised. When

FIGURE 30-3 Cross section shows blunt dissection of the bladder off the uterus to expose the lower uterine segment.

FIGURE 30-4 The myometrium is carefully incised to avoid cutting the fetal head.

the placenta is incised, fetal hemorrhage may be severe. Thus, delivery and cord clamping should be performed as soon as possible.

At times, a low-transverse hysterotomy is selected but provides inadequate room for delivery. In such instances, one

corner of the hysterotomy incision is extended cephalad into the contractile portion of the myometrium—a *J incision*. If this is completed bilaterally, a *U incision* is formed. Last, some prefer to extend in the midline—a *T incision*. As expected, these have been linked with higher intraoperative blood loss (Boyle, 1996; Patterson, 2002). Moreover, as these extend into the contractile portion, a trial of labor and vaginal delivery are more likely contraindicated in future pregnancies.

Delivery of the Fetus. In a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head. The head is elevated gently with the fingers and palm through the incision. Once the head enters the incision, delivery may be aided by modest transabdominal fundal pressure (Fig. 30-6).

After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. This situation can have disastrous results, and there are three considerations for delivery. First, a “push” method may be used. With this, upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and allow its delivery above the symphysis. Relief of such head impaction increases the risk of hysterotomy extension and associated blood loss as well as fetal skull fracture. As an alternative, a “pull” method is used in which the fetal legs are grasped and delivered through the hysterotomy opening. The fetus is then delivered by traction as one would complete a breech extraction. Support for this latter approach comes only from small randomized trials and case series (Bastani, 2012; Shazly, 2013; Veisi, 2012). Last, a low vertical hysterotomy incision, which will give more room for the “pull” technique, may be selected. If a low transverse

FIGURE 30-5 After entering the uterine cavity, the incision is extended laterally with fingers or with bandage scissors (*inset*).

FIGURE 30-6 Delivery of the fetal head.

incision has already been made, then this can be extended to a J-, U-, or T-incision for room.

Conversely, in women without labor, the fetal head may be unmolded and without a leading cephalic point. The round head may be difficult to lift through the uterine incision in a relatively thick lower segment that is unattenuated by labor. In such instances, either forceps or a vacuum device may be used to deliver the fetal head as shown in [Figure 30-7](#).

After head delivery, a finger should be passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. If an umbilical cord coil is felt, it should be slipped over the head. The head is rotated to an occiput transverse position, which aligns the fetal bisacromial diameter vertically. The

sides of the head are grasped with two hands, and gentle downward traction is applied until the anterior shoulder enters the hysterotomy incision ([Fig. 30-8](#)). Next, by upward movement, the posterior shoulder is delivered. During delivery, abrupt or powerful force is avoided to avert brachial plexus injury. With steady outward traction, the rest of the body then readily follows. Gentle fundal pressure may aid this.

With some exceptions, current American Heart Association neonatal resuscitation recommendations eschew suctioning immediately following birth, even with meconium present (Kattwinkel, 2010). A fuller discussion of this and the timing of umbilical cord clamping as it relates to neonatal outcome are found in Chapter 27 (p. 539). The umbilical cord is clamped, and the newborn is given to the team member who will conduct resuscitative efforts as needed (Chap. 32, p. 625).

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that “a qualified person who is skilled in neonatal resuscitation should be in the delivery room, with all equipment needed for neonatal resuscitation, to care for the neonate.” Jacob and Phenninger (1997) compared 834 cesarean deliveries with 834 low-risk vaginal deliveries. They found that with regional analgesia, there is rarely a need for infant resuscitation after elective repeat cesarean delivery or cesarean delivery for dystocia without fetal heart rate abnormalities and that a pediatrician may not be necessary at such deliveries. At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries.

After birth, an intravenous infusion containing two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min. Some prefer higher infusion dosages, however, bolus doses are avoided because of associated hypotension (Roach, 2013). Once the uterus contracts satisfactorily, the rate can be reduced. An alternative is carbetocin—a longer-acting oxytocin derivative that is not available in the United States—that provides suitable, albeit more expensive, hemorrhage

FIGURE 30-7 A. The first cesarean forceps blade is placed. **B.** Slight upward and outward traction is used to lift the head through the incision.

FIGURE 30-8 The anterior (A) and then the posterior (B) shoulder are delivered.

prophylaxis (Su, 2012). Second-tier agents are ergot-alkaloids, which carry hypertensive side effects, and misoprostol, which provides inferior postpartum hemorrhage protection compared with oxytocin. Last, the use of tranexamic acid (Cyklokapron) has recently been described in a few small studies to lower blood loss during cesarean delivery (Abdel-Aleem, 2013; Güngördük, 2011). Its antifibrinolytic action and effects on thromboembolism rates in pregnant surgical patients are unclear, and larger trials are needed before widespread use. Additional discussions of all these agents are found in Chapters 27 (p. 547) and 41 (p. 785).

Placental Delivery. The uterine incision is observed for any vigorously bleeding sites. These should be promptly clamped with Pennington or ring forceps. The placenta is then delivered unless it has already done so spontaneously. Many surgeons prefer manual removal, but spontaneous delivery, as shown in Fig. 30-9, along with some cord traction may reduce the risk of operative blood loss and infection (Anorlu, 2008; Baksu, 2005). Fundal massage may begin as soon as the fetus is delivered to hasten placental separation and delivery.

Immediately after delivery and gross inspection of the placenta, the uterine cavity is suctioned and wiped out with a gauze sponge to remove avulsed membranes, vernix, and clots. Previously, double-gloved fingers or ring forceps placed through the hysterotomy incision were used to dilate an ostensibly closed cervix. This practice does not improve infection rates from potential hematometra and is not recommended (Güngördük, 2009; Liabsuetrakul, 2011).

Uterine Repair. After placental delivery, the uterus is lifted through the incision onto the draped abdominal wall, and the fundus is covered with a moistened laparotomy sponge. Although some clinicians prefer to avoid such uterine exteriorization, it often has benefits that outweigh its disadvantages. For example, the relaxed, atonic uterus can be recognized quickly and massage applied. The incision and bleeding points are more easily visualized and repaired, especially if there have been extensions. Adnexal exposure is superior, and thus, tubal sterilization is easier. The principal disadvantage is discomfort

FIGURE 30-9 Placenta bulging through the uterine incision as the uterus contracts. A hand gently massages the fundus to help aid placental separation.

and vomiting caused by traction in cesarean deliveries performed under regional analgesia. Importantly, rates of febrile morbidity or blood loss do not appear to be increased with uterine exteriorization (Coutinho, 2008; Walsh, 2009).

Before hysterotomy closure, previously clamped large vessels may be ligated separately or incorporated within the running incision closure. One angle of the uterine incision is grasped to stabilize and maneuver the incision. The uterine incision is then closed with one or two layers of continuous 0- or No. 1 absorbable suture (Fig. 30-10). Chromic suture is used by many, but some prefer synthetic delayed-absorbable sutures. Single-layer closure is typically faster and is not associated with higher rates of infection or transfusion (CAESAR study collaborative group, 2010; Dodd, 2008; Hauth, 1992). Moreover, most studies observed that the type of uterine closure does not significantly affect complications in the next pregnancy (Chapman, 1997; Durnwald, 2003; Roberge, 2011).

At Parkland Hospital, we favor the one-layer uterine closure. The initial suture is placed just beyond one angle of the uterine incision. A running-lock suture for hemostasis is then performed, with each suture penetrating the full thickness of the myometrium. Concern has been expressed by some clinicians that sutures through the decidua may lead to endometriosis or adenomyosis in the hysterotomy scar, but this is rare. It is important to carefully select the site of each stitch and to avoid withdrawing the needle once it penetrates the myometrium. This minimizes perforation of unligated vessels and subsequent bleeding. The running-lock suture is continued just beyond the opposite incision angle. If approximation is not satisfactory

after a single-layer continuous closure or if bleeding sites persist, then more sutures are required. Either another layer of running suture is placed to achieve approximation and hemostasis, or individual bleeding sites can be secured with figure-of-eight or mattress sutures.

Traditionally, serosal edges overlying the uterus and bladder have been approximated with a continuous 2-0 chromic catgut suture. Multiple randomized trials suggest that omission of this step causes no postoperative complications (Grundsell, 1998; Irion, 1996; Nagele, 1996). If tubal sterilization is to be performed, it is now done as described in Chapter 39 (p. 720).

Adhesions

Following cesarean delivery, adhesions commonly form within the vesicouterine space or between the anterior abdominal wall and uterus. And with each successive pregnancy, the percentage of affected women and adhesion severity increases (Morales, 2007; Tulandi, 2009). Adhesions can significantly lengthen incision-to-delivery times and total operative time (Rossouw, 2013; Sikirica, 2012). Although occurring infrequently, rates of cystotomy and bowel injury are also increased (Rahman, 2009; Silver, 2006).

Intuitively, scarring can be reduced by handling tissues delicately, achieving hemostasis, and minimizing tissue ischemia, infection, and foreign-body reaction. Data are conflicting regarding closure of the bladder flap (visceral peritoneum) or of the abdominal cavity (parietal peritoneum) and its effect on subsequent adhesions. Some note benefit from closure of one, but not the other, or neither (CAESAR study collaborative group, 2010; Cheong, 2009; Kapustian, 2012; Lyell, 2005, 2012).

Benefit from placement of an adhesion barrier at the repaired hysterotomy site is limited to only two nonrandomized studies (Chapa, 2011; Fushiki, 2005). Currently, there is an ongoing multicenter randomized trial to evaluate use of the barrier *Seprafilm* at the time of cesarean delivery (National Institutes of Health, 2012).

Abdominal Closure

Any laparotomy sponges are removed, and the paracolic gutters and cul-de-sac are gently suctioned of blood and amniotic fluid. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. Routine irrigation in low-risk women, however, leads to greater intraoperative nausea and without lower postoperative infection rates (Harrigill, 2003; Viney, 2012).

After sponge and instrument counts are found to be correct, the abdominal incision is closed in layers. Many surgeons omit the parietal peritoneal closure. In addition to ambiguity regarding adhesion prevention, data are also conflicting as to whether nonclosure of parietal peritoneum decreases postoperative discomfort and analgesia requirements (Chanrachakul, 2002; Lyell, 2005; Rafique, 2002). However, if there is distended bowel in the incision site, we find that peritoneal closure may help to protect the bowel when fascial sutures are placed.

As each layer is closed, bleeding sites are located, clamped, and ligated or coagulated with an electrosurgical blade. The

FIGURE 30-10 The cut edges of the uterine incision are approximated with a running-lock suture anchored at either angle of the incision.

rectus abdominis muscles are allowed to fall into place. With significant diastasis, the rectus muscles may be approximated with one or two figure-of-eight sutures of 0 or No. 1 chromic gut suture. The overlying rectus fascia is closed by a continuous, nonlocking technique with a delayed-absorbable suture. In patients with a higher risk for infection, there may be theoretical value in selecting a monofilament suture here rather than braided material.

The subcutaneous tissue usually need not be closed if it is less than 2 cm thick. With thicker layers, however, closure is recommended to minimize seroma and hematoma formation, which can lead to wound infection and/or disruption (Bohman, 1992; Chelmow, 2004). Addition of a subcutaneous drain does not prevent significant wound complications (Hellums, 2007; Ramsey, 2005). Skin is closed with a running subcuticular stitch using 4-0 delayed-absorbable suture or with staples. In comparison, final cosmetic results and infection rates appear similar, skin suturing takes longer, but wound separation rates are higher with staples (Basha, 2010; Figueroa, 2013; Mackeen, 2012; Tuuli, 2011).

Joel-Cohen and Misgav-Ladach Techniques

The Pfannenstiel-Kerr technique just described has been used for decades. More recently, the Joel-Cohen and Misgav-Ladach modifications have been described. These differ from traditional Pfannenstiel-Kerr entry mainly by their initial incision placement and greater use of blunt dissection.

The Joel-Cohen technique creates a straight 10-cm transverse skin incision 3 cm below the level of the anterior superior iliac spines. The subcutaneous tissue layer is opened sharply 2 to 3 cm in the midline. This is carried down, without lateral extension, to the fascia. A small transverse incision is made in the fascia, and a finger from each hand is hooked into the lateral angles of this fascial incision. The incision is then stretched transversely. Once the fascia is opened and rectus abdominis muscle bellies identified, an index finger from each hand is inserted between the bellies. One is moved cranially and the other caudally, in opposition, to further separate the bellies. Index finger dissection is used to enter the peritoneum, and again, cranial and caudad opposing stretch with index fingers will open this layer. All the layers of the abdominal wall are then manually stretched laterally in opposition to further open the incision. The visceral peritoneum is incised in the midline above the bladder, and the bladder is bluntly reflected inferiorly to separate it from the underlying lower uterine segment. The myometrium is incised transversely in the midline and then opened and extended laterally with one finger hooked into each corner of the hysterotomy incision. Interrupted sutures are used for hysterotomy closure. Neither visceral nor parietal peritoneum is closed. The Misgav-Ladach technique is similar and differs mainly in that myometrial incision closure is completed with a single-layer locking continuous suture (Hofmeyr, 2009; Holmgren, 1999).

These techniques have been associated with shorter operative times and with lower rates of intraoperative blood loss and postoperative pain (Hofmeyr, 2008). They may, however, prove difficult for women with anterior rectus fibrosis and peritoneal adhesions (Bolze, 2013). Moreover, long-term outcomes

with these techniques, such as subsequent uterine rupture, are unknown.

Classical Cesarean Incision

This incision is usually avoided because it encompasses the active upper uterine segment and thus is prone to rupture with subsequent pregnancies.

Indications. A classical incision is occasionally preferred for delivery. Some indications stem from difficulty in exposing or safely entering the lower uterine segment. For example, a *densely adhered bladder* from previous surgery is encountered; a *leiomyoma* occupies the lower uterine segment; the cervix has been *invaded by cancer*; or *massive maternal obesity* precludes safe access to the lower uterine segment. A classical incision is also preferred in some cases of *placenta previa with anterior implantation*, especially those complicated by placenta accrete syndromes.

In other instances, fetal indications dictate the need. *Transverse lie of a large fetus*, especially if the membranes are ruptured and the shoulder is impacted in the birth canal, usually necessitates a classical incision. A fetus presenting as a back-down transverse lie is particularly difficult to deliver through a transverse uterine incision. In instances when the fetus is very small, especially if breech, a classical incision may be preferable (Osmundson, 2013). In such cases, the poorly developed lower uterine segment provides inadequate space for the manipulations required for breech delivery. Or, less commonly, the small fetal head may become entrapped by a contracting uterine fundus following membrane rupture. Last, with multiple fetuses, a classical incision again may be needed to provide suitable room for extraction of fetuses that may be malpositioned or preterm.

Uterine Incision and Repair. A vertical uterine incision is initiated with a scalpel beginning as low as possible and preferably within the lower uterine segment (Fig. 30-11). If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Once the uterus is entered with a scalpel, the incision is extended cephalad with bandage scissors until it is long enough to permit delivery of the fetus. With scissor use, the fingers of the nondominant hand are insinuated between the myometrium and fetus to prevent fetal laceration. As the incision is opened, numerous large vessels that bleed profusely are commonly encountered within the myometrium. The remainder of fetal and placental delivery mirrors that with a low transverse hysterotomy.

For incision closure, one method employs a layer of 0- or No. 1 chromic catgut with a continuous stitch to approximate the deeper halves of the incision (Fig. 30-12). The outer depth of myometrium is then closed with similar suture and with a running stitch or figure-of-eight sutures. No unnecessary needle tracks should be made lest myometrial vessels be perforated, leading to subsequent hemorrhage or hematomas. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant compress the uterus on each side of the wound toward the midline as each stitch is placed.

FIGURE 30-11 An initial small vertical hysterotomy incision is made in the lower uterine segment. Fingers are insinuated between the myometrium and fetus to avoid fetal laceration. Scissors extend the incision cephalad as needed for delivery.

PERIPARTUM HYSTERECTOMY

Indications

Hysterectomy is more commonly performed during or after cesarean delivery but may be needed following vaginal birth. If all deliveries are considered, the rate ranges from 0.4 to 2.5 per 1000 births and has risen significantly during the past few decades. During a 25-year period, the rate of peripartum hysterectomy at Parkland Hospital was 1.7 per 1000 births (Hernandez, 2012). Most of this increase is attributed to the increasing rates of cesarean delivery and its associated complications in subsequent pregnancy (Bateman, 2012; Bodelon, 2009; Flood, 2009; Orbach, 2011). Of hysterectomies, approximately one half to two thirds are total, whereas the remaining cases are supracervical (Rossi, 2010; Shellhaas, 2009).

Cesarean hysterectomies are most commonly performed to arrest or prevent hemorrhage from intractable uterine atony or abnormal placentation (Bateman, 2012; Hernandez, 2012; Owolabi, 2013). These as well as other less frequent indications are found in Table 30-3. For example, large leiomyomas may preclude satisfactory hysterotomy closure and necessitate hysterectomy. Or, postpartum infectious morbidity from an infected, necrotic uterus will prompt uterine removal for recovery (Fig. 37-4, p. 688). Logically, risk factors for

FIGURE 30-12 Classical incision closure. The deeper half (A) and superficial half (B) of the incision are closed in a running fashion.

peripartum hysterectomy mirror the risks of these indicated complications, which are described throughout the text.

Major complications of peripartum hysterectomy include increased blood loss and greater risk of urinary tract damage. Blood loss is usually appreciable because hysterectomy is being

TABLE 30-3. Some Indications for Peripartum Hysterectomy

Ovarian neoplasia

performed for hemorrhage that frequently is torrential, and the procedure itself is associated with substantial blood loss. Although many cases with such hemorrhage cannot be anticipated, those with abnormal implantation can often be identified antepartum. Preoperative preparations for placenta accreta are discussed in Chapter 41 (p. 807) and have also been outlined by the Society for Maternal-Fetal Medicine (2010) and American College of Obstetricians and Gynecologists (2012c).

An important factor affecting the cesarean hysterectomy complication rate is whether the operation is performed electively or emergently (Briery, 2007). After anticipated or planned cesarean hysterectomy, there are lower rates of blood loss, less need for blood transfusions, and fewer urinary tract complications compared with emergent procedures (Briery, 2007; Glaze, 2008; Sakse, 2007).

■ Peripartum Hysterectomy Technique

Supracervical or total hysterectomy is performed using standard operative techniques. For this, adequate exposure is essential. Initially, placement of a self-retaining retractor such as a Balfour is not necessary. Rather, satisfactory exposure is obtained with cephalad traction on the uterus by an assistant, along with handheld retractors such as a Richardson or Deaver. The bladder flap is deflected downward to the level of the cervix if possible to permit total hysterectomy. In cases in which cesarean hysterectomy is planned or strongly suspected, extended bladder flap dissection is ideally completed before initial hysterotomy. Later attempts at bladder dissection may be obscured by bleeding, or excess blood may be lost while this dissection is performed.

FIGURE 30-13 The round ligaments are clamped, doubly ligated, and transected bilaterally.

FIGURE 30-14 The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, utero-ovarian ligaments, and ovarian vessels.

FIGURE 30-15 The utero-ovarian ligament and fallopian tube are doubly clamped and cut bilaterally. The lateral pedicle is doubly ligated.

FIGURE 30-16 The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligament.

FIGURE 30-17 The bladder is dissected sharply from the lower uterine segment.

After cesarean delivery, the placenta is typically removed. In cases of placenta accrete syndromes, in which hysterectomy is already planned, the placenta is usually left undisturbed in situ. In either situation, if the hysterotomy incision is bleeding appreciably, it can be sutured or Pennington or sponge forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligaments are divided close to the uterus between Kocher clamps and doubly ligated (**Fig. 30-13**). Either 0 or No. 1 suture can be used in either chromic gut or delayed-absorbable material. The incision in the vesicouterine serosa that was made to mobilize the bladder is extended laterally and upward through the anterior leaf of the broad ligament to reach the incised round ligaments. The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tubes, uteroovarian ligaments, and ovarian vessels (**Fig. 30-14**). These structures together are then doubly clamped close to the uterus and divided, and the lateral pedicle is doubly ligated (**Fig. 30-15**). The posterior leaf of the broad ligament is divided toward the uterosacral ligaments (**Fig. 30-16**). Next, the bladder and attached peritoneal flap are further deflected and dissected as needed from the lower uterine segment and retracted out of the operative field. If the bladder flap is unusually adhered, as it may be after previous hysterotomy incisions, careful sharp dissection may be necessary (**Fig. 30-17**).

Special care is required from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, an assistant places constant traction to pull the uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified near their origin. These pedicles are then doubly clamped immediately adjacent to the uterus, divided, and doubly suture ligated. As shown in **Figure 30-18**, we prefer to use three heavy clamps—Heaney or Ballantine—to incise the tissue between the most medial clamps, and then ligate the pedicle in the clamps lateral to the uterus.

With cesarean hysterectomy, it may be more advantageous in cases of profuse hemorrhage to rapidly double clamp and divide all of the vascular pedicles between clamps to gain hemostasis. The operator can then return to ligate all of the pedicles.

Total Hysterectomy

Even if total hysterectomy is planned, we find it in many cases technically easier to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the cervical stump for traction and hemostasis.

FIGURE 30-18 **A.** The uterine artery and veins on either side are doubly clamped immediately adjacent to the uterus and divided. A third medial clamp will prevent “back bleeding.” **B & C.** The vascular pedicle is doubly suture ligated.

Self-retaining retractors also may be placed at this time. To remove the cervix, the bladder is mobilized further if needed. This carries the ureters caudad as the bladder is retracted beneath the symphysis and will prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure.

If the cervix is effaced and dilated considerably, its softness may obscure palpable identification of the cervicovaginal junction. The junction location can be ascertained through a vertical uterine incision made anteriorly in the midline, either through the open hysterotomy incision or through an incision created at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix and the anterior vaginal fornix. The contaminated glove is replaced. Another useful method to identify the cervical margins is to transvaginally place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges in cases of planned hysterectomy.

The cardinal ligaments, the uterosacral ligaments, and the many large vessels these ligaments contain are clamped systematically with Heaney-type curved or straight clamps ([Fig. 30-19](#)). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised, and the lateral pedicle is suture ligated. These steps are repeated caudally until the level of the lateral vaginal fornix is reached. In this way, the descending branches of the uterine vessels are clamped,

cut, and ligated as the cervix is dissected from the cardinal ligaments.

Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix, and the tissue is incised above the clamp ([Fig. 30-20](#)). The excised lateral vaginal fornix can be simultaneously doubly ligated and sutured to the stump of the cardinal ligament. The cervix is inspected to ensure that it has been completely removed, and the vagina is then repaired. Each of the angles of the lateral vaginal fornix is secured to the cardinal and uterosacral ligaments to mitigate later vaginal prolapse ([Fig. 30-21](#)). Following this step, some surgeons prefer to close the vagina using figure-of-eight sutures. Others achieve hemostasis by using a running-lock stitch placed through the mucosa and adjacent endopelvic fascia around the circumference of the vaginal cuff ([Fig. 30-22](#)).

If a self-retaining retractor has not already been placed, some clinicians choose to insert one at this point. The bowel is then packed out of the field, and all sites are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters. The abdominal wall normally is closed in layers, as previously described for cesarean delivery (p. 597).

Supracervical Hysterectomy

To perform a subtotal hysterectomy, the uterine body is amputated immediately above the level of uterine artery ligation. The

FIGURE 30-19 The cardinal ligaments are clamped, incised, and ligated.

cervical stump may be closed with continuous or interrupted chromic catgut sutures of 0 or No. 1 gauge. Subtotal hysterectomy is often all that is necessary to stop hemorrhage. It may be preferred for women who would benefit from a shorter surgery or for those with extensive adhesions that threaten significant urinary tract injury.

FIGURE 30-20 A curved clamp is placed across the lateral vaginal fornix below the level of the cervix, and the tissue incised medially to the point of the clamp.

FIGURE 30-21 The lateral angles of the vaginal cuff are secured to the cardinal and uterosacral ligaments.

Salpingo-Oophorectomy

Because of the large adnexal vessels and their close proximity to the uterus, it may be necessary to remove one or both adnexa to obtain hemostasis. Briery and colleagues (2007) reported unilateral or bilateral oophorectomy in a fourth of cases. Preoperative counseling should include this possibility.

FIGURE 30-22 A running-lock suture approximates the vaginal wall edges.

FIGURE 30-23 Cystotomy repair. **A.** The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayed-absorbable or absorbable suture. **B.** Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure.

Cystotomy

Rarely, and usually in women who have had a previous cesarean delivery, the bladder may be lacerated. This complication may occur during cesarean delivery, but it is more common with cesarean hysterectomy, especially if there is abnormal placental implantation.

Bladder injury is typically identified at the time of surgery, and initially, a gush of clear fluid into the operating field may be seen. If cystotomy is suspected, it may be confirmed with retrograde instillation of sterile infant formula through a Foley catheter into the bladder. Leakage of opaque milk aids in laceration identification and delineation of its borders. In some cases, cystoscopy may be indicated to further define bladder injury. Primary repair is preferred and lowers the risk of postoperative vesicovaginal fistula formation. Once ureteral patency is confirmed, the bladder may be closed with a two- or three-layer running closure using a 3-0 absorbable or delayed-absorbable suture (Fig. 30-23). The first layer inverts the mucosa into the bladder, and subsequent layers reapproximate bladder muscularis. Postoperative care requires continuous bladder drainage for 7 to 10 days.

PERIPARTUM MANAGEMENT

Intravenous Fluids

During and after cesarean delivery, requirements for intravenous fluids can vary considerably. Intravenously administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5-percent dextrose. Typically, at least 2 to 3 L is infused during surgery. Blood loss with uncomplicated

cesarean delivery approximates 1000 mL. The average-sized woman with a hematocrit of 30 percent or more and with a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both commonly lead to underestimation.

Blood loss averages 1500 mL with elective cesarean hysterectomy, although this is variable (Pritchard, 1965). Most peripartum hysterectomies are unscheduled, and blood loss in these cases is correspondingly greater. Thus, in addition to close monitoring of vital signs and urine output, the hematocrit should be determined intra- or postoperatively as indicated (Chap. 41, p. 781).

Recovery Suite

Close monitoring of the amount of vaginal bleeding is necessary for at least an hour in the immediate postoperative period. The uterine fundus is also identified frequently by palpation to ensure that the uterus remains firmly contracted. Unfortunately, as conduction analgesia fades or the woman awakens from general anesthesia, abdominal palpation is likely to produce pain. An analgesic given by intermittent intravenous injection can be effective (Table 30-4). A sterile thin abdominal wound dressing is sufficient, and indeed, a thick, heavily taped padded dressing will interfere with fundal palpation and massage. Deep breathing and coughing are encouraged. Once regional analgesia begins to fade or the woman becomes fully awake following general anesthesia, criteria for transfer to the postpartum ward include minimal bleeding, stable vital signs, and adequate urine output.

TABLE 30-4. Typical Settings for Administration of Intravenous Opioids via a Patient-Controlled Analgesia Pump**Recovery room:**

IV meperidine, 25 mg every 5 min up to 100 mg

or

IV morphine, 2 mg every 5 min up to 10 mg

Postpartum ward (first 24 hr after surgery)^a:

IM meperidine, 50–75 mg every 3–4 hr as needed

or

PCA intravenous meperidine, 10 mg with a 6 min lockout interval and maximum dose of 200 mg in 4 hr as needed. An additional 25-mg booster dose is permitted for a maximum of 2 doses

or

IM morphine, 10–15 mg every 3–4 hr as needed

or

PCA intravenous morphine, 1 mg with a 6-min lockout interval and maximum dose of 30 mg in 4 hr as needed. An additional 2-mg booster dose is permitted for a maximum of 2 doses

^aEach postpartum ward regimen also included promethazine, 25 mg intravenously every 6 hr as needed for nausea.

IM = intramuscular; IV = intravenous; PCA = patient-controlled analgesia.

From Yost, 2004, with permission.

Hospital Care until Discharge**Analgesia, Vital Signs, Intravenous Fluids**

A number of schemes are suitable for postoperative pain control. Some basic regimens are shown in Table 30-4. In a trial at Parkland Hospital, Yost and associates (2004) found that morphine provided superior pain relief to meperidine and was associated with significantly higher rates of breast feeding and continuation of infant rooming in. Breast feeding can be initiated the day of surgery. If the mother elects not to breast feed, a binder that supports the breasts without marked compression usually will minimize discomfort (Chap. 36, p. 675).

After transfer to her room, the woman is assessed at least hourly for 4 hours, and thereafter at intervals of 4 hours. Vital signs, uterine tone, urine output, and bleeding are evaluated. The hematocrit is routinely measured the morning after surgery. It is checked sooner if there was unusual blood loss or if there is hypotension, tachycardia, oliguria, or other evidence to suggest hypovolemia. If the hematocrit is decreased significantly from the preoperative level, the measurement is repeated and a search is instituted to identify the cause. If the hematocrit stabilizes, the mother can be allowed to ambulate, and if there is little likelihood of further blood loss, iron therapy is preferred to transfusion.

As described in Chapter 36 (p. 671), the puerperium is characterized by excretion of fluid that was retained during

pregnancy. At least with elective cesarean delivery, significant extracellular fluid sequestration in the bowel wall and lumen does not occur, unless perhaps it was necessary to pack the bowel away from the operative field. Thus, the woman who undergoes routine cesarean delivery rarely develops fluid sequestration in the extracellular space. On the contrary, she normally begins surgery with a physiologically enlarged extravascular volume acquired during pregnancy that she mobilizes and excretes after delivery. As a generalization, 3 L of fluid should prove adequate during the first 24 hours after surgery. If urine output falls below 30 mL/hr, however, the woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Women undergoing unscheduled cesarean delivery may have pathological retention or constriction of the extracellular fluid compartment caused by severe preeclampsia, sepsis syndrome, vomiting, prolonged labor without adequate fluid intake, and increased blood loss.

Bladder and Bowel Function

The Foley catheter most often can be removed by 12 hours postoperatively, or more conveniently, the morning after surgery. The prevalence of urinary retention following cesarean delivery approximates 3 to 7 percent. Regional analgesia and failure to progress in labor are identified risks (Chai, 2008; Liang, 2007). Thus, surveillance for bladder overdistention should be implemented as with vaginal delivery.

In uncomplicated cases, solid food may be offered within 8 hours of surgery (Bar, 2008; Orji, 2009). Although some degree of adynamic ileus follows virtually every abdominal operation, in most cases of cesarean delivery, it is negligible. Symptoms include abdominal distention, gas pains, and an inability to pass flatus or stool. The pathophysiology of postoperative ileus is complex and involves inflammatory and neural factors that are incompletely understood (van Bree, 2012). If associated with otherwise unexplained fever, an unrecognized bowel injury may be responsible. Treatment for ileus has changed little during the past several decades and involves intravenous fluid and electrolyte supplementation. If severe, nasogastric decompression is necessary.

Ambulation and Wound Care

As discussed on page 590, women undergoing cesarean delivery have an increased risk of venous thromboembolism compared with those delivering vaginally. Additional risks include age > 35; obesity; parity > 3; emergency cesarean; cesarean hysterectomy; concurrent infection, major illness, preeclampsia, or gross varicosities; recent immobility; and prior deep-vein thrombosis or thrombophilia (Marik, 2008). Postoperative thromboprophylaxis is discussed in Chapter 52 (p. 1045). Early ambulation lowers the risk of venous thromboembolism. In most instances, by the day after surgery, a woman should get briefly out of bed with assistance at least twice to walk. Ambulation can be timed so that a recently administered analgesic will minimize discomfort. By the second day, she may walk without assistance.

The incision is inspected each day, and skin sutures or clips often can be removed on the fourth postoperative day. If there

is concern, however, for superficial wound separation—for example, in obese patients—the suture or clips should remain in place for 7 to 10 days. By the third postpartum day, showering is not harmful to the incision.

Hospital Discharge

Unless there are complications during the puerperium, the mother generally is discharged on the third or fourth postpartum day (Buie, 2010). Data from small studies suggest that earlier discharge may be feasible for properly selected and motivated women (Strong, 1993; Tan, 2012). Activities during the first week should be restricted to self-care and newborn care with assistance. Driving can be resumed when pain does not limit the ability to brake quickly and when narcotic medications are not in use. Return to work is variable. Six weeks is commonly cited, although many women use the Family and Medical Leave Act to allow up to 12 weeks for recovery and newborn bonding.

CHAPTER 31

Prior Cesarean Delivery

100 YEARS OF CONTROVERSY	609
FACTORS THAT INFLUENCE A TRIAL OF LABOR	610
TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY	610
CANDIDATES FOR A TRIAL OF LABOR	612
LABOR AND DELIVERY CONSIDERATIONS	615
UTERINE RUPTURE	617
COMPLICATIONS WITH MULTIPLE REPEAT CESAREAN DELIVERIES	618
STATE OF VAGINAL BIRTH AFTER CESAREAN—2014	618

Once a cesarean, always a cesarean.
Cragin, 1916

Once a cesarean, always a trial of labor?
Pauerstein, 1966

Once a cesarean, always a controversy.
Flamm, 1997

Few issues in modern obstetrics have been as controversial as the management of the woman who has undergone a prior cesarean delivery. As we approach the 100th anniversary of the oft-quoted remark by Cragin, the issue remains unsettled.

100 YEARS OF CONTROVERSY

Management of the woman who has undergone a previous cesarean delivery has been—for good reasons—a controversial topic for more than 100 years. By the beginning of the 20th century, cesarean delivery had become relatively safe. But, as

women survived the first operation and conceived again, they were now at risk for uterine rupture. This was because of the prevailing use of vertical hysterotomy—and especially the classical incision (Williams, 1903). The inherent dangers of uterine rupture led to the dictum above by Edwin B. Cragin (1916). It was not until later that Kerr (1921) described use of a transverse low-segment uterine incision that was predicted to be less likely to rupture with subsequent labor.

Perhaps contrary to popular belief, these events did not result in strict adherence to repeat cesarean delivery. In the 10th edition of *Williams Obstetrics*, Eastman (1950) stated a preference for vaginal delivery in these women and described a 30-percent vaginal delivery rate at Johns Hopkins Hospital. But while only 2 percent of women who labored had a uterine rupture, they had a 10-percent maternal mortality rate. Subsequent observational studies from the 1960s also suggested that vaginal delivery was a reasonable option (Pauerstein 1966, 1969). Germane to this is that through the 1960s, the overall cesarean delivery rate was only approximately 5 percent. Beginning then, however, well-intentioned efforts to improve perinatal outcomes were accompanied by a rapidly escalating cesarean delivery rate that exceeded 20 percent by 1985 (Chap. 30, p. 587). In addition, the concept of *cesarean delivery on maternal request* has increased the primary operation rate (American College of Obstetricians and Gynecologists, 2013b). And as expected, as the primary cesarean rate increased, the rate for repeat operations followed (Rosenstein, 2013).

To address this, a National Institutes of Health (NIH) Consensus Development Conference (1981) was convened, and it questioned the necessity of routine repeat cesarean delivery. With support and encouragement from the American College of Obstetricians and Gynecologists (1988, 1994), enthusiastic attempts were begun to increase the use of *vaginal birth after cesarean—VBAC*. These attempts were highly successful, and VBAC rates increased from 3.4 percent in 1980 to a peak of 28.3 percent in 1996. These rates, along with a concomitant

FIGURE 31-1 Total and primary cesarean delivery (CS) rates and vaginal birth after previous cesarean (VBAC) rate: United States, 1989–2010. Epochs denoted within rectangles represent contemporaneous ongoing events related to these rates. (Data from National Institutes of Health: NIH Consensus Development Conference, 2010; Martin, 2012a,b).

decline in total cesarean delivery rates for the United States, are shown in Figure 31-1.

As the vaginal delivery rate increased, so did reports of uterine rupture-related maternal and perinatal morbidity and mortality (McMahon, 1996; Sachs, 1999). These dampened prevailing enthusiasm for a *trial of labor* and stimulated the American College of Obstetricians and Gynecologists (1998) to caution that such trials should be attempted only in appropriately equipped institutions with physicians *readily available* to provide emergency care. Less than a year later, the College (1999) recommended that physicians should be *immediately available*. Many believe that this one-word change—from *readily* to *immediately* available—was in large part responsible for the decade-long decline in national VBAC rates illustrated in Figure 31-1 (Cheng, 2014; Leeman, 2013). The VBAC rate leveled at approximately 8 percent by 2009 and 2010, while the total cesarean delivery rate increased to 32.8 percent in 2011 (Martin, 2011, 2012a,b). Because the success rate of a trial of labor resulting in a VBAC is not 100 percent, another way of examining these changes was described by Uddin and colleagues (2013). These investigators reported the proportion of women with a prior cesarean delivery who underwent a trial of labor. This number peaked in 1997, when slightly more than half of all of these women chose a trial of labor. Thereafter, this percentage plummeted and reached a nadir of about 16 percent in 2005. Since that time, the proportion has increased and averaged 20 to 25 percent through 2009. Ironically, during this same decade, there were continuing reports that described the success and safety of VBAC in selected clinical settings.

In reality, there are several other interrelated factors—both medical and nonmedical—that have undoubtedly contributed to declining VBAC rates. Because of their complexity and importance, the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) and the Office of Medical Applications of Research (OMAR) convened

a National Institutes of Health Consensus Development Conference Panel (2010) to study these issues. The Panel report included a contemporaneous summary concerning the risks and benefits of repeat cesarean versus vaginal delivery. These findings are subsequently described along with summaries of current recommendations by various professional organizations. However, data from California indicate that VBAC rates have not perceptibly increased since the 2010 NIH Consensus Conference that encouraged greater access to a trial of labor after cesarean delivery (Barger, 2013).

FACTORS THAT INFLUENCE A TRIAL OF LABOR

Delivery planning for the woman who has had a previous cesarean delivery can begin with preconceptional counseling, but should definitely be addressed early in prenatal care. Importantly, any decision arrived

at is subject to continuing revisions as dictated by exigencies that arise during the course of pregnancy. Assuming no mitigating circumstances, there are two basic choices. First is a *trial of labor after cesarean (TOLAC)* with the goal of achieving VBAC. If cesarean delivery becomes necessary during the trial, then it is termed a “failed trial of labor.” A second choice is *elective repeat cesarean delivery (ERCD)*. This includes scheduled cesarean delivery as well as unscheduled but planned cesarean delivery for spontaneous labor or another indication.

Selection should consider factors known to influence a successful trial of labor as well as benefits and risks. In general, appropriately selected women who attempt VBAC have success rates that approximate 75 percent. These rates vary between institutions and providers and are affected by prepregnancy, antepartum, intrapartum, and nonmedical factors.

Some medical variables that influence a successful trial of labor are listed in Table 31-1. As for economical and medicolegal factors, professional liability concerns and insufficient resources to provide adequate staffing for hospitals to accommodate a trial of labor weigh heavily.

TRIAL OF LABOR VERSUS REPEAT CESAREAN DELIVERY

As evidence mounted that the risk of uterine rupture and perinatal morbidity and mortality might be greater than expected, the American College of Obstetricians and Gynecologists (1988, 1998, 1999, 2013a) issued updated Practice Bulletins supporting labor trials but also urging a more cautious approach. It is problematic that both options have risks and benefits to mother and fetus but that these are not always congruent.

Maternal Risks

Uterine rupture and its associated complications clearly are increased with a trial of labor. It is this increased risk that

TABLE 31-1. Some Factors That Influence a Successful Trial of Labor in a Woman with Prior Cesarean Delivery

Low-Risk	Favors Success	Increased Failure Rate	High-Risk ^a
Transverse incision	Teaching hospital	Single mother	Classical or T incision
Prior vaginal delivery	White race	Increased maternal age	Prior rupture
Appropriate counseling	Spontaneous labor	Macrosomic fetus	Patient refusal
Sufficient personnel and equipment	Prior fetal malpresentation	Obesity	Transfundal surgery
	1 or 2 prior transverse incisions	Breech	Obstetrical contraindication, e.g., previa
	Nonrecurrent indication	Multifetal pregnancy	Inadequate facilities
	Current preterm pregnancy	Preeclampsia	
		EGA > 40 weeks	
		Low-vertical incision	
		Unknown incision	
		Labor induction	
		Medical disease	
		Multiple prior cesarean deliveries	
		Education < 12 years	
		Short interdelivery interval	
		Liability concerns	

^aMost consider these absolute contraindications.

EGA = estimated gestational age.

underpins most of the angst in attempting a trial of labor. Despite this, some have argued that these factors should weigh only minimally in the decision to attempt a trial because their absolute risk is low. One of the largest and most comprehensive studies designed to examine risks associated with vaginal birth in women with a prior cesarean delivery was conducted by the Maternal-Fetal Medicine Units (MFMU) Network (Landon, 2004). In this prospective study conducted at 19 academic

medical centers, the outcomes of nearly 18,000 women who attempted a trial of labor were compared with those of more than 15,000 women who underwent elective repeat cesarean delivery. As shown in Table 31-2, although the risk of uterine rupture was higher among women undergoing a trial of labor, the absolute risk was small—only 7 per 1000. To the contrary, however, there were no uterine ruptures in the elective cesarean delivery group. Not surprisingly, rates of stillbirth

TABLE 31-2. Complications in Women with a Prior Cesarean Delivery Enrolled in the NICHD Maternal-Fetal Medicine Units Network, 1999–2002

Complication	Trial of Labor Group n = 17,898 No. (%)	Elective Repeat Cesarean Group n = 15,801 No. (%)	Odds Ratio (95% CI)	p value

^aDenominator is 15,338 for the trial of labor group and 15,014 for the elective repeat cesarean delivery group.

CI = confidence interval; HIE = hypoxic ischemic encephalopathy; NA = not applicable; NICHD = National Institute of Child Health and Human Development; NS = not significant.

Adapted from Landon, 2004.

and hypoxic ischemic encephalopathy were significantly greater in the trial of labor arm. Others have reported similar results (Chauhan, 2003; Mozurkewich, 2000). In one study of nearly 25,000 women with a prior cesarean delivery, perinatal death risk was 1.3 per 1000 among the 15,515 women who had a trial of labor (Smith, 2002). Although the absolute risk is small, it is *11 times greater* than the risk found in 9014 women with a planned repeat cesarean delivery.

Most studies suggest that the maternal *mortality* rate does not differ significantly between women undergoing a trial of labor compared with those undergoing an elective repeat cesarean delivery (Landon, 2004; Mozurkewich, 2000). One outlier was a retrospective cohort study of more than 300,000 Canadian women with a prior cesarean delivery (Wen, 2005). In this study, the maternal death rate for women undergoing an elective repeat cesarean delivery was 5.6 per 100,000 compared with 1.6 per 100,000 for those having a trial of labor.

Estimates of maternal *morbidity* have also produced conflicting results. In the metaanalysis by Mozurkewich and Hutton (2000), women undergoing a trial of labor were approximately half as likely to require a blood transfusion or hysterectomy compared with those undergoing repeat cesarean delivery. Conversely, in the MFMU Network study, Landon and coworkers (2004) observed that the risks of transfusion and infection were significantly greater for women attempting a trial of labor (see Table 31-2). Rossi and D'Addario (2008) reported similar findings in their metaanalysis. McMahon and associates (1996), in a population-based study of 6138 women, found that major complications—hysterectomy, uterine rupture, or operative injury—were almost twice as common in women undergoing a trial of labor compared with those undergoing an elective cesarean delivery. *Importantly, compared with a successful trial of labor, the risk of these major complications was fivefold greater in women whose attempted vaginal delivery failed.* The metaanalysis cited above also reported an increased incidence of overall maternal complications when women with a failed vaginal delivery were compared with those undergoing successful vaginal delivery—17 versus 3 percent, respectively (Rossi, 2008). Similar findings have been reported from the Network Cesarean Registry (Babbar, 2013).

■ Fetal and Neonatal Risks

The Panel found little or no evidence regarding short- and long-term neonatal outcomes after TOLAC versus ERCD. Most of the available evidence documents differences comparing *actual* rather than *intended* mode of delivery and is of low quality. A trial of labor is associated with significantly higher *perinatal mortality* rates compared with ERCD—perinatal mortality rate 0.13 versus 0.05 percent; neonatal mortality rate 0.11 versus 0.06 (Guise, 2010). A trial of labor also appears to be associated with a higher risk of *hypoxic ischemic encephalopathy (HIE)* than ERCD. The Maternal-Fetal Medicine Networks Unit study reported the incidence of HIE at term to be 46 per 100,000 trials of labor compared with zero cases in women undergoing ERCD (Landon, 2004).

Analysis of pooled data suggests that the absolute risk of *transient tachypnea of the newborn* is slightly higher with ERCD compared with TOLAC—4.2 versus 3.6 percent (Guise, 2010). But, neonatal bag and mask ventilation was used more often in

infants delivered following TOLAC than in those delivered by ERCD—5.4 versus 2.5 percent. Finally, there are no significant differences in *5-minute Apgar scores* or *neonatal intensive care unit admissions* for infants delivered by TOLAC compared with those delivered by ERCD. *Birth trauma* from lacerations is more commonly seen in infants born by ERCD.

■ Maternal versus Fetal Risks

Relative risks for mother and baby differ between modes of delivery. Regarding overall risks, the Panel (2010) concluded that in a hypothetical group of 100,000 women of *any* gestational age who undergo TOLAC, there will be 4 maternal deaths, 468 cases of uterine rupture, and 133 perinatal deaths. In comparison, in a hypothetical group of 100,000 women of *any* gestational age who undergo ERCD, there will be 13 maternal deaths, 26 uterine ruptures, and 50 perinatal deaths.

Despite potential concerns of increased complications, an elective repeat cesarean delivery is considered by many women to be preferable to a trial of labor. Frequent reasons include the convenience of a scheduled delivery and the fear of a prolonged and potentially dangerous labor. In an earlier study, Abitbol and colleagues (1993) found that these preferences persisted despite extensive antepartum counseling.

CANDIDATES FOR A TRIAL OF LABOR

There are few high-quality data available to guide selection of trial of labor candidates (Guise, 2004; Hashima, 2004). That said, having fewer complicating risk factors increases the likelihood of success (Gregory, 2008). Several algorithms and nomograms have been developed to aid prediction, but none has demonstrated reasonable prognostic value (Grobman, 2007b, 2008, 2009; Macones, 2006; Metz, 2013; Srinivas, 2007). Use of a predictive model for failed trial of labor, however, was found to be somewhat predictive of uterine rupture or dehiscence (Stanhope, 2013). Despite these limitations for precision, several points are pertinent to the evaluation of these women and are described in the next sections. Current recommendations of the American College of Obstetricians and Gynecologists (2013a) are that most women with one previous cesarean delivery with a low-transverse hysterotomy are candidates, and if appropriate, they should be counseled regarding a trial of labor versus elective repeat cesarean delivery.

■ Prior Uterine Incision

Prior Incision Type

The type and number of prior cesarean deliveries are overriding factors in recommending a trial of labor. Women with one prior low-transverse hysterotomy have the lowest risk of symptomatic scar separation (Table 31-3). The highest risks are with prior vertical incisions extending into the fundus, such as the classical incision shown in Figure 31-2 (Society for Maternal Fetal Medicine, 2013). Importantly, in some women, the classical scar will rupture before the onset of labor, and this can happen several weeks before term. In a review of 157 women

TABLE 31-3. Types of Prior Uterine Incisions and Estimated Risks for Uterine Rupture

Prior Incision	Estimated Rupture Rate (%)
Classical	2–9
T-shaped	4–9
Low-vertical ^a	1–7
One low-transverse	0.2–0.9
Multiple low-transverse	0.9–1.8
Prior preterm cesarean delivery	“increased”
Prior uterine rupture	
Lower segment	2–6
Upper uterus	9–32

Data from the American College of Obstetricians and Gynecologists, 2013a; Cahill, 2010b; Chauhan, 2002; Landon, 2006; Macones, 2005; Martin, 1997; Miller, 1994; Sciscione, 2008; Society for Maternal-Fetal Medicine, 2012; Tahseen, 2010.

with a prior classical cesarean delivery, one woman had a complete uterine rupture before the onset of labor, whereas 9 percent had a uterine dehiscence (Chauhan, 2002).

The risk of uterine rupture in women with a prior vertical incision that did not extend into the fundus is unclear. Martin (1997) and Shipp (1999) and their coworkers reported that these low-vertical uterine incisions did not have an increased risk for rupture compared with low-transverse incisions. The

American College of Obstetricians and Gynecologists (2013a) concluded that although there is limited evidence, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for a trial of labor. This is in contrast to prior classical or T-shaped uterine incisions, which are considered by most as contraindications to labor.

Currently, there are few indications for a primary vertical incision (Osmundson, 2013). In those instances—for example, preterm breech fetus with an undeveloped lower segment—the “low vertical” incision almost invariably extends into the active segment. It is not known, however, how far upward the incision has to extend before risks become those of a true classical incision. It is helpful in the operative report to document its exact extent.

Prior preterm cesarean delivery may have an increased risk for rupture. Although the type of prior incision was not known, Sciscione and associates (2008) reported that women who had a prior preterm cesarean delivery were twice as likely to suffer a uterine rupture compared with those with a prior term cesarean delivery. This may be in part explained by the increased likelihood with a preterm fetus of extension of the uterine incision into the contractile portion. Conversely, Harper and colleagues (2009) did not find a significantly increased rate of rupture during subsequent VBAC in women with a prior cesarean delivery performed at or before 34 weeks.

There are special considerations for women with uterine malformations who have undergone cesarean delivery. Earlier reports suggested that the uterine rupture risk in a subsequent pregnancy was increased compared with the risk in those with a prior low-transverse hysterotomy and normally formed uterus (Ravasia, 1999). But, in a study of 103 women with müllerian duct anomalies who had one prior cesarean delivery and who attempted a trial of labor, there were no cases of uterine rupture (Erez, 2007). Given the wide range of risk for uterine rupture associated with the various uterine incision types, it is not surprising that most fellows of the American College of Obstetricians and Gynecologists consider the type of prior incision to be the most important factor when considering a trial of labor (Coleman, 2005).

Prior Incision Closure

As discussed in Chapter 30 (p. 596), the low-transverse hysterotomy incision can be sutured in either one or two layers. Whether the risk of subsequent uterine rupture is affected by these is unclear. Chapman (1997) and Tucker (1993) and their associates found no relationship between a one- and two-layer closure and the risk of subsequent uterine rupture. And although Durnwald and Mercer (2003) also found no increased risk of rupture, they reported that uterine dehiscence was more common after single-layer closure. In contrast, Bujold and coworkers (2002) found that a single-layer closure was associated with nearly a fourfold increased risk of rupture compared with a double-layer closure. In response, Vidaeff and Lucas (2003) argued that experimental models have not demonstrated advantages of a double-layer closure and that the evidence is insufficient to routinely recommend a double-layer closure. At Parkland Hospital we routinely suture the low-segment incision with one running locking suture.

FIGURE 31-2 Ruptured vertical cesarean section scar (arrow) identified at time of repeat cesarean delivery early in labor. The two black asterisks to the left indicate some sites of densely adhered omentum.

Number of Prior Cesarean Incisions

There are at least three studies that reported a doubling of the rupture rate—from approximately 0.6 to 1.85 percent—in women with two versus one prior transverse hysterotomy incision (Macones, 2005a; Miller, 1994; Tahseen, 2010). In contrast, analysis of the MFMU Network database by Landon and colleagues (2006) did not confirm this. Instead, they reported an insignificant difference in the uterine rupture rate in 975 women with multiple prior cesarean deliveries compared with 16,915 women with a single prior operation—0.9 versus 0.7 percent, respectively. As discussed subsequently, other serious maternal morbidity increases along with the number of prior cesarean deliveries (Marshall, 2011).

Imaging of Prior Incision

Sonographic measurement of a prior hysterotomy incision has been used to predict the likelihood of rupture with a trial of labor. Large defects in the hysterotomy scar in a non-pregnant uterus forecast a greater risk for rupture (Osser, 2011). Naji and associates (2013a,b) found that the *residual myometrial thickness* decreased as pregnancy progressed and that rupture correlates with a thinner scar. From their review, however, Jastrow and coworkers (2010) found no ideal thickness to be suitably predictive. The optimal safe threshold value for the lower uterine segment—smallest measurement from amnionic fluid to bladder—ranged from 2.0 to 3.5 mm. For the myometrial layer—smallest measurement of the hypoechoic portion of the lower segment, it was 1.4 to 2.0 mm. With a lower segment < 2.0 mm, the risk of uterine rupture was increased 11-fold. With myometrial thickness < 1.4 mm, uterine rupture was increased fivefold. The measurements, however, are not predictive for an individual woman (Bergeron, 2009).

Prior Uterine Rupture

Women who have previously sustained a uterine rupture are at increased risk for recurrence during a subsequent attempted VBAC. As shown in Table 31-3, those with a previous low-segment rupture have a 2- to 6-percent recurrence risk, whereas prior upper segment uterine rupture confers a 9- to 32-percent risk (Reyes-Ceja, 1969; Ritchie, 1971). We believe that women with a prior uterine rupture or classical or T-shaped incision ideally should undergo repeat cesarean delivery when fetal pulmonary maturity is assured, and preferably before the onset of labor. They should also be counseled regarding the hazards of unattended labor and signs of possible uterine rupture.

Interdelivery Interval

Magnetic resonance imaging studies of myometrial healing suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle, 1997). To explore this further, Shipp and colleagues (2001) examined the relationship between interdelivery interval and uterine rupture in 2409 women who had one prior cesarean delivery. There were

29 women with a uterine rupture—1.4 percent. Interdelivery intervals of ≤ 18 months were associated with a threefold increased risk of symptomatic rupture during a subsequent trial of labor compared with intervals > 18 months. Similarly, Stamilio and coworkers (2007) noted a threefold increased risk of uterine rupture in women with an interpregnancy interval of < 6 months compared with one ≥ 6 months. But they also reported that interpregnancy intervals of 6 to 18 months did not significantly increase the risk.

Prior Vaginal Delivery

Prior vaginal delivery, either before or after a cesarean birth, significantly improves the prognosis for a subsequent vaginal delivery with either spontaneous or induced labor (Grinstead, 2004; Hendler, 2004; Mercer, 2008). Prior vaginal delivery also lowers the risk of subsequent uterine rupture and other morbidities (Cahill, 2006; Hochler, 2014; Zelop, 2000). Indeed, the most favorable prognostic factor is prior vaginal delivery.

Indication for Prior Cesarean Delivery

Considering all women who elect trial of labor, 60 to 80 percent will have a successful vaginal delivery (American College of Obstetricians and Gynecologists, 2013a). Women with a nonrecurrent indication—for example, breech presentation—have the highest success rate of nearly 90 percent (Wing, 1999). Those with a prior cesarean delivery for fetal compromise have an approximately 80-percent success rate, and for those done for labor arrest, success rates approximate 60 percent (Bujold, 2001; Peaceman, 2006). Prior second-stage cesarean delivery can be associated with second-stage uterine rupture in a subsequent pregnancy (Jastrow, 2013).

Fetal Size

Most studies show that increasing fetal size is inversely related to successful trial of labor. The risk for uterine rupture is less robust. Zelop and associates (2001) compared the outcomes of almost 2750 women undergoing a trial of labor, and 1.1 percent had a uterine rupture. The rate increased—albeit not significantly—with increasing fetal weight. The rate was 1.0 percent for fetal weight < 4000 g, 1.6 percent for > 4000 g, and 2.4 percent for > 4250 g. Similarly, Elkousy and colleagues (2003) reported that the relative risk of rupture doubled if birthweight was > 4000 g. Conversely, Baron and coworkers (2013a) did not find increased uterine rupture with birthweights > 4000 g.

Fetal size at the opposite end of the spectrum may increase the chances of a successful VBAC. Specifically, women who attempt a trial of labor with a preterm fetus have higher successful VBAC rates and lower rupture rates (Durnwald, 2006; Quiñones, 2005).

Multifetal Gestation

Perhaps surprisingly, twin pregnancy does not appear to increase the uterine rupture risk with trial of labor. Ford and associates (2006) analyzed the outcomes of 1850 such women and reported

a 45-percent successful vaginal delivery rate and a rupture rate of 0.9 percent. Similar studies by Cahill (2005) and Varner (2007) and their colleagues reported rupture rates of 0.7 to 1.1 percent and vaginal delivery rates of 75 to 85 percent. According to the American College of Obstetricians and Gynecologists (2013a), women with twins and a prior low-transverse hysterotomy who are otherwise candidates for vaginal delivery can safely undergo a trial of labor.

Maternal Obesity

Obesity decreases the success rate of trial of labor. Hibbard and coworkers (2006) reported the following vaginal delivery rates: 85 percent with a normal body mass index (BMI), 78 percent with a BMI between 25 and 30, 70 percent with a BMI between 30 and 40, and 61 percent with a BMI of 40 or greater. Similar findings were reported by Juhasz and associates (2005).

Fetal Death

Most women with a prior cesarean delivery and fetal death in the current pregnancy would prefer a VBAC. Although fetal concerns are obviated, available data suggest that maternal risks are increased. Nearly 46,000 women with a prior cesarean delivery in the Network database had a total of 209 fetal deaths (Ramirez, 2010). There were 76 percent who had a trial of labor with a success rate of 87 percent. Overall, the rupture rate was 2.4 percent. Four of five ruptures were during induction in 116 women with one prior transverse incision—3.4 percent.

LABOR AND DELIVERY CONSIDERATIONS

If elective repeat cesarean delivery is planned, it is essential that the fetus be mature. As shown in [Figure 31-3](#), significant and appreciable adverse neonatal morbidity has been reported

FIGURE 31-3 Neonatal morbidity and mortality rates seen with 13,258 elective repeat cesarean deliveries. Any adverse outcome includes death. Sepsis includes suspected and proven. RDS = respiratory distress syndrome; TTN = transient tachypnea of the newborn. (From Tita, 2009.)

with elective delivery before 39 completed weeks (Chiossi, 2013; Clark, 2009; Tita, 2009). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have established the following guidelines for timing an elective operation, and at least one of these three must be documented:

1. Ultrasound measurement < 20 weeks supports a gestational age of ≥ 39 weeks.
2. Fetal heart sounds have been documented for 30 weeks by Doppler ultrasound.
3. A positive serum or urine β -hCG test result has been documented for ≥ 36 weeks.

Accurate gestational dating is suitable using any of the above criteria. Other options are to await spontaneous labor or to document fetal pulmonary maturation by amniotic-fluid analysis (Chap. 34, p. 655).

Informed Consent

The risks and benefits of a trial of labor versus a repeat cesarean delivery should be thoroughly discussed, and the decision to attempt a trial of labor is made by the informed woman in conjunction with her health-care provider (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). As previously emphasized, no woman with a prior uterine incision should be forced to undergo a trial of labor.

Intrapartum Care

Because of the risks of uterine rupture for women undergoing a trial of labor, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend that such trials be undertaken only in facilities with staff immediately available to provide emergency care. Moreover, these centers should have a plan for managing uterine rupture.

Some argue that these provisions deny women full access to choices. For example in an earlier survey of Ohio hospitals, 15 percent of Level I, 63 percent of Level II, and 100 percent of Level III institutions met these requirements (Lavin, 2002). Moreover, an obstetrical anesthesia workforce survey reported that these rules were in place in 86 percent of hospitals with ≥ 1500 annual deliveries, in 45 percent of those with 500 to 1499 deliveries, and in 33 percent of those with < 500 deliveries.

Cervical Ripening and Labor Stimulation

As discussed, labor induction is associated with a higher failure rate for a trial of labor. The risks for uterine rupture, however, are less clear with induction or augmentation, with the exception of prostaglandin E_1 —misoprostol—which is contraindicated (American College of Obstetricians and Gynecologists, 2013a; Ophir, 2012). While most institutions are not so conservative, we do not induce or augment labor

pharmacologically in these women at Parkland Hospital. Instead, we attempt induction by amniotomy. Other considerations are to avoid induction or augmentation in women with an unknown prior incision type, an unfavorable cervix, or pregnancy > 40 weeks.

Oxytocin

Induction or augmentation of labor with oxytocin has been *implicated* in increased rates of uterine rupture in some studies (Zelop, 1999). In the Network study reported by Landon and colleagues (2004), uterine rupture was more frequent in women induced—1.1 percent—than in those in spontaneous labor—0.4 percent. Among women in this trial who had never had a prior vaginal delivery, the uterine rupture risk associated with an oxytocin induction was 1.8 percent—a fourfold increased risk compared with spontaneous labor (Grobman, 2007a). In contrast, in one case-control study, induction was not associated with a higher risk for rupture (Harper, 2012a). In an observational study, the success rate of induction was 67 percent (Shatz, 2012).

Cahill and coworkers (2008) reported a dose-related risk of rupture with oxytocin. At an infusion dose of 21 to 30 mU/min, the uterine rupture risk was fourfold greater than that in women not given oxytocin. Goetzl and associates (2001) described similar findings. They concluded, however, that differences in the dose or patterns of oxytocin use associated with uterine rupture were not substantive enough to require development of different induction protocols.

Prostaglandins

Various prostaglandin preparations that are commonly employed for cervical ripening or labor induction are discussed in Chapter 26 (p. 526). Safety with their use in women with a prior cesarean delivery is not clear because of conflicting data. For example, Wing and colleagues (1998) described a comparative study of PGE₁—*misoprostol*—versus oxytocin for labor induction in women with a prior cesarean delivery. They terminated their trial after two of the first 17 women assigned to misoprostol developed a uterine rupture. Other studies confirmed this, and most consider misoprostol to be contraindicated (American College of Obstetricians and Gynecologists, 2013a).

Studies to evaluate other prostaglandins for induction have mixed results. Ravasia and coworkers (2000) compared uterine rupture in 172 women given PGE₂ gel with 1544 women in spontaneous labor. The rupture rate was significantly greater in women treated with PGE₂ gel—2.9 percent—compared with 0.9 percent in those with spontaneous labor. Lydon-Rochelle and associates (2001) also reported that induction with prostaglandins for a trial of labor increased the uterine rupture risk.

Not all studies report an increased risk of uterine rupture with prostaglandins. In the Network study cited previously, there was a uterine rupture rate of 1.4 percent when any prostaglandin was used in combination with oxytocin (Landon, 2004). But in the subgroup of 227 women in whom labor was induced with a prostaglandin only, there were no ruptures.

Similar findings were reported in that intravaginal prostaglandins were not found to be associated with an increased uterine rupture risk (Macones, 2005b). These latter investigators, along with Kayani and colleagues (2005), found that sequential use of a prostaglandin followed by oxytocin was associated with a threefold-increased risk of rupture compared with spontaneous labor.

After reviewing these more contemporaneous reports, the American College of Obstetricians and Gynecologists (2013a) concluded that labor induction for some women who attempt a trial of labor is a reasonable option. The College also concluded that it is reasonable to (1) avoid misoprostol, (2) select women most likely to have a successful trial of labor, and (3) avoid sequential use of prostaglandins and oxytocin.

Epidural Analgesia

Concerns that epidural analgesia for labor might mask the pain of uterine rupture have not been verified. Fewer than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign of rupture (Kieser, 2002). That said, Cahill and coworkers (2010a) documented that more frequent episodes of epidural dosing were associated with increasing uterine rupture rates. Successful VBAC rates are similar, and in some cases higher, among women with labor epidural analgesia compared with those using other forms of analgesia (Landon, 2005). Perhaps related, almost a fourth of successful VBAC deliveries were completed with either forceps or vacuum (Inbar, 2013). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) have concluded that epidural analgesia may safely be used during a trial of labor.

Uterine Scar Exploration

Some clinicians routinely document the integrity of a prior scar by placing a hand through the dilated cervix and along the inner surface of the lower uterine segment following successful vaginal delivery. However, routine uterine exploration is considered by others to be unnecessary. Currently, the benefits of scar evaluation in the asymptomatic woman are unclear. There is general agreement, however, that surgical correction of a scar dehiscence is necessary only if significant bleeding is encountered. Our practice is to routinely examine these prior incision sites. Any decision for laparotomy and repair takes into consideration the extent of the tear, whether the peritoneal cavity has been entered, and the presence of active bleeding.

External Cephalic Version

External cephalic version for breech presentation is acceptable in women with a prior cesarean delivery who are contemplating a trial of labor (American College of Obstetricians and Gynecologists, 2013a). This procedure is addressed in Chapter 28 (p. 570).

UTERINE RUPTURE

Classification

Uterine rupture typically is classified as either (1) *complete* when all layers of the uterine wall are separated, or (2) *incomplete* when the uterine muscle is separated but the visceral peritoneum is intact. Incomplete rupture is also commonly referred to as *uterine dehiscence*. As expected, morbidity and mortality rates are appreciably greater when rupture is complete. The greatest risk factor for either form of rupture is prior cesarean delivery. In a review of all uterine rupture cases in Nova Scotia between 1988 and 1997, Kieser and Baskett (2002) reported that 92 percent were in women with a prior cesarean birth. Holmgren and associates (2012) described 42 cases of rupture in women with a prior hysterotomy. Of these, 36 were in labor at the time of rupture.

Diagnosis

Progress of labor in women attempting VBAC is similar to regular labor, and there is no specific pattern that presages uterine rupture (Graseck, 2012; Harper, 2012b). Before hypovolemic shock develops, symptoms and physical findings in women with uterine rupture may appear bizarre unless the possibility is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in diaphragmatic irritation with pain referred to the chest—directing one to a diagnosis of pulmonary or amniotic fluid embolism instead of uterine rupture. The most common sign of uterine rupture is a nonreassuring fetal heart rate pattern with variable heart rate decelerations that may evolve into late decelerations and bradycardia as shown in **Figure 31-4** (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). In 36 cases of such rupture during a trial of labor, there were fetal signs in 24, maternal in eight, and both in three (Holmgren, 2012). Few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters has not been shown to assist reliably in the diagnosis (Rodriguez, 1989).

FIGURE 31-4 Fetal heart rate tracing in a woman whose uterus ruptured during labor while pushing. The rupture apparently stimulated a reflex push, after which uterine tone diminished and fetal bradycardia worsened.

In some women, the appearance of uterine rupture is identical to that of placental abruption. In most, however, there is remarkably little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or epidural analgesia, pain and tenderness may not be readily apparent. The condition usually becomes evident because of fetal distress signs and occasionally because of maternal hypovolemia from concealed hemorrhage.

If the fetal presenting part has entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the uterine rupture site, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus.

Decision-to-Delivery Time

With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are dismal, and reported mortality rates range from 50 to 75 percent. *Fetal condition depends on the degree to which the placental implantation remains intact, although this can change within minutes.* With rupture, the only chance of fetal survival is afforded by immediate delivery—most often by laparotomy—otherwise, hypoxia is inevitable. If rupture is followed by immediate total placental separation, then very few intact fetuses will be salvaged. *Thus, even in the best of circumstances, fetal salvage will be impaired.* The Utah experiences are instructive here (Holmgren, 2012). Of the 35 laboring patients with a uterine rupture, the decision-to-delivery time was < 18 minutes in 17, and none of these infants had an adverse neurological outcome. Of the 18 born > 18 minutes from decision time, the three infants with long-term neurological impairments were delivered at 31, 40, and 42 minutes. There were no deaths, thus severe neonatal neurological morbidity developed in 8 percent of these 35 women with uterine rupture.

In a study using the Swedish Birth Registry, Kaczmarczyk and colleagues (2007) found that the risk of neonatal death following uterine rupture was 5 percent—a 60-fold increase in risk compared with pregnancies not complicated by uterine rupture. In the Network study, seven of the 114 uterine ruptures—6 percent—associated with a trial of labor were complicated by the development of neonatal hypoxic ischemic encephalopathy (Spong, 2007).

Maternal deaths from rupture are uncommon. For example, of 2.5 million women who gave birth in Canada between 1991 and 2001, there were 1898 cases of uterine rupture, and four of these—0.2 percent—resulted in maternal death (Wen, 2005). In other regions of the world, however, maternal mortality rates associated with uterine rupture are

much higher. In a report from rural India, for example, the maternal mortality rate associated with uterine rupture was 30 percent (Chatterjee, 2007).

Hysterectomy versus Repair

With complete rupture during a trial of labor, hysterectomy may be required. In the reports by McMahon (1996) and Miller (1997) and their coworkers, 10 to 20 percent of such women required hysterectomy for hemostasis. In selected cases, however, suture repair with uterine preservation may be performed. Sheth (1968) described outcomes from a series of 66 women in whom repair of a uterine rupture was elected rather than hysterectomy. In 25 instances, the repair was accompanied by tubal sterilization. Thirteen of the 41 mothers who did not have tubal sterilization had a total of 21 subsequent pregnancies. Uterine rupture recurred in four of these—approximately 25 percent. Usta and associates (2007) identified 37 women with a prior complete uterine rupture delivered during a 25-year period in Lebanon. Hysterectomy was performed in 11, and in the remaining 26 women, the rupture was repaired. Twelve of these women had 24 subsequent pregnancies, one third of which were complicated by recurrent uterine rupture. In another study, however, women with a uterine dehiscence were not more likely to have uterine rupture with a subsequent pregnancy (Baron, 2013b).

COMPLICATIONS WITH MULTIPLE REPEAT CESAREAN DELIVERIES

Because of the concerns with attempting a trial of labor—even in the woman with excellent criteria that forecast successful VBAC—most women in the United States undergo elective repeat cesarean delivery. This choice is not without several significant maternal complications, and rates of these increase in women who have multiple repeat operations. The incidences of some common complications for women with one prior transverse cesarean delivery who undergo an elective repeat cesarean delivery were shown in Table 31-2. Finally, half of cesarean hysterectomies done at Parkland Hospital are in women with one or more prior cesarean deliveries (Hernandez, 2013).

The Network addressed issues of increased morbidity in a cohort of 30,132 women who had from one to six repeat cesarean deliveries (Silver, 2006). This report addressed a list of morbidities, most of which increased as a trend with increasing number of repeat operations. The rates of some of the more common or serious complications are depicted in Figure 31-5. In addition to the ones shown, rates of bowel or bladder injury, admission to an intensive care unit or ventilator therapy, and maternal mortality, as well as operative and hospitalization length, showed significantly increasing trends. Similar results have been reported by others (Nisenblat, 2006; Usta, 2005). More difficult to quantify are risks for bowel obstructions and pelvic pain from peritoneal adhesive disease, both of which increase with each successive cesarean delivery (Andolf, 2010; Mankuta, 2013).

FIGURE 31-5 Maternal-Fetal Medicine Units Network: rates of some complications with increasing number of repeat cesarean deliveries. (Data from Silver, 2006.)

Cook and colleagues (2013) from the United Kingdom Obstetric Surveillance System (UKOSS) described adverse sequelae of women with multiple cesarean deliveries. Outcomes of those undergoing a fifth or greater operation were compared with those from women having a second through fourth procedure. Those having five or more cesarean deliveries had significantly increased rates of morbidity compared with rates in women having fewer than five procedures. Specifically, the major hemorrhage rate increased 18-fold; visceral damage, 17-fold; critical care admissions, 15-fold; and delivery < 37 weeks, sixfold. Much of this morbidity was in the 18 percent who had placenta previa or accrete syndromes (Chap. 41, p. 799). A percreta may invade the bladder or other adjacent structures. With this, difficult resection carries an inordinately high risk of hysterectomy, massive hemorrhage with transfusion, and maternal mortality.

STATE OF VAGINAL BIRTH AFTER CESAREAN—2014

The “best answer” for a given woman with a prior cesarean delivery is unknown. We agree with Scott (2011) regarding a “common-sense” approach. Thus, the woman—and her partner if she wishes—are encouraged to actively participate with her health-care provider in the final decision after appropriate counseling. For women who wish TOLAC despite a factor that increases their specific risk, additions to the consent form are recommended (American College of Obstetricians and Gynecologists, 2013a). Bonanno and colleagues (2011) have provided such an example.

TABLE 31-4. Some Recommendations of Professional Societies Concerning a Trial of Labor to Attempt VBAC

	Counseling	Facilities	Other
American College of Obstetricians and Gynecologists (2013a)	Offer to most women with one prior low-transverse incision; consider for two prior low-transverse incisions	Safest with ability for immediate cesarean delivery; patients should be allowed to accept increased risk when not available	Not precluded: twins, macrosomia, prior low-vertical or unknown type of incision
Society of Obstetricians and Gynaecologists of Canada (2005)	Offer to women with one prior transverse low-segment cesarean delivery; with > 1 prior CD then VBAC likely successful but increased risks	Should deliver in hospital in which timely cesarean delivery is available; approximate timeframe of 30 minutes	Oxytocin or Foley catheter induction safe, but prostaglandins should not be used; macrosomia, diabetes, postterm pregnancy, twins are not contraindications
Royal College of Obstetricians and Gynaecologists (2007)	Discuss VBAC option with women with prior low-segment cesarean delivery; decision between obstetrician and patient	Suitable delivery suite with continuous care and monitoring; immediate cesarean delivery capability	Caution with twins and macrosomia

CD = cesarean delivery; VBAC = vaginal birth after cesarean.

Brief synopses of professional society guidelines are shown in [Table 31-4](#). Guidelines that tend to be more conservative are shown in [Table 31-5](#).

TABLE 31-5. Conservative Guidelines to Approach a Trial of Labor Following Cesarean Delivery

Follow ACOG practice guidelines

Education and counseling

Preconceptionally

Provide ACOG patient pamphlet

Early during prenatal care

Develop preliminary plan

Revisit at least each trimester

Be willing to alter decision

Have facilities availability

Risk assessment

Review previous operative note(s)

Review relative and absolute contraindications

Reconsider risks as pregnancy progresses

Tread carefully: > 1 prior transverse CD, unknown incision, twins, macrosomia

Labor and delivery

Cautions for induction—unfavorable cervix, high station

Consider AROM

Avoid prostaglandins

Respect oxytocin—know when to quit

Beware of abnormal labor progress

Respect EFM pattern abnormalities

Know when to abandon a trial of labor

ACOG = American College of Obstetricians and Gynecologists; AROM = artificial rupture of membranes; CD = cesarean delivery; EFM = electronic fetal monitoring.

SECTION 9

THE NEWBORN

CHAPTER 32

The Newborn

INITIATION OF AIR BREATHING 624

CARE IN THE DELIVERY ROOM 625

EVALUATION OF NEWBORN CONDITION 627

PREVENTIVE CARE 631

ROUTINE NEWBORN CARE 632

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend attendance at delivery of at least one person whose primary responsibility is the neonate and who is capable of initiating resuscitation that includes intubation, vascular access, and medication administration. This usually is a pediatrician, nurse practitioner, anesthesiologist, nurse anesthetist, or specially trained nurse. However, in their absence, the responsibility for neonatal resuscitation falls to the obstetrical attendant. Thus, obstetricians should be well versed in measures for immediate care of the newborn.

INITIATION OF AIR BREATHING

Immediately following birth, the infant must promptly convert to air breathing as the fluid-filled alveoli expand with air and pulmonary perfusion is established. The newborn begins to breathe and cry almost immediately after birth, which indicates establishment of active respiration. Some factors that appear to influence the first breath include:

- Physical stimulation—examples include handling the neonate during delivery.
- Oxygen deprivation and carbon dioxide accumulation—these serve to increase the frequency and magnitude of

- breathing movements both before and after birth (Dawes, 1974).
- Thoracic compression—this occurs during pelvic descent, following which vaginal birth forces fluid from the respiratory tract in volume equivalent to approximately a fourth of the ultimate functional residual capacity (Saunders, 1978).
 - Aeration of the newborn lung does not involve the inflation of a collapsed structure, but instead, the rapid replacement of bronchial and alveolar fluid by air. After delivery, the residual alveolar fluid is cleared through the pulmonary circulation and to a lesser degree, through the pulmonary lymphatics (Chernick, 1978). Delay in fluid removal from the alveoli probably contributes to the syndrome of transient tachypnea of the newborn (TTN) (Guglani, 2008). As fluid is replaced by air, compression of the pulmonary vasculature is reduced considerably, and in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes (Fig. 7-8, p. 136).

High negative intrathoracic pressures are required to bring about the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung, and with each successive breath, lower pulmonary opening pressure is required. In the normal mature newborn, by approximately the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts from the shallow episodic inspirations characteristic of the fetus to regular, deeper inhalations (Chap. 17, p. 337). Surfactant, which is synthesized by type II pneumocytes and already present in the alveoli, lowers alveolar surface tension and thereby prevents lung collapse. Insufficient surfactant, common in preterm infants, leads promptly to respiratory distress syndrome, which is described in Chapter 34 (p. 653).

CARE IN THE DELIVERY ROOM

Personnel designated for infant support are responsible for immediate care and for acute resuscitation initiation if needed.

Immediate Care

Before and during delivery, careful consideration must be given to several determinants of neonatal well-being including: (1) maternal health status; (2) prenatal complications, including any suspected fetal malformations; (3) gestational age; (4) labor complications; (5) duration of labor and ruptured membranes; (6) type and duration of anesthesia; (7) difficulty with delivery; and (8) medications given during labor and their dosages, administration routes, and timing relative to delivery.

Newborn Resuscitation

The International Liaison Committee on Resuscitation (ILCOR) updated its guidelines for neonatal resuscitation that are sanctioned by the American Academy of Pediatrics and the American Heart Association (Biban, 2011; Perlman, 2010). These substantially revised guidelines are incorporated into the following sections.

Approximately 10 percent of newborns require some degree of active resuscitation to stimulate breathing, and 1 percent require extensive resuscitation. It is perhaps not coincidental that there is a two- to threefold risk of death for newborns delivered at home compared with those delivered in hospitals (American College of Obstetricians and Gynecologists, 2013b). When deprived of oxygen, either before or after birth, neonates demonstrate a well-defined sequence of events leading to apnea (Fig. 32-1). With oxygen deprivation, there is a transient period of rapid breathing, and if it persists, breathing stops, which is termed *primary apnea*. This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation and exposure to oxygen will usually reverse primary apnea. If

oxygen deprivation and asphyxia persist, however, the newborn will develop deep gasping respirations, followed by secondary apnea. This latter stage is associated with a further decline in heart rate, falling blood pressure, and loss of neuromuscular tone. Neonates in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death follows. Clinically, primary and secondary apneas are indistinguishable. Thus, secondary apnea must be assumed and resuscitation of the apneic newborn must be started immediately.

Resuscitation Protocol

The updated algorithm for newborn resuscitation recommended by ILCOR and the International Consensus on Cardiopulmonary Resuscitation is shown in Figure 32-2. Many of its tenets follow below.

Basic Measures

The vigorous newborn is first placed in a warm environment to minimize heat loss, the airway is cleared, and the infant dried. Routine gastric aspiration has been shown to be nonbeneficial and even harmful (Kiremitci, 2011). And although previously recommended, there is no evidence that bulb suctioning for clear or meconium-stained fluid is beneficial, even if the newborn is depressed (Chap. 33, p. 638). With stimulation, the healthy newborn will take a breath within a few seconds of birth and cry within half a minute, after which routine supportive care is provided.

Assessment at 30 Seconds of Life. Apnea, gasping respirations, or heart rate < 100 bpm beyond 30 seconds after delivery should prompt administration of positive-pressure ventilation with *room air* (Fig. 32-3). Assisted ventilation rates of 30 to 60 breaths per minute are commonly employed, and the percent of oxygen saturation is monitored by pulse oximetry. At this point, supplemental oxygen can be given in graduated increasing percentages to maintain oxygen saturation (SpO₂) values within a normal range (Vento, 2011). Adequate ventilation is indicated by improved heart rate.

Assessment at 60 Seconds of Life. If the heart rate remains < 100 bpm, then ventilation is inadequate. The head position should be checked as shown in Figure 32-3, secretions cleared, and if necessary, inflation pressure increased. If the heart rate persists below 100 bpm beyond 60 seconds, tracheal intubation is considered. A number of conditions may be the cause of inadequate response, including the following:

- Hypoxemia or acidosis from any cause
- Drugs administered to the mother before delivery
- Immaturity
- Upper airway obstruction
- Pneumothorax
- Lung abnormalities
- Meconium aspiration
- Central nervous system developmental abnormality
- Sepsis syndrome.

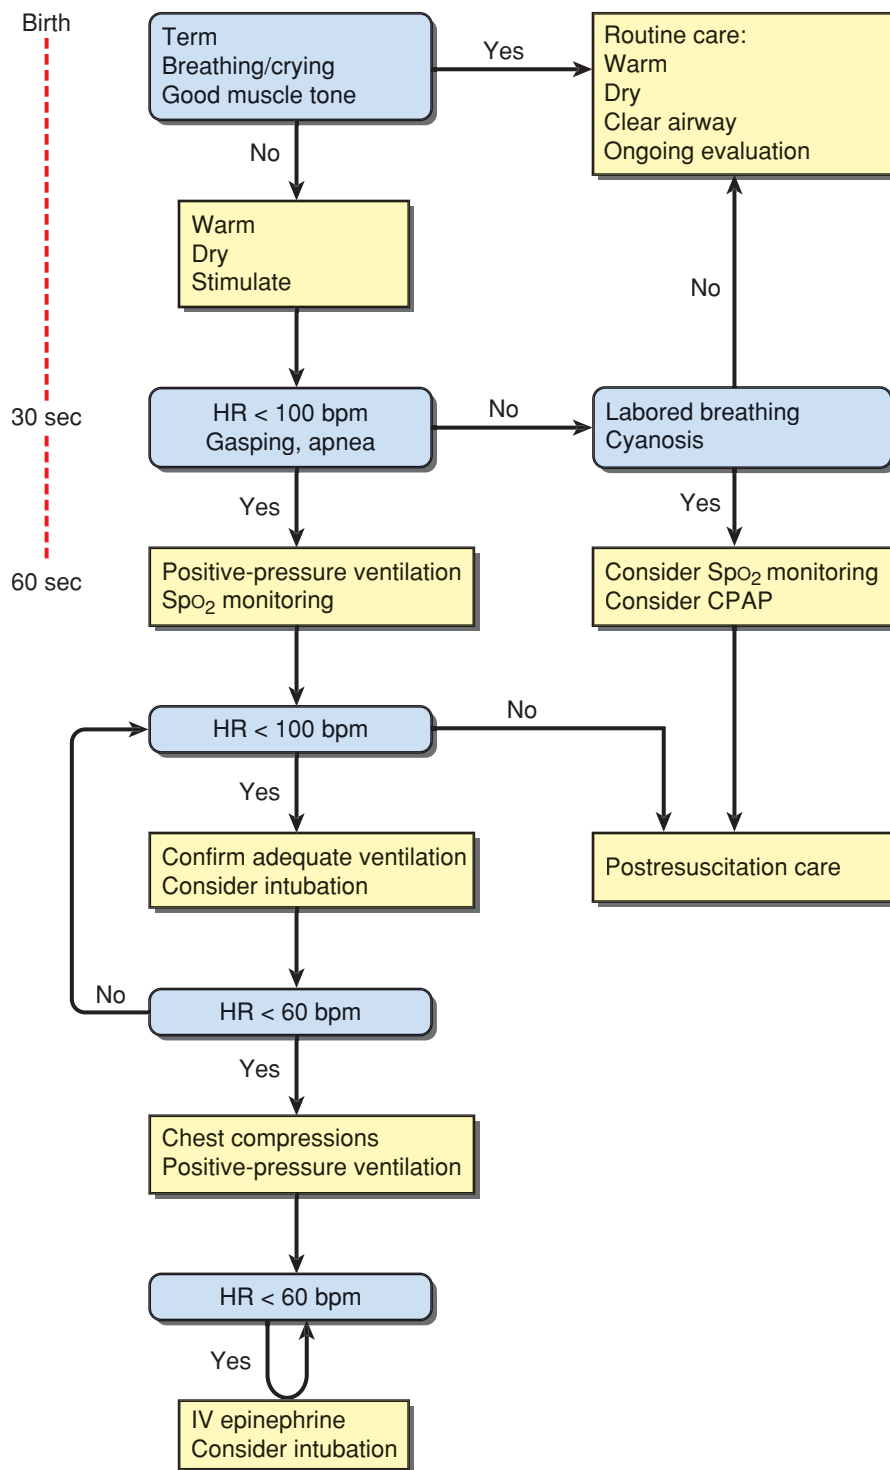

FIGURE 32-2 Algorithm for resuscitation of the newborn. CPAP = continuous positive airway pressure; HR = heart rate; IV = intravenous. (Adapted from Perlman, 2010.)

Tracheal Intubation

If bag-and-mask ventilation is ineffective or prolonged, tracheal intubation is then performed. Other indications include the need for chest compressions or tracheal administration of medications, or special circumstances such as extremely low birthweight or a congenital diaphragmatic hernia. A laryngoscope with a straight blade—size 0 for a preterm infant and size 1 for a term neonate—

is introduced at the side of the mouth and then directed posteriorly toward the oropharynx as shown in [Figure 32-4](#). The laryngoscope is next moved gently into the vallecula—the space between the base of the tongue and the epiglottis. Gentle elevation of the laryngoscope tip will raise the epiglottis and expose the glottis and the vocal cords. The tube is then introduced through the vocal cords. Gentle cricoid pressure may be useful. Tube sizes vary from 3.5 to 4.0 mm for term infants down to 2.5 mm for those < 28 weeks or < 1000 g.

Several steps are taken to ensure that the tube is positioned in the trachea and not the esophagus: observation for symmetrical chest wall motion; auscultation for equal breath sounds, especially in the axillae; and auscultation for the absence of breath sounds or gurgling over the stomach. Tracheal suctioning is no longer recommended or discouraged. Using an appropriate ventilation bag attached to the tracheal tube, puffs of air are delivered into the tube at 1- to 2-second intervals with a force adequate to gently lift the chest wall. In term infants, pressures of 30 to 40 cm H₂O typically will expand the alveoli without causing barotrauma. For preterm infants, pressures are 20 to 25 cm H₂O. An increase in heart rate and SpO₂ levels within acceptable ranges reflect a positive response.

Chest Compressions

If the heart rate remains < 60 bpm despite adequate ventilation for 30 seconds, chest compressions are initiated. These are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. A 3:1 compressions-to-ventilation ratio is recommended, with 90 compressions and 30 breaths to achieve approximately 120 events each minute. The heart rate is reassessed every 30 seconds, and chest compressions are continued until the spontaneous heart rate is at least 60 bpm.

Epinephrine and Volume Expansion

Intravenously administered epinephrine is indicated when the heart rate remains < 60 bpm after adequate ventilation and chest compressions. Epinephrine may be given through the endotracheal tube if venous access has not been established. The recommended intravenous dose is 0.01 to 0.03 mg/kg. If given through the tracheal tube, higher doses are employed—0.05 to 0.1 mg/kg.

FIGURE 32-3 Correct use of bag-and-mask ventilation. The head should be in a sniffing position with the tip of the nose pointing to the ceiling. The neck should not be hyperextended.

For infants with blood loss, early volume replacement with crystalloid or packed red cells is indicated if they do not respond to resuscitation.

Discontinuation of Resuscitation

As expected, newborns with cardiopulmonary arrest who do not respond promptly to resuscitation are at great risk for death, and if they survive, for severe morbidity (Haddad, 2000). The International Consensus Committee concluded that discontinuation of resuscitative efforts may be appropriate in a neonate without a heartbeat for 10 minutes of continuous and adequate resuscitative efforts (Perlman, 2010). This committee cites lack of data for more specific recommendations regarding the infant whose heart rate remains < 60 bpm.

EVALUATION OF NEWBORN CONDITION

Apgar Score

The scoring system described in 1953 by Dr. Virginia Apgar remains a useful clinical tool to identify those neonates who require resuscitation and to assess the effectiveness of any resuscitative measures. As shown in [Table 32-1](#), each of the five easily identifiable characteristics—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and

FIGURE 32-4 Sagittal view of laryngoscope positioning during intubation. The laryngoscope blade is inserted between the tongue base and epiglottis. Upward tilting of the tongue also lifts the epiglottis. The endotracheal tube is then threaded below the epiglottis and between the vocal cords (*inset*) to enter the trachea.

assigned a value of 0 to 2. The total score, based on the sum of the five components, is determined in all neonates at 1 and 5 minutes after delivery. In depressed infants, the score may be calculated at further 5-minute intervals until a 20-minute Apgar score is assessed.

The 1-minute Apgar score reflects the need for immediate resuscitation. The 5-minute score, and particularly the change in score between 1 and 5 minutes, is a useful index of the effectiveness of resuscitative efforts. The 5-minute Apgar score also has prognostic significance for neonatal survival because survival is related closely to the condition of the neonate in the delivery room (Apgar, 1958). In an analysis of more than 150,000 infants delivered at Parkland Hospital, Casey and associates (2001b) assessed the significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term neonates, the risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10. This risk compares with a mortality rate of 1 in 4 for term infants with 5-minute scores of 3 or less. Low 5-minute scores were comparably predictive of neonatal death in preterm infants. These investigators concluded that the Apgar scoring system

TABLE 32-1. Apgar Scoring System

Sign	0 Points	1 Point	2 Points
Heart rate	Absent	< 100 bpm	≥ 100 bpm
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some extremity flexion	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Blue, pale	Body pink, extremities blue	Completely pink

bpm = beats per minute.

Data from Apgar, 1953.

is as relevant for the prediction of neonatal survival today as it was more than 50 years ago.

There have been attempts to use Apgar scores to define asphyxial injury and to predict subsequent neurological outcome—uses for which the Apgar score was never intended. Such associations are difficult to measure with reliability given that both asphyxial injury and low Apgar scores are infrequent outcomes. For example, according to United States birth certificate records for 2010, only 1.8 percent of newborns had a 5-minute score below 7 (Martin, 2012). Similarly, in a population-based study of more than 1 million term infants born in Sweden between 1988 and 1997, the incidence of 5-minute Apgar scores of 3 or less was approximately 2 per 1000 (Thorngren-Jerneck, 2001).

Despite the methodological challenges, erroneous definitions of asphyxia by many groups were established based solely on low Apgar scores. These prompted the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2010) to issue a series of joint opinions with important caveats regarding limitations of use of the Apgar score. One is that because certain elements of the Apgar score are partially dependent on the physiological maturity of the newborn, a healthy preterm infant may receive a low score only because of immaturity (Catlin, 1986). Apgar scores may be influenced by a variety of factors including, but not limited to, fetal malformations, maternal medications, and infection. Therefore, it is inappropriate to use an Apgar score alone to diagnose asphyxia. A 5-minute Apgar score of 3 correlates poorly with adverse future neurological outcomes, and thus scores are measured also at 10, 15, and 20 minutes when the score remains 3 or less (Freeman, 1988; Nelson, 1981).

Importantly, the Apgar score alone cannot establish hypoxia as the cause of cerebral palsy. As discussed in Chapter 33 (p. 638), a neonate who has had an asphyxial insult proximate to delivery that is severe enough to result in acute neurological injury will demonstrate most of the following: (1) profound acidemia with cord artery blood pH < 7 and acid-base deficit ≥ 12 mmol/L; (2) Apgar score of 0–3 persisting for 10 minutes or longer; (3) neurological manifestations such as seizures, coma, or hypotonia; and (4) multisystem organ dysfunction—cardiovascular, gastrointestinal, hematological, pulmonary, or renal (American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2003).

■ Umbilical Cord Blood Acid-Base Studies

Blood taken from umbilical vessels may be used for acid-base studies to assess the metabolic status of the neonate. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps placed near the neonate and another two clamps nearer the placenta. The importance of clamping the cord is underscored by the fact that delays of 20 to 30 seconds can alter both the P_{CO_2} and pH (Valero, 2012; White, 2012). The cord is then cut between the two proximal clamps and then the two distal clamps.

Arterial blood is drawn from the isolated cord segment into a 1- to 2-mL commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. Once sampling is completed, the needle is capped and the syringe transported, on ice, to the laboratory. Although efforts should be made for prompt transport, neither the pH nor P_{CO_2} values change significantly in blood kept at room temperature for up to 60 minutes (Duerbeck, 1992). Mathematical models have been developed that allow reasonable prediction of birth acid-base status in properly collected cord blood samples analyzed as late as 60 hours after delivery (Chauhan, 1994). Also, Swedish investigators reported significant variances in acid-base measurements with the use of different analyzers (Mokarami, 2012).

■ Fetal Acid-Base Physiology

The fetus produces both carbonic and organic acids. Carbonic acid (H_2CO_3) is formed by oxidative metabolism of CO_2 . The fetus usually rapidly clears CO_2 through the placental circulation. If CO_2 clearance is lowered, then carbonic acid levels rise. When H_2CO_3 accumulates in fetal blood and there is no concurrent increase in organic acids, the result is termed respiratory acidemia. This often follows impaired placental exchange.

In contrast, organic acids primarily include lactic and β -hydroxybutyric acids. Levels of these increase with persistent placental exchange impairment and result from anaerobic glycolysis. These organic acids are cleared slowly from fetal blood, and when they accumulate without a concurrent increase in H_2CO_3 , the result is termed metabolic acidemia. With the development of metabolic acidemia, bicarbonate (HCO_3^-) decreases because it is used to buffer the organic acid. An increase in H_2CO_3 accompanied by an increase in organic acid reflected by decreased HCO_3^- causes mixed respiratory-metabolic acidemia.

In the fetus, respiratory and metabolic acidemia and ultimately tissue acidosis are most likely part of a progressively worsening continuum. This is different from the adult pathophysiology, in which distinct conditions result in either respiratory acidosis—for example, pulmonary disease, or metabolic acidosis—for example, diabetes. In the fetus, the placenta serves as both the lungs and to a certain degree, the kidneys. One principal cause of fetal acidemia is a decrease in uteroplacental perfusion. This results in the retention of CO_2 , that is, respiratory acidemia, and if protracted and severe enough, a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood is dependent on the proportion of carbonic and organic acids and the amount of bicarbonate, which is the major buffer in blood. This can best be illustrated by the Henderson–Hasselbalch equation:

$$pH = pK + \log \frac{[\text{base}]}{[\text{acid}]} \quad \text{or} \quad pH = pK + \log \frac{HCO_3^-}{H_2CO_3}$$

For clinical purposes, HCO_3^- represents the metabolic component and is reported in mEq/L. The H_2CO_3 concentration

represents the respiratory component and is reported as the PCO_2 in mm Hg. Thus:

$$\text{pH} = \text{pK} + \log \frac{\text{metabolic (HCO}_3^- \text{ mEq/L)}}{\text{respiratory (PCO}_2 \text{ mm Hg)}}$$

The result of this equation is a pH value. Because pH is a logarithmic term, it does not give a linear measure of acid accumulation. For example, a change in hydrogen ion concentration associated with a fall in pH from 7.0 to 6.9 is almost twice that which is associated with a fall in pH from 7.3 to 7.2. For this reason, the change in base, termed delta base, offers a more linear measure of the degree of accumulation of metabolic acid (Armstrong, 2007). The delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3^-). The formula for calculating the base excess (BE) is as follows:

$$\text{BE} = 0.02786 \times \text{PCO}_2 \times 10^{(\text{pH} - 6.1)} \times 13.77 \times \text{pH} - 124.58$$

Shown in **Figure 32-5** is a nomogram developed from which these can be calculated if only two parameters are known. For example, HCO_3^- concentration will be decreased with a metabolic acidemia as it is consumed to maintain a

normal pH. A base deficit occurs when HCO_3^- concentration decreases to below normal levels, and a base excess occurs when HCO_3^- values are above normal. Importantly, a mixed respiratory–metabolic acidemia with a large base deficit and a low HCO_3^- , for example 12 mmol/L, is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3^- level.

Clinical Significance of Acidemia

Fetal oxygenation and pH generally decline during the course of normal labor. Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in **Table 32-2**. Similar values have been reported for preterm infants (Dickinson, 1992; Ramin, 1989; Riley, 1993). The lower limits of normal pH in the newborn have been found to range from 7.04 to 7.10 (Boylan, 1994). Thus, these values should be considered to define neonatal acidemia. Even so, most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (Freeman, 1988; Gilstrap, 1989). However, in a study of newborns with a pH < 7.0 from Parkland Hospital, there were inordinate proportions of neonatal deaths—8 percent, intensive-care admission—39 percent, intubations—14 percent, and seizures—13 percent (Goldaber, 1991). And in a study from Oxford of more than 51,000 term infants, the incidence of neonatal encephalopathy with the pH < 7.0 was 3 percent (Yeh, 2012).

Another important prognostic consideration is the direction of pH change from birth to the immediate neonatal period. For example, the risk of seizures during the first 24 hours of life was reduced fivefold if an umbilical artery cord pH below 7.2 normalized within 2 hours after delivery (Casey, 2001a).

Respiratory Acidemia

Acute interruption in placental gas exchange is accompanied by subsequent CO_2 retention and respiratory acidemia. The most common antecedent factor is transient umbilical cord compression. Generally, respiratory acidemia is not harmful to the fetus (Low, 1994).

The degree to which pH is affected by PCO_2 —the respiratory component of the acidosis—can be calculated. First, the upper normal neonatal PCO_2 of 49 mm Hg is subtracted from the cord blood gas PCO_2 value.

FIGURE 32-5 Nomogram for determining the delta base. (Adapted from Siggaard-Andersen, 1963).

TABLE 32-2. Umbilical Cord Blood pH and Blood Gas Values in Normal Term Newborns

Values	Ramin, 1989 ^a Spontaneous Delivery n = 1292 ^c	Riley, 1993 ^b Spontaneous Delivery n = 3522 ^c	Kotaska, 2010 ^b Spontaneous Delivery n = 303 ^d	Kotaska, 2010 ^e Cesarean Delivery n = 189 ^d
Arterial Blood				
pH	7.28 (0.07)	7.27 (0.069)	7.26 (7.01–7.39)	7.3 (7.05–7.39)
Pco ₂ (mm Hg)	49.9 (14.2)	50.3 (11.1)	51 (30.9–85.8)	54 (37.5–79.5)
HCO ₃ [–] (mEq/L)	23.1 (2.8)	22.0 (3.6)	—	—
Base excess (mEq/L)	–3.6 (2.8)	–2.7 (2.8)	—	—

^dData shown as range with 2.5 or 97.5 percentile.

^eCesarean delivery—labor not stated.

Each additional 10 mm Hg Pco₂ increment will lower the pH by 0.08 units (Eisenberg, 1987). Thus, in a mixed respiratory–metabolic acidemia, the benign respiratory component can be calculated. As an example, acute cord prolapse during labor prompts cesarean delivery of an infant 20 minutes later. The umbilical artery blood gas pH was 6.95 and the Pco₂ was 89 mm Hg. To calculate the degree to which the cord compression and subsequent impairment of CO₂ exchange affected the pH, the relationship given earlier is applied: 89 mm Hg minus 49 mm Hg = 40 mm Hg excess CO₂. To correct pH: (40 ÷ 10) × 0.08 = 0.32; 6.95 + 0.32 = 7.27. Therefore, the pH before cord prolapse was approximately 7.27, well within normal limits, and thus the low pH resulted from respiratory acidosis.

Metabolic Acidemia

The fetus begins to develop metabolic acidemia when oxygen deprivation is of sufficient duration and magnitude to require anaerobic metabolism for cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit ≥ 12 mmol/L and severe fetal acidosis as a base deficit ≥ 16 mmol/L. In the Parkland study of more than 150,000 newborns cited earlier, metabolic acidemia was defined using umbilical cord blood gas cutoffs that were 2 standard deviations below the mean (Casey, 2001b). Thus, metabolic acidemia was an umbilical artery blood pH < 7.00 accompanied by a Pco₂ of ≤ 76.3 mm Hg, with higher values indicating a respiratory component; HCO₃[–] concentration ≤ 17.7 mmol/L; and base deficit ≥ 10.3 mEq/L. From the standpoint of possible cerebral palsy causation, the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003), in their widely endorsed monograph, defined metabolic acidosis as umbilical arterial pH < 7.0 and a base deficit ≥ 12 mmol/L.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction. In rare cases, such hypoxia-induced metabolic acidemia may be so severe that it causes subsequent neurological impairment—*hypoxic-ischemic encephalopathy* (Chap. 33, p. 639). In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury. That said, severe metabolic acidosis is poorly predictive of subsequent neurological impairment in the term neonate. Although metabolic acidosis was associated with an increase in immediate neonatal complications in a group of infants with depressed 5-minute Apgar scores, there were no differences in umbilical artery blood gas measurements among infants who subsequently developed cerebral palsy compared with those with normal neurological outcomes (Socol, 1994).

In very-low-birthweight infants, that is, those < 1000 g, newborn acid-base status may be more closely linked to long-term neurological outcome (Gaudier, 1994; Low, 1995). In the study cited above, Casey and coworkers (2001b) described the association between metabolic acidemia, low Apgar scores, and neonatal death in term and preterm infants. Regarding term neonates, as shown in Figure 32-6, relative to newborns with a 5-minute Apgar score of at least 7, the risk of neonatal death was more than 3200-fold greater in term infants with metabolic acidemia and 5-minute scores of 3 or less.

Recommendations for Cord Blood Gas Determinations

A cost-effectiveness analysis for universal cord blood gas measurements has not been conducted. In some centers, such as ours at Parkland Hospital, cord gas analysis is performed in all neonates at birth. The American College of Obstetricians and

FIGURE 32-6 Relative risk for neonatal death in term infants with low Apgar score or umbilical artery acidemia—or both. The relative risk is cited above each bar. (Data from Casey, 2001b.)

Gynecologists (2012) recommends that cord blood gas and pH analyses be obtained in the following circumstances:

- Cesarean delivery for fetal compromise
- Low 5-minute Apgar score
- Severe fetal-growth restriction
- Abnormal fetal heart rate tracing
- Maternal thyroid disease
- Intrapartum fever
- Multifetal gestation.

Although umbilical cord acid-base blood determinations are poorly predictive of either immediate or long-term adverse neurological outcome, they provide the most objective evidence of the fetal metabolic status at birth.

PREVENTIVE CARE

Eye Infection Prophylaxis

Gonococcal Infection

Ophthalmia neonatorum is mucopurulent conjunctivitis of newborns. Some form of conjunctivitis affects 1 to 12 percent of all neonates, and gonococcal and chlamydial infections are some of the most common causes (Zuppa, 2011). Blindness was previously common in children who developed *Neisseria gonorrhoeae* infection. However, in 1884, Credé, a German obstetrician, introduced a 1-percent ophthalmic solution of silver nitrate that largely eliminated this. Various other antimicrobial agents have also proven to be effective, and gonococcal prophylaxis is now mandatory for all neonates (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Recommendations for gonococcal eye prophylaxis include a single application of either 1-percent silver nitrate solution or 0.5-percent erythromycin or 1-percent tetracycline ophthalmic ointment soon after delivery. Treatment of presumptive gonococcal ophthalmia, that is, conjunctivitis in a neonate born to a mother with untreated gonorrhea, is given with single-dose ceftriaxone, 100 mg/kg, either

intramuscularly or intravenously. Testing for both gonococcus and chlamydia should be obtained before treatment.

Chlamydial Infection

Adequate neonatal prophylaxis against chlamydial conjunctivitis is complex. Ideally, prenatal screening and treatment for *Chlamydia trachomatis* obviates conjunctival infection (Hammerslag, 2011). Of neonates delivered vaginally of mothers with an active chlamydial infection, from 12 to 25 percent will develop conjunctivitis for up to 20 weeks (Teoh, 2003). Prophylactic topical eye treatments do not reliably reduce the incidence of chlamydial conjunctivitis. In a study from Kenya, 2.5-percent povidone-iodine solution was reported to be superior to either 1-percent silver nitrate solution or 0.5-percent erythromycin ointment in preventing chlamydial conjunctivitis (Isenberg, 1995). In another study from Iran, povidone-iodine eye drops were twice as effective in preventing clinical conjunctivitis as erythromycin drops—9 versus 18 percent failure rate, respectively (Ali, 2007). In an Israeli study, tetracycline ointment was marginally superior to povidone-iodine (David, 2011). For all of these reasons, conjunctivitis in a newborn up to 3 months old should prompt consideration for chlamydial infection. Treatment for chlamydial infection is with oral azithromycin for 5 days or erythromycin for 14 days.

Hepatitis B Immunization

Routine immunization of all newborns with thimerosal-free vaccine against hepatitis B before hospital discharge is standard practice (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). This vaccine does not appear to increase the number of febrile episodes, sepsis evaluations, or adverse neurological sequelae (Lewis, 2001). Some advocate treatment of high-risk or even all seropositive women with antiviral nucleoside or nucleotide analogues during pregnancy to minimize transmission to the fetus (Dusheiko, 2012; Tran, 2012). Certainly, if the mother is seropositive for hepatitis B surface antigen, then the neonate should also be passively immunized with hepatitis B immune globulin as discussed in Chapter 55 (p. 1090).

Vitamin K

This injection is provided to prevent vitamin K-dependent hemorrhagic disease of the newborn, which is discussed in Chapter 33 (p. 644). A single dose of 0.5- to 1-mg intramuscular vitamin K is given within 1 hour of birth (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

Newborn Screening

State-based public-health newborn screening programs were solidified when, in response to calls for a uniform national policy, the Maternal and Child Health Bureau appointed a committee of the American College of Medical Genetics to recommend a panel of tests (Watson, 2006). Technical advances have made a large number of relatively simply performed mass

TABLE 32-3. Newborn Screening Core Panel—Estimated Number of Children Shown in Parentheses Identified in the United States in 2006

Acylcarnitine Disorders ^a				
Organic Acid Metabolism	Fatty Acid Metabolism	Amino Acid Metabolism ^a	Hemoglobin Disorders	Others
Isovaleric (32)	Medium-chain acyl-CoA dehydrogenase (239)	Phenylketonuria (215)	SS disease (1128)	Congenital hypothyroidism (2156)
Glutaric type I (38)	Very long-chain acyl-CoA dehydrogenase (69)	Maple syrup (urine) (26)	S- β -thalassemia (163)	Biotinidase (62)
3-Hydroxy-3-methylglutaric (3)	Long-chain 3-OH acyl-CoA dehydrogenase (13)	Homocystinuria (11)	SC disease (484)	Congenital adrenal hyperplasia (202)
Multiple carboxylase (3)	Trifunctional protein (2)	Citrullinemia (24)		Galactosemia (224)
Methylmalonic mutase (50)	Carnitine uptake (85)	Arginosuccinic (7)		Hearing loss (5073)
3-Methylcrotonyl-CoA carboxylase (100)		Tyrosinemia I		Cystic fibrosis (1248)
Methylmalonic acid (cobalamine A, B) (12)				Critical congenital heart disease ^b
Propionic (15)				Severe combined immunodeficiency ^b
β -Ketothiolase (7)

From Centers for Disease Control and Prevention, 2012b; Watson, 2006.

screening tests available for newborn conditions, and many are mandated by various state laws (American College of Obstetricians and Gynecologists, 2011b). Since then, two have been added to the original core panel of 29 congenital conditions, and all are shown in [Table 32-3](#).

According to the Centers for Disease Control and Prevention (2012b), the programs have been successful and cost effective. For example, neonatal screening for hearing loss was shown in a Dutch study to diagnose problems a mean of 6 months earlier and improve long-term outcomes (Durieux-Smith, 2008). A successful screening program for medium chain acyl-CoA dehydrogenase deficiency was described in a Danish study (Anderson, 2012). The use of pulse oximetry to screen for severe congenital heart disease was reviewed by Thangaratinam (2012).

Most states require that all tests in the core panel be performed. Supplemental conditions—*secondary targets*—are also listed on the Maternal and Child Health Bureau website. Some states require some of these 24 in addition to their mandated core panel. Each practitioner should be familiar with their individual state requirements, which are available at <http://genes-r-us.uthscsa.edu/resources/consumer/statemap.htm> and <http://www.hrsa.gov/advisorycommittee/mchbadvisory/heritabledisorders/recommendedpanel/index/html>.

ROUTINE NEWBORN CARE

Gestational Age Estimation

Newborn gestational age can be estimated very soon after delivery. The relationship between gestational age and

birthweight should be used to identify neonates at risk for complications (McIntire, 1999). For example, neonates who are either small or large for gestational age are at increased risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012).

Care of Skin and Umbilical Cord

All excess vernix, blood, and meconium should be gently wiped off at the time of delivery while keeping the infant warm. Any remaining vernix is readily absorbed and disappears within 24 hours. The first bath should be postponed until the neonate's temperature has stabilized.

Aseptic precautions should be observed in the immediate care of the cord. The American Academy of Pediatrics and the American College of Obstetrics and Gynecologists (2012) have concluded that keeping the cord dry is sufficient care. The umbilical cord begins to lose water from Wharton jelly shortly after birth. Within 24 hours, the cord stump loses its characteristic bluish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs and leaves a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks, with a range of 3 to 45 days (Novack, 1988). The umbilical cord dries more quickly and separates more readily when exposed to air. Thus, a dressing is not recommended.

In resource-poor countries, prophylaxis is reasonable. Triple-dye applied to the cord was reported superior to soap and water care in preventing colonization and exudate formation

(Janssen, 2003). In a Nepalese study, cleansing the cord stump with 4-percent chlorhexidine reduced severe omphalitis by 75 percent compared with soap and water cleansing (Mullany, 2006). Likewise, 0.1-percent chlorhexidine powder was superior to dry cord care (Kapellen, 2009).

Despite precautions, a serious umbilical infection—omphalitis—is sometimes encountered. In a German study of more than 750 newborns with aseptic cord care, 1.3 percent developed omphalitis (Kapellen, 2009). The most likely offending organisms are *Staphylococcus aureus*, *Escherichia coli*, and group B streptococcus. Typical signs of cellulitis and stump discharge usually aid diagnosis. However, mild erythema and some bleeding at the stump site with cord detachment is common, and some cases may present no outward signs. Thus, the diagnosis can be elusive.

■ Feeding and Weight Loss

According to the American College of Obstetricians and Gynecologists (2013a), exclusive breast feeding is preferred until 6 months. In many hospitals, infants begin breast feeding in the delivery room. Most term newborns thrive best when fed 8 to 12 times daily for approximately 15 minutes per episode. Preterm or growth-restricted newborns require feedings at shorter intervals.

One goal of *Healthy People 2020* of the United States Department of Health and Human Services (2010) is to increase the proportion of mothers who breast feed their infants. Substantial progress toward this goal has been made. In 2009, 77 percent of infants were initially breast fed, and 47 percent were still breast fed at 6 months and 26 percent at 1 year (Centers for Disease Control and Prevention, 2012a). Breast feeding is discussed further in Chapter 36 (p. 673). Because most neonates actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk has been established or other feeding is instituted. Preterm infants lose relatively more weight and regain their birthweight more slowly. Conversely, growth-restricted but otherwise healthy infants regain their initial weight more quickly than those born preterm. With proper nourishment, birthweight of term infants usually is regained by the end of the 10th day.

■ Stools and Urine

For the first 2 or 3 days after birth, the colon contains soft, brownish-green meconium. This consists of desquamated epithelial cells from the intestinal tract, mucus, epidermal cells, and lanugo (fetal hair) that have been swallowed along with amniotic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours, and most of the rest within 36 hours. Usually, newborns first void shortly after birth, but may not until the second day. Meconium and urine passage indicates patency of the gastrointestinal and urinary tracts, respectively. Failure of the newborn to stool or urinate after these times

suggests a congenital defect, such as imperforate anus or a urethral valve. After the third or fourth day, as a result of milk ingestion, meconium is replaced by light-yellow homogenous feces with a consistency similar to peanut butter.

■ Icterus Neonatorum

Between the second and fifth day of life approximately one third of all neonates develop so-called physiological jaundice of the newborn. It has special significance considering most hospitals have policies for early discharge. Correspondingly, it has been the subject of several recent reviews and is discussed further in Chapter 33 (p. 644) (Dijk, 2012; Gazzin, 2011; Hansen, 2011; Lauer, 2011).

■ Newborn Male Circumcision

Neonatal circumcision has been a controversial topic in the United States for at least 25 years. For centuries, newborn male circumcision has been performed as a religious ritual. Even so, scientific evidence supports several medical benefits that include prevention of phimosis, paraphimosis, and balanoposthitis. Circumcision also decreases the incidence of penile cancer and of cervical cancer among their sexual partners. In 1999, the American Academy of Pediatrics concluded that existing evidence was insufficient to recommend *routine* neonatal circumcision. It seems that this policy has had only a negligible effect on practices in this country. Specifically, the Centers for Disease Control and Prevention (2011) estimated that the newborn male circumcision rate decreased during a 12-year period from approximately 60 percent in 2009 to only 55 percent in 2010.

Subsequent studies have again endorsed health benefits of circumcision. In two large randomized trials from regions of Africa with a high prevalence of human immunodeficiency virus (HIV), adult male circumcision was found to lower the risk of HIV acquisition by half (Bailey, 2007; Gray, 2007). And adult male circumcision was reported to decrease incidences of HIV, HPV, and herpes infections (Tobian, 2009). These and other studies were considered by the American Academy of Pediatrics Task Force on Circumcision (2012). In its policy statement, the Task Force concluded that health benefits of newborn male circumcision outweigh the risks, and thus, access to the procedure is justified for families who choose it. Benefits cited include prevention of urinary infections, penile cancer, and transmission of some sexually transmitted infections, including HIV infection. The Task Force stopped short of recommending circumcision for *all* newborns. The American College of Obstetricians and Gynecologists (2011a) endorses these views.

■ Anesthesia for Circumcision

The American Academy of Pediatrics Task Force (2012) recommends that if circumcision is performed, procedural analgesia should be provided. Various pain relief techniques have been described, including lidocaine-prilocaine topical cream, local analgesia infiltration, dorsal penile nerve block, or ring block. Several studies attest to the efficacy of the dorsal penile

nerve block (Arnett, 1990; Stang, 1988). Studies show that the dorsal penile nerve block or the ring block techniques are both superior to topical analgesia (Hardwick-Smith, 1998; Lander, 1997; Taddio, 1997). The use of a pacifier dipped in sucrose is a useful adjunct to these methods (Kaufman, 2002).

After appropriate penile cleansing, the ring block technique consists of placing a wheal of 1-percent lidocaine at the base of the penis and advancing the needle in a 180-degree arc around the base of the penis first to one side and then the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. *No vasoactive compounds such as epinephrine should ever be added to the local analgesic agent.*

Surgical Technique

Newborn circumcision should be performed only on a healthy neonate. Other contraindications include any genital abnormalities such as hypospadias and a family history of a bleeding disorder unless excluded in the infant. The most commonly used instruments are shown in Figure 32-7 and include Gomco and Mogen clamps and the Plastibell device. Compared with the Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the newborn. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. In all techniques: (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and ensure

that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before amputating the prepuce (Lerman, 2001). For a detailed description of surgical techniques, see the second edition of *Operative Obstetrics* (Mastrobattista, 2002).

Circumcision Complications

As with any surgical procedure, there is a risk of bleeding, infection, and hematoma formation. These risks, however, are low (Christakis, 2000). Unusual complications reported as isolated cases include distal glans amputation, acquisition of human immunodeficiency virus-1 (HIV-1) infection or other sexually transmitted diseases, meatal stenosis, penile denudation, penile destruction with electrosurgical coagulation, subsequent epidermal inclusion cyst and urethrocuteaneous fistula, and ischemia following the inappropriate use of lidocaine with epinephrine (Amukele, 2003; Berens, 1990; Gearhart, 1989; Neulander, 1996; Nicoll, 1997; Pippi-Salle, 2013; Upadhyay, 1998).

Rooming-In

This model of maternity care place newborns in their mothers' rooms instead of central nurseries. Termed rooming-in, this approach first appeared in United States hospitals in the early 1940s (Temkin, 2002). In part, rooming-in stems from a trend to make all phases of childbearing as natural as possible and to foster early mother-child relationships. By 24 hours, the mother is generally fully ambulatory. Thereafter, with rooming-in, she can usually provide routine care for herself and her newborn. An obvious advantage is her increased ability to assume full care of the infant when she arrives home.

Hospital Discharge

Traditionally, the newborn is discharged with its mother, and in most cases, maternal stay has determined that of the neonate. Safe discharge for late preterm infants has special concerns (Whyte, 2012). From 1970 to the mid-1990s, average maternal postpartum length of stay declined steadily, and many mothers were discharged in under 48 hours. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. For example, using data from the Canadian Institute for Health Information, Liu and colleagues (2000) examined readmission rates in more than 2.1 million neonatal discharges. As the length of hospital stay decreased from 4.2 days in 1990 to 2.7 days in 1997, the readmission rate increased from 27 to 38 per 1000 births. Dehydration and jaundice accounted for most of these readmissions, and brain damage from icterus neonatorum is discussed in Chapter 33 (p. 644). Using Washington state neonatal discharge data, Malkin and coworkers (2000) found that the 28-day mortality rate was increased fourfold and the 1-year mortality rate increased twofold in newborns discharged within 30 hours of birth.

Because of the increased scrutiny regarding short hospital stays, federal legislation—*The Newborns' and Mothers' Health Protection Act of 1996*—was enacted to prohibit insurers from

FIGURE 32-7 Three different tools used for circumcision. **A.** Mogen clamp. The arms of the clamp open to a 3-mm maximum width. **B.** Gomco clamp, assembled. **C.** Plastibell device.

restricting hospital stays for mothers and newborns to less than 2 days for vaginal delivery or 4 days for cesarean delivery. As a result, the average length of hospital stay for childbirth increased from 2.1 days in 1995 to 2.5 days in 2000. This increase reflected the reduced number of very short hospital stays following childbirth (Hall, 2002). Although Mosen and associates (2002) found that implementation of the new legislation was associated with a 6-percent increase in cost, readmission rates within 7 days of discharge decreased by nearly half. In an analysis of more than 662,000 births in California, Datar and Sood (2006) found decreased rates of readmission of 9, 12, and 20 percent, respectively, at 1, 2, and 3 years after the legislation was implemented.

CHAPTER 33

Diseases and Injuries of the Term Newborn

RESPIRATORY DISTRESS SYNDROME	637
NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY	638
HEMATOLOGICAL DISORDERS	643
INJURIES OF THE NEWBORN	645

Term newborns are susceptible to a wide spectrum of illnesses. In many instances, clinical manifestations of these disorders are extensions of pathological effects already incurred by the fetus. A common example is the newborn who is depressed and acidotic because of intrapartum septicemia. Because many of these disorders are differently manifested, those more common in term newborns are considered here, whereas those more frequent in preterm neonates are discussed in Chapter 34. Specific disorders that are the direct consequence of maternal diseases are discussed in pertinent chapters.

RESPIRATORY DISTRESS SYNDROME

At the time of delivery, the newborn must convert rapidly to air breathing as described in Chapter 7 (p. 142). With inspiration, there is alveolar expansion, fluid clearance, and surfactant secretion by type II pneumocytes to prevent lung collapse. Interference with these functions can create respiratory insufficiency with hypoxemia and compensatory tachypnea, which is generally referred to as neonatal *respiratory distress syndrome* or simply *RDS*. In preterm infants, this is caused by lung immaturity and insufficient surfactant, and variants may be seen in severely ill older children and adults (Chap. 47, p. 943). All of these have some element of surfactant deficiency because the inciting agent damages alveolar epithelium. As fetuses approach term, surfactant deficiency as a cause of RDS diminishes. In a

report from Beijing that described 125 term infants with RDS, the most frequent causes were perinatal infection with sepsis syndrome in 50 percent, elective cesarean delivery in 27 percent, severe asphyxia in 10 percent, and meconium aspiration in 7 percent (Liu, 2010).

Surfactant Deficiency

Inadequate surfactant secretion that leads to respiratory distress syndrome becomes less frequent with increasing gestational age. That said, even with a low incidence in term infants, RDS from surfactant deficiency is not rare (Berthelot-Ricou, 2012). Male gender and white race are independent risk factors (Anadkat, 2012). Also, mutations of genes that encode for surfactant protein synthesis may augment the deficiency (Garmany, 2008; Wambach, 2012). Regardless of etiology, when surfactant secretion is diminished, the pulmonary pathophysiology, clinical course, and management are similar to that for preterm infants. Treatment includes mechanical ventilation and replacement of surfactant by insufflation (Chap. 34, p. 654). There is no evidence that antenatal maternal corticosteroid treatment will enhance surfactant synthesis in late preterm fetuses (Gyamfi-Bannerman, 2012). The prognosis in term newborns largely depends on the cause, severity, and response to treatment.

Meconium Aspiration Syndrome

The physiology of meconium passage and amniotic fluid contamination is considered in detail in Chapter 24 (p. 493). In some instances, inhalation of meconium-stained fluid at or near delivery causes acute airway obstruction, chemical pneumonitis, surfactant dysfunction or inactivation, and pulmonary hypertension (Swarnam, 2012). If severe, hypoxemia may lead to neonatal death or long-term neurological sequelae in survivors.

Given the high frequency—10 to 20 percent—of meconium-stained amniotic fluid in laboring women at term, it is

reasonable to assume that meconium aspiration must be relatively common. Fortunately, severe aspiration leading to overt respiratory failure is much less frequent. And although the exact incidence of meconium aspiration is not known, Singh and associates (2009) reported it to be 1.8 percent for all deliveries. In a French study of nearly 133,000 term newborns, the prevalence of severe aspiration syndrome was 0.07 percent, and this increased progressively from 37 to 43 weeks' gestation (Fischer, 2012). Mortality rates depend on severity. In an earlier report from Parkland Hospital, for all patients, meconium aspiration caused 1 death per 1000 live births (Nathan, 1994).

Fetal morbidity is more often associated with thicker meconium content. It is presumed that in most cases, amniotic fluid is ample to dilute the meconium to permit prompt clearance by normal fetal physiological mechanisms. Meconium aspiration syndrome occasionally develops with light staining. Many newborns are affected after a normal labor and uncomplicated delivery. However, some associated obstetrical factors include postterm pregnancy and fetal-growth restriction. These fetuses are at highest risk because there frequently is diminished amniotic fluid and labor with cord compression or uteroplacental insufficiency. These may increase the likelihood of meconium passage that is thick and undiluted (Leveno, 1984).

Prevention

It was once widely held that aspiration was stimulated by fetal hypoxic episodes, and fetal heart rate tracing abnormalities were used to identify fetuses at greatest risk during labor. Unfortunately, this was found to be an unreliable predictor (Dooley, 1985). Preliminary studies reported that the incidence and severity of the syndrome could be mitigated by *oropharyngeal suctioning* after delivery of the fetal head, but before the chest. For a while, this was standard care, but it was abandoned when shown that strict adherence to this protocol did not reduce syndrome incidence or severity (Davis, 1985; Wiswell, 1990). At the same time, reports described that pulmonary hypertension caused by aspirated meconium was characterized by abnormal arterial muscularization beginning well before birth. These findings led some to conclude that only chronically asphyxiated fetuses developed meconium aspiration syndrome (Katz, 1992). Proof of this never materialized, and Richey (1995) and Bloom (1996) and their colleagues found no correlation between meconium aspiration and markers of *acute* asphyxia—for example, umbilical artery acidosis. Conversely, others have reported that thick meconium is an independent risk factor for neonatal acidosis (Maisonneuve, 2011).

Conflicted findings regarding suctioning stimulated performance of an 11-center randomized trial designed to compare suctioning with no suctioning (Vain, 2004). There was an identical 4-percent incidence of meconium aspiration syndrome in both groups. Subsequently, a committee that represented the American Heart Association and American Academy of Pediatrics (Perlman, 2010), as well as the American College of Obstetricians and Gynecologists (2013b), has recommended *against* routine intrapartum oro- and nasopharyngeal suctioning at delivery.

Instead, for depressed newborns, management includes intubation and suctioning to remove meconium and other aspirated material from beneath the glottis (Chap. 32, p. 626).

Intrapartum amnioinfusion has been used successfully in laboring women with decreased amniotic fluid volume and frequent variable fetal heart rate decelerations (Chap. 24, p. 494). It has also been studied as a preventive measure in labors complicated by meconium staining (Spong, 1994). Although amnioinfusion apparently posed little or no increased risk, it was found to be of no benefit because fetuses usually inhaled meconium before labor (Bryne, 1987; Wenstrom, 1995). To further settle this issue, a trial was conducted with almost 2000 women at 36 weeks' gestation or later and in whom labor was complicated by thick meconium (Fraser, 2005). The perinatal death rate with and without amnioinfusion was 0.05 percent in both groups. Rates of moderate or severe meconium aspiration were also not significantly different—4.4 percent with and 3.1 percent without amnioinfusion. Finally, cesarean delivery rates were similar—32 versus 29 percent, respectively. Currently, the American College of Obstetrics and Gynecologists (2012c) does not recommend amnioinfusion to reduce meconium aspiration syndrome.

Treatment

Ventilatory support is given as needed. Because some aspects of meconium aspiration syndrome are caused by surfactant deficiency, replacement therapy has been given in some studies. *Extracorporeal membrane oxygenation—ECMO*—therapy is reserved for neonates who remain poorly oxygenated despite maximal ventilatory assistance. In their Cochrane review of randomized trials, El Shahed and colleagues (2007) found that surfactant replacement significantly decreased need for extracorporeal membrane oxygenation. Although they found that surfactant administration did not lower the mortality rate, a subsequent trial suggested that it was reduced (Dargaville, 2011). The proportion that requires ECMO treatment varies. In the report by Singh and coworkers (2009), 1.4 percent of 7518 term newborns with the syndrome required such treatment, and these had a 5-percent mortality rate. Ramachandrapa and colleagues (2011) reported a higher mortality rate in late-preterm infants compared with term infants. Finally, pulmonary lavage with surfactant is being evaluated (Choi, 2012).

NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY

Few events evoke more fear and apprehension in parents and obstetricians than the specter of “brain damage,” which immediately conjures visions of disabling cerebral palsy and hopeless intellectual disability. Although most brain disorders or injuries are less horrific, history has helped to perpetuate the more dismal outlook. In the first edition of this textbook, J. Whitridge Williams (1903) limited discussions of brain injury to that sustained from birth trauma. When later editions introduced the concept that *asphyxia neonatorum* was another cause of cerebral palsy, this too was linked to traumatic birth. Even as brain damage caused by traumatic delivery became uncommon during the ensuing decades, the belief—albeit erroneous—was that

intrapartum events caused most neurological disability. This was a major reason for the escalating cesarean delivery rate beginning in the 1970s. Unfortunately, because in most cases the genesis of cerebral palsy occurred long before labor, this did little to mitigate risks for cerebral palsy (O'Callaghan, 2013).

These realizations stimulated scientific investigations to determine the etiopathogenesis of fetal brain disorders to include those leading to cerebral palsy. Seminal observations include those of Nelson and Ellenberg (1984, 1985, 1986a), discussed subsequently. These investigators are appropriately credited with proving that these neurological disorders are due to complex multifactorial processes caused by a combination of genetic, physiological, environmental, and obstetrical factors. Importantly, these studies showed that few neurological disorders were associated with peripartum events. Continuing international interest was garnered to codify the potential role of intrapartum events. In 2000, President Frank Miller of the American College of Obstetricians and Gynecologists appointed a task force to study the vicissitudes of neonatal encephalopathy and cerebral palsy. From this, the 2003 Task Force findings were promulgated by the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2003). The multispecialty coalition reviewed contemporaneous data and provided criteria to define various neonatal brain disorders.

In 2010, 10 years later, President Richard Waldman of the American College of Obstetricians and Gynecologists appointed a second task force to update these findings. The 2014 Task Force has now published its findings (American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2014). The 2014 Task Force findings are more circumspect in contrast to the earlier ones. Specifically, more limitations are cited in identifying cause(s) of peripartum *hypoxic-ischemic encephalopathy* compared with other etiologies of neonatal encephalopathy. The 2014 Task Force recommends multidimensional assessment of each affected infant. They add the caveat that no one strategy is infallible, and thus, no single strategy will achieve 100-percent certainty in attributing a cause to neonatal encephalopathy.

■ Neonatal Encephalopathy

The 2014 Task Force defined neonatal encephalopathy as a syndrome of neurological dysfunction identified in the earliest days of life in neonates born at ≥ 35 weeks' gestation. It is manifested by subnormal levels of consciousness or seizures and often accompanied by difficulty with initiating and maintaining respiration and by depressed tone and reflexes. The incidence of encephalopathy has been cited to be 0.27 to 1.1 per 1000 term liveborn neonates, and it is much more frequent in preterm infants (Ensing, 2013; Plevani, 2013; Takenouchi, 2012; Wu, 2011). Although the 2014 Task Force concluded that there are many causes of encephalopathy and cerebral palsy, it focused on those termed *hypoxic-ischemic encephalopathy* (HIE) and thought to be incurred intrapartum. To identify affected infants, a thorough evaluation is necessary, including maternal history, obstetrical antecedents, intrapartum factors, placental pathology, and newborn course, along with laboratory and neuroimaging findings.

There are three clinically defined levels. *Mild encephalopathy* is characterized by hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. *Moderate encephalopathy* is manifest by lethargy, severe hypertonia, and occasional seizures. *Severe encephalopathy* is manifest by coma, multiple seizures, and recurrent apnea.

The 2014 Task Force also concluded that of the several forms of cerebral palsy, only the *spastic quadriplegic* type can result from acute peripartum ischemia. Other forms—*hemiparetic* or *hemiplegic cerebral palsy*, *spastic diplegia*, and *ataxia*—are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson, 1998).

Criteria for Hypoxic-Ischemic Encephalopathy

The 2014 Task Force radically revised its 2003 criteria used to define an acute peripartum event that is consistent with a hypoxic-ischemic episode and neonatal encephalopathy. These are outlined in [Table 33-1](#) and are considered with the following caveats.

Apgar Scores. Low 5- and 10-minute Apgar scores are associated with increased risks for neurological impairment. There are many causes of low Apgar scores, and most of these infants will not develop cerebral palsy. If the 5-minute Apgar is ≥ 7 , it is unlikely that peripartum HIE caused cerebral palsy.

Acid-Base Studies. Low pH and base deficit levels increase the likelihood that neonatal encephalopathy was caused by HIE. Decreasing levels form a continuum of increasing risk, but most acidemic neonates will be neurologically normal (Wayock, 2013). A cord artery pH > 7.2 is very unlikely to be associated with HIE.

Neuroimaging Studies. Magnetic resonance (MR) imaging or spectroscopy (MRS) is the best modality with which to

TABLE 33-1. Findings Consistent with an Acute Peripartum or Intrapartum Event Leading to Hypoxic-Ischemic Encephalopathy

Neonatal Findings

- Apgar score: < 5 at 5 and 10 minutes
- Umbilical arterial acidemia: pH < 7.0 and/or base deficit ≥ 12 mmol/L
- Neuroimaging evidence of acute brain injury: MRI or MRS consistent with HIE
- Multisystem involvement consistent with HIE

Type and Timing of Contributing Factors

- Sentinel hypoxic or ischemic event occurring immediately before or during delivery
- Fetal heart rate monitor patterns consistent with an acute peripartum or intrapartum event

HIE = hypoxic ischemic encephalopathy; MRI = magnetic resonance imaging; MRS = magnetic resonance spectroscopy.

From the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, 2014.

visualize findings consistent with HIE. The 2014 Task Force concludes that cranial sonography and computed tomography (CT) lack sensitivity in the term newborn. Normal MR imaging/MRS findings after the first 24 hours of life, however, effectively exclude a hypoxic-ischemic cause of encephalopathy. MR imaging between 24 and 96 hours may be more sensitive for the timing of peripartum cerebral injury, and MR imaging at 7 to 21 days following birth is the best technique to delineate the full extent of cerebral injury.

Multisystem Involvement. Neonatal manifestations of multisystem injury are consistent with HIE. These include renal, gastrointestinal, hepatic, or cardiac injury; hematological abnormalities; or combinations of these. The severity of neurological injury does not necessarily correlate with injuries to these other systems.

Contributing Factors

The 2014 Task Force also found that certain contributing factors may be consistent with an acute peripartum event.

Sentinel Event. Adverse obstetrical events that may lead to catastrophic clinical outcomes are designated sentinel events. Examples given by the 2014 Task Force include ruptured uterus, severe placental abruption, cord prolapse, and amniotic fluid embolism. Martinez-Biarge and associates (2012) studied almost 58,000 deliveries and identified 192 cases with one of these sentinel events. Of these 192 infants, 6 percent died intrapartum or in the early neonatal period, and 10 percent developed neonatal encephalopathy. In a study of 307 cases of cord prolapse, the fetal death rate was 6.8 percent (Hartigan, 2013). Besides these sentinel events, other risk factors for neonatal acidosis include prior cesarean delivery, maternal age ≥ 35 years, thick meconium, chorioamnionitis, and general anesthesia (Johnson, 2014; Maisonneuve, 2011).

Fetal Heart Rate Patterns. The 2014 Task Force emphasized the importance of differentiating an abnormal fetal heart rate (FHR) tracing on presentation versus one that develops subsequently. A category 1 or 2 FHR tracing associated with Apgar scores ≥ 7 at 5 minutes, normal cord gases (± 1 SD), or both, is not consistent with an acute HIE event (Anderson, 2013). An FHR pattern at the time of presentation with persistently minimal or absent variability and lacking accelerations, with duration ≥ 60 minutes, and even without decelerations is suggestive of an already compromised fetus. The Task Force further recommended that if fetal well-being cannot be established with these findings present, the woman should be evaluated for the method and timing of delivery.

Application of 2003 Task Force Criteria

It seemed likely that strict adherence to all of the criteria set forth by the 2003 Task Force would exclude some infants who go on to develop cerebral palsy as a result of neonatal encephalopathy (Strijbis, 2006). To test these criteria, Phelan and coworkers (2011) retrospectively applied the 2003 Task Force criteria to 39 term infants with permanent central nervous system impairment. They found that the Task Force criteria and these 39 cases correlated in varying degrees. Of

the essential criteria, pH < 7.0 and base deficit ≥ 12 mmol/L showed a 97- and 100-percent correlation, respectively; moderate to severe encephalopathy—97 percent correlation; spastic quadriplegia or dyskinetic form—92 percent; and no other identifiable cause—100 percent. Of the nonspecific criteria, a sentinel hypoxic event had an 80-percent correlation; fetal heart rate requirements—100 percent; Apgar score ≤ 3 beyond 5 minutes—29 percent; and multisystem involvement—100 percent. As discussed subsequently, a sentinel event alone had only a 10-percent predictive value for newborn encephalopathy (Martinez-Biarge, 2012).

Prevention

Most prophylactic measures for neonatal encephalopathy have been evaluated in preterm infants (Chap. 42, p. 854). One of these—hypothermia—may prevent death and mitigate moderate to severe neurological disability in term infants (Nelson, 2014; Pfister, 2010; Shankaran, 2005, 2012). MR imaging studies have demonstrated a slowing of diffusional abnormalities and fewer infarctions with hypothermia (Bednarek, 2012; Shankaran, 2012). Most randomized trials have shown improved outcomes with hypothermia in infants born at 36 weeks or older (Azzopardi, 2009; Guillet, 2012; Jacobs, 2011). In a metaanalysis of more than 1200 newborns, Tagin and colleagues (2012) concluded that hypothermia improves survival rates and neurodevelopment. More recently, clinical trials to evaluate concomitant erythropoietin therapy for neuroprophylaxis are being conducted (Wu, 2012). Preliminary data from a Dutch multicenter trial of maternal allopurinol therapy indicate some mitigation of cerebral damage from hypoxia and ischemia (Kaandorp, 2013).

Cerebral Palsy

This term refers to a group of nonprogressive disorders of movement or posture caused by abnormal development or damage to brain centers for motor control. Cerebral palsy is further classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. Together, the major types are *spastic quadriplegia*—the most common—which has a strong association with mental retardation and seizure disorders; *diplegia*, which is common in preterm or low-birthweight infants; *hemiplegia*; *choreoathetoid types*; and *mixed varieties*. Although epilepsy and mental retardation frequently accompany cerebral palsy, these two disorders seldom are associated with perinatal asphyxia in the absence of cerebral palsy.

Incidence and Epidemiological Correlates

According to the Centers for Disease Control and Prevention (2011), the prevalence of cerebral palsy is variably reported in the United States. In one multisite surveillance program in 2006, the average prevalence was 2.9 per 1000 8-year-old children. *It is crucial to emphasize that this rate is derived from all children—including preterm infants.* Because of the remarkably increased survival rates of the latter, the overall rate of cerebral palsy and other developmental disabilities reported in the 1950s has remained essentially unchanged (Boyle, 2011).

Long-term follow-up studies of more than 900,000 Norwegian nonanomalous term infants cite an incidence of 1 per 1000 (Moster, 2008). By contrast, the incidence was 91 per 1000 for infants born at 23 to 27 weeks. In absolute numbers, term infants comprise half of cerebral palsy cases because there are proportionately far fewer preterm births. It is again emphasized that most studies have not made distinctions between term and preterm infants.

As noted earlier, Nelson and Ellenberg (1984, 1985, 1986a) made many foundational observations concerning cerebral palsy. Their initial studies emanated from data from the Collaborative Perinatal Project. This included children from almost 54,000 pregnancies who were followed until age 7. They found that the most frequently associated risk factors for cerebral palsy were: (1) evidence of genetic abnormalities such as maternal mental retardation or fetal congenital malformations; (2) birthweight < 2000 g; (3) birth before 32 weeks; and (4) perinatal infection. They also found that obstetrical complications were not strongly predictive, and only a fifth of affected children had markers of perinatal asphyxia. *For the first time, there was solid evidence that the cause of most cases of cerebral palsy was unknown, and importantly, only a small proportion was caused by neonatal hypoxic-ischemic encephalopathy.* Equally importantly, there was no foreseeable single intervention that would likely prevent a large proportion of cases.

Numerous studies have since confirmed many of these findings and identified an imposing list of other risk factors that are shown in Table 33-2. As expected, preterm birth continues to be the single most important risk factor (Goepfert, 1996; Thorngren-Jerneck, 2006). Small-for-gestational-age infants are also at increased risk. Stoknes and associates (2012) showed that in more than 90 percent of growth-restricted infants, cerebral palsy was due to antepartum factors. A myriad other placental and neonatal risk factors has been correlated with neurodevelopmental abnormalities (Ahlin, 2013; Avagliano, 2010; Blair, 2011; Redline, 2005, 2008). Some placental factors are discussed further in Chapter 6, and in just one example, there is a substantively increased risk with chorioamnionitis (Gilbert, 2010; Shatrov, 2010). An example of a neonatal cause is arterial ischemic stroke, which may be associated with inherited fetal thrombophilias (Gibson, 2005; Harteman, 2013; Kirton, 2011). Also, neonates with isolated congenital heart lesions have an increased risk for microcephaly, possibly due to chronic fetal hypoxemia (Barbu, 2009). Other miscellaneous causes of cerebral palsy include fetal anemia, twin-twin transfusion syndrome, intra-uterine transfusions, and fetal alcohol syndrome (DeJong, 2012; Lindenburg, 2013; O'Leary, 2012; Rossi, 2011; Spruijt, 2012).

Intrapartum Events. The National Collaborative Perinatal Project found that intrapartum hypoxemia was linked to a minority of cerebral palsy cases. However, because the study was carried out in the 1960s, there were inconsistent criteria to accurately assign cause. The contribution of hypoxic-ischemic encephalopathy to subsequent neurological disorders is discussed in detail on page 639. Thus, the 2003 Task Force applied these criteria to more contemporaneous outcomes and determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia. This

TABLE 33-2. Perinatal Risk Factors Reported to Be Increased in Children with Cerebral Palsy

Risk Factors	Risk Ratio	95% CI
Hydramnios	6.9	1.0–49.3
Placental abruption	7.6	2.7–21.1
Interval between pregnancies < 3 months or > 3 years	3.7	1.0–4.4
Spontaneous preterm labor	3.4	1.7–6.7
Preterm delivery at 23–27 weeks	78.9	56.5–110
Breech or face presentation, transverse lie	3.8	1.6–9.1
Severe birth defect	5.6	8.1–30.0
Nonsevere birth defect	6.1	3.1–11.8
Time to cry > 5 minutes	9.0	4.3–18.8
Low placental weight	3.6	1.5–8.4
Placental infarction	2.5	1.2–5.3
Chorioamnionitis		
Clinical	2.4	1.5–3.8
Histological	1.8	1.2–2.9
Others ^a	—	—

^aIncludes respiratory distress syndrome, meconium aspiration, emergent cesarean or operative vaginal delivery, hypoglycemia, gestational hypertension, hypotension, advanced maternal age, nighttime delivery, seizures, fetal-growth restriction, male gender, and nulliparity. From Ahlin, 2013; Blair, 2011; Livinec, 2005; McIntyre, 2013; Moster, 2008; Nelson, 1985; 1986a, 2012; O'Callaghan, 2011; Redline, 2005; Shatrov, 2010; Takenouchi, 2012; Torfs, 1990; Wu, 2012.

finding is supported by a study from Western Australia that spanned from 1975 to 1980 (Stanley, 1991). These latter investigators concluded that intrapartum injury as the cause of cerebral palsy was unlikely in 92 percent of cases; in 3 percent, it was possible; and in only 5 percent was it likely. In another review of 209 infants with neurological impairment, 75 percent were classified as nonpreventable (Phelan, 1996). In yet another study of 213 such children, only 2 percent of cases could be attributed to intrapartum hypoxia (Strijbis, 2006).

Intrapartum Fetal Heart Rate Monitoring

Despite persistent attempts to validate continuous intrapartum electronic fetal monitoring as effective to prevent adverse perinatal outcomes, evidence does not support its ability to predict or reduce cerebral palsy risk (Clark, 2003; Devoe, 2011; MacDonald, 1985; Thacker, 1995). Importantly, there are no specific fetal heart rate patterns predictive of cerebral palsy, and no relationship has been found between the clinical response to abnormal patterns and neurological outcome (Melone, 1991; Nelson, 1996). Indeed, an abnormal heart rate pattern in fetuses that ultimately develop cerebral palsy may reflect a preexisting neurological abnormality (Phelan, 1994). Because of these studies, the American College of Obstetricians and Gynecologists (2013a) has concluded that electronic fetal monitoring does not reduce the incidence of long-term neurological impairment.

Apgar Scores

In general, 1- and 5-minute Apgar scores are poor predictors of long-term neurological impairment. When the 5-minute Apgar score is 3 or less, however, neonatal death or the risk of neurological sequelae is increased substantially (Dijxhoorn, 1986; Nelson, 1984). In a Swedish study, 5 percent of such children subsequently required special schooling (Stuart, 2011). In a Norwegian study, the incidence of these low Apgar scores was 0.1 percent in more than 235,000 newborns. Almost a fourth died, and 10 percent of survivors developed cerebral palsy (Moster, 2001).

Persistence past 5 minutes of these extremely low scores correlates strongly with an increased risk for neurological morbidity and death (Grünebaum, 2013). This of course is not absolute, and the 2003 Task Force cited a 10-percent risk for cerebral palsy for infants with 10-minute scores of 0 to 3. For 15-minute scores ≤ 2 , there is a 53-percent mortality rate and a 36-percent cerebral palsy rate, and for 20-minute scores ≤ 2 , there is a 60-percent mortality rate and a 57-percent rate of cerebral palsy. Some outcomes in the Norwegian Study of infants with these low 5-minute Apgar scores are shown in Table 33-3. Survivors with Apgar scores of 0 at 10 minutes have even worse outcomes. In a review of 94 such infants, 78 died, and *all* survivors assessed had long-term disabilities (Harrington, 2007).

Umbilical Cord Blood Gas Studies

As outlined on page 639, objective evidence for metabolic acidosis—cord arterial blood pH < 7.0 and base deficit ≥ 12 mmol/L—is a risk factor for encephalopathy as well as for cerebral palsy. The risk increases as acidosis worsens. From their review of 51 studies, Malin and coworkers (2010) found that low cord arterial pH correlates with increased risk for neonatal encephalopathy and cerebral palsy. When used alone, however, these determinations are not accurate in predicting long-term neurological sequelae (Dijxhoorn, 1986; Yeh, 2012).

TABLE 33-3. Comparison of Mortality and Morbidity in Norwegian Infants Weighing > 2500 g According to 5-Minute Apgar Scores			
Outcome	Apgar 0–3	Apgar 7–10	Relative Risk (95% CI)
Number	292	233, 500	
Mortality rates			
Neonatal	16.5%	0.05%	386 (270–552)
Infant	19.2%	0.3%	76 (56–103)
1–8 years	3%	0.2%	18 (8–39)
Morbidity rates			
Cerebral palsy	6.8%	0.09%	81 (48–128)
Mental retardation	1.3%	0.1%	9 (3–29)
Other neurological	4.2%	0.5%	9 (5–17)
Non-neurological	3.4%	2.0%	2 (0.8–5.5)

Data from Moster, 2001.

Data from several studies corroborate that a pH < 7.0 is the threshold for clinically significant acidemia (Gilstrap, 1989; Goldaber, 1991). The likelihood of neonatal death increases as the cord artery pH falls to 7.0 or less. Casey and colleagues (2001) reported that when the pH was 6.8 or lower, the neonatal mortality rate was increased 1400-fold. When the cord pH was ≤ 7.0 and the 5-minute Apgar score was 0 to 3, there was a 3200-fold increased risk of neonatal death.

In the study from Oxford, adverse neurological outcomes were 0.36 percent with pH < 7.1 and 3 percent with pH < 7.0 (Yeh, 2012). As mentioned, newborn complications increase coincident with increasing severity of acidemia at birth. According to the American College of Obstetricians and Gynecologists (2012d), encephalopathy develops in 10 percent of newborns whose umbilical arterial base deficit is 12 to 16 mmol/L, and in 40 percent of those whose deficit is > 16 mmol/L. In a Swedish study, researchers observed that cord blood lactate levels may prove to be superior to base deficit for prognostication of neurological disorders (Wiberg, 2010).

Nucleated Red Blood Cells and Lymphocytes

Both immature red cells and lymphocytes enter the circulation of term infants in response to hypoxia or hemorrhage. During the past two decades, quantification of these cells has been proposed as a measure of hypoxia, but most studies do not support this premise (Hankins, 2002; Silva, 2006; Walsh, 2011, 2013). The 2003 Task Force concluded that their use was investigational.

Neuroimaging Studies in Encephalopathy and Cerebral Palsy

Various neuroimaging techniques have provided important insight into the etiology and evolution of perinatal hypoxic-ischemic encephalopathy and later cerebral palsy (p. 639). Importantly, findings are highly dependent on fetal age. The preterm neonatal brain responds quite differently to an ischemic episode compared with that of a term infant. Other factors include insult severity and duration as well as restoration of cerebrovascular hypoperfusion. *Thus, precise timing of an injury with neuroimaging studies is not a realistic goal.* Reports are of two types—those in which neuroimaging was done during the neonatal period and those done when older children are diagnosed with cerebral palsy.

Neuroimaging in Neonatal Period

Regarding early use, the 2014 Task Force concluded that these imaging techniques provide the following information:

1. Sonographic studies are generally normal on the day of birth. Increasing echogenicity in the thalami and basal ganglia is seen beginning at approximately 24 hours. This progresses over 2 to 3 days and persists for 5 to 7 days.
2. Computed tomography scans are usually normal the first day in term infants. Decreased density in the thalami or basal ganglia is seen beginning at about 24 hours and persists for 5 to 7 days.
3. Magnetic resonance imaging will detect some abnormalities on the first day. Within 24 hours, MR imaging may

show restricted water diffusion that peaks at about 5 days and disappears within 2 weeks. Acquisitions with T1- and T2-weighted images show variable abnormalities, which have an onset from less than 24 hours to several days. In a study of 175 term infants with acute encephalopathy, it was reported that MR imaging showing basal ganglia lesions accurately predicted motor impairment at 2 years of age (Martinez-Biarge, 2012).

The 2014 Task Force concluded that for term infants, imaging studies are helpful in timing an injury, but they provide only a window in time that is imprecise. Findings in preterm infants are considered in Chapter 34 (p. 656).

Neuroimaging in Older Children with Cerebral Palsy

Imaging studies performed in children diagnosed with cerebral palsy frequently show abnormal findings. Wu and associates (2006) used CT or MR imaging to study 273 children who were born after 36 weeks and who were diagnosed later in childhood with cerebral palsy. Although a third of these studies were normal, focal arterial infarction was seen in 22 percent; brain malformations in 14 percent; and periventricular white-matter injuries in 12 percent. In another study of 351 children with cerebral palsy—about half were born near term—MR imaging findings were abnormal in 88 percent (Bax, 2006). Similar findings were reported in an Australian study (Robinson, 2008).

CT and MR imaging techniques have also been used in older children in an attempt to define the timing of fetal or perinatal cerebral injury. Wiklund and coworkers (1991a,b) studied 83 children between ages 5 and 16 years who were born at term and who developed hemiplegic cerebral palsy. Nearly 75 percent had abnormal CT findings, and these investigators concluded that more than half had CT findings that suggested a *prenatal injury*. Approximately 20 percent was attributed to a *perinatal injury*. In a similar study, Robinson and colleagues (2008) used MR imaging. They reported pathological findings in 84 percent of children with spastic quadriplegia, which is the neurological lesion that the 2014 Task Force reported to correlate with neonatal encephalopathy.

Intellectual Disability and Seizure Disorders

The term *intellectual disability* is the preferred substitute term for the older culturally insensitive term *mental retardation* (Centers for Disease Control and Prevention, 2012). It describes a spectrum of disabilities and seizure disorders that frequently accompany cerebral palsy. But when either of these manifests alone, they are seldom caused by perinatal hypoxia (Nelson, 1984, 1986a,b). Severe mental retardation has a prevalence of 3 per 1000 children, and its most frequent causes are chromosomal, gene mutations, and other congenital malformations. Finally, preterm birth is a common association for these (Moster, 2008).

The major predictors of seizure disorders are fetal malformations—cerebral and noncerebral; family history of seizures; and neonatal seizures (Nelson, 1986b). Neonatal encephalopathy causes a small proportion of seizure disorders. Reports from

the Neonatal Research Network and other studies concluded that increasing severity of encephalopathy correlates best with seizures (Glass, 2011; Kwon, 2011).

Autism Spectrum Disorders

According to the Centers for Disease Control and Prevention (2012), the frequency of autism is almost 0.5 percent, and for attention deficit hyperactivity disorders, it is 6.7 percent. Although these may be associated with maternal metabolic conditions, none has been linked convincingly to peripartum events (Krakowiak, 2012).

HEMATOLOGICAL DISORDERS

There are a few neonatal disorders of erythrocytes, platelets, and coagulation with which the obstetrician should be familiar. As is the case for most other conditions manifest by the newborn shortly after birth, many of these hematological problems were acquired by the fetus and persist in the newborn.

Anemia

After 35 weeks' gestation, the mean cord hemoglobin concentration is approximately 17 g/dL, and values below 14 g/dL are considered abnormal. A review of nearly 3000 deliveries found that late cord clamping was associated with a mean hemoglobin increase of 2.2 g/dL (McDonald, 2008). Unfortunately, this practice almost doubled the incidence of hyperbilirubinemia requiring phototherapy. The American College of Obstetricians and Gynecologists (2012b) has concluded that optimal timing of cord clamping for term infants is unknown. Conversely, cord blood hemoglobin concentration may be abnormally low, or it may fall after delivery. Fetal anemia results from many causes and is discussed in Chapter 15 (p. 306).

Acute anemia with hypovolemia is seen with deliveries in which the placenta is cut or torn, if a fetal vessel is perforated or lacerated, or if the infant is held well above the level of the placenta for some time before cord clamping. Intracranial or extracranial injury or trauma to fetal intraabdominal organs can also cause hemorrhage with acute anemia (Akin, 2011).

Polycythemia and Hyperviscosity

Neonatal polycythemia with hyperviscosity can be associated with chronic hypoxia in utero, twin-twin transfusion syndrome, placental- and fetal-growth restriction, fetal macrosomia from maternal diabetes, and transfusion at delivery. Current recommendations by the International Liaison Committee on Resuscitation (ILCOR) are to delay cord clamping for at least 1 minute after delivery (Davis, 2012). When the hematocrit rises above 65, blood viscosity markedly increases and may cause neonatal plethoria, cyanosis, or neurological aberrations. Because of the shorter lifespan of macrocytic fetal erythrocytes, hyperbilirubinemia commonly accompanies polycythemia as subsequently discussed. Other findings include thrombocytopenia, fragmented erythrocytes, and hypoglycemia. Partial exchange transfusion may be necessary in some neonates.

Hyperbilirubinemia

Even in term fetuses, hepatic maturation is not complete, and thus some unconjugated bilirubin—either albumin bound or free—is cleared by placental transfer to be conjugated in the maternal liver (Chap. 7, p. 141). Fetal protection from unconjugated bilirubin is lost after delivery if it is not cleared rapidly. Because clearance is totally dependent on neonatal hepatic function, varying degrees of neonatal hyperbilirubinemia result. Even in the mature newborn, serum bilirubin usually increases for 3 to 4 days to reach levels up to 10 mg/dL. After this, concentrations usually fall rapidly. In one large study, 1 to 2 percent of neonates delivered at 35 weeks' gestation or later had a maximum serum bilirubin level > 20 mg/dL (Eggert, 2006). In approximately 15 percent of term newborns, bilirubin levels cause clinically visible skin color changes termed *physiological jaundice* (Burke, 2009). As expected, in preterm infants, the bilirubin increase is greater and more prolonged.

Acute Bilirubin Encephalopathy and Kernicterus

Excessive serum bilirubin levels can be neurotoxic for newborns (Dijk, 2012; Watchko, 2013). The pathogenesis is complex, and toxicity has two forms. *Acute bilirubin encephalopathy* is encountered in the first days of life and is characterized by hypotonia, poor feeding, lethargy, and abnormal auditory-evoked responses (Kaplan, 2011). Immediate recognition and treatment will usually mitigate progressive neurotoxicity. The chronic form is termed *kernicterus*—from Greek *jaundice of the nuclei*. Neurotoxicity follows bilirubin deposition and staining of the basal ganglia and hippocampus and is further characterized by profound neuronal degeneration. Survivors have spasticity, muscular incoordination, and varying degrees of mental retardation. Although there is a positive correlation between kernicterus and unconjugated bilirubin levels above 18 to 20 mg/dL, it can develop at much lower concentrations, especially in very preterm neonates (Sgro, 2011). Continuing hemolysis is a risk factor for kernicterus, and experiences from the Collaborative Perinatal Project were that bilirubin levels \geq 25 mg/dL correlated with kernicterus only with ongoing Coombs-positive hemolysis (Kuzniewicz, 2009). This was recently verified in a study by Vandborg and associates (2012).

Prevention and Treatment

Various forms of phototherapy are used to prevent as well as treat neonatal hyperbilirubinemia (Hansen, 2011). These “bili-lights” emit a spectrum of 460 to 490 nm, which increases bilirubin oxidation to enhance its renal clearance and lower serum levels. Light that penetrates the skin also increases peripheral blood flow, which further enhances photo-oxidation. It is problematic that available devices are not standardized (Bhutani, 2011). Another advantage is that exchange transfusions are seldom required with phototherapy. There are studies in both preterm and term newborns that attest to phototherapy efficacy (Watchko, 2013). A Neonatal Research Network study reported that aggressive phototherapy in low-birthweight neonates reduced rates of neurodevelopmental impairment (Newman, 2006).

For term infants, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists

(2012b) stress early detection and prompt phototherapy to prevent bilirubin encephalopathy. Despite these measures, bilirubin encephalopathy persists, and this is somewhat related to early hospital discharges (Gazzin, 2011; Kaplan, 2011; Sgro, 2011). According to Burke and coworkers (2009), hospitalizations for kernicterus in term infants were 5.1 per 100,000 in 1988. Since then, however, this rate has decreased to 0.4 to 2.7 cases per 100,000 births (Watchko, 2013).

Hemorrhagic Disease of the Newborn

This disorder is characterized by spontaneous internal or external bleeding beginning any time after birth. Most hemorrhagic disease results from abnormally low levels of the vitamin K-dependent clotting factors—V, VII, IX, X, prothrombin, and proteins C and S (Zipursky, 1999). Infants whose mothers took anticonvulsant drugs are at higher risk because these suppress maternal hepatic synthesis of some of these factors (Chap. 60, p. 1190). Classic hemorrhagic disease is usually apparent 2 to 5 days after birth in infants not given vitamin K prophylaxis at delivery (Busfield, 2013). Delayed hemorrhage may occur at 2 to 12 weeks in exclusively breast-fed infants because breast milk contains little vitamin K. Other causes of neonatal hemorrhage include hemophilia, congenital syphilis, sepsis, thrombocytopenia purpura, erythroblastosis, and intracranial hemorrhage.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommends routine prophylaxis for hemorrhagic disease with a 0.5 to 1 mg dose of vitamin K₁ (phytonadione) given intramuscularly. Oral administration is not effective, and maternal vitamin K administration results in very little transport to the fetus. For treatment of active bleeding, vitamin K is injected intravenously.

Thrombocytopenia

Abnormally low platelet concentrations in term newborns may be due to various etiologies such as immune disorders, infections, drugs, or inherited platelet defects, or they may be part of a congenital syndrome. In many, thrombocytopenia is an extension of a fetal disorder such as infection with B19 parvovirus, cytomegalovirus, toxoplasmosis, and others discussed in Chapters 64 and 65. Term infants admitted to neonatal intensive care units, especially those with sepsis, have accelerated platelet consumption (Eissa, 2013). In these, transfusions are occasionally indicated (Sallmon, 2012).

Immune Thrombocytopenia

In women with an autoimmune disorder such as systemic lupus erythematosus or immunological thrombocytopenia, maternal antiplatelet IgG is transferred to the fetus and can cause accelerated platelet destruction. Most cases are mild, and platelet levels usually reach a nadir at 48 to 72 hours. Maternal corticosteroid therapy generally has no effect on fetal platelets. Fetal blood sampling for platelet determination is seldom necessary, and platelets are usually adequate to prevent fetal hemorrhage during delivery (Chap. 56, p. 1115).

Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia (AIT) or neonatal alloimmune thrombocytopenia (NAIT) is caused by maternal-fetal platelet antigen disparity. If maternal alloimmunization is stimulated, then transplacental antiplatelet IgG antibodies cause severe fetal thrombocytopenia, which is considered in detail in Chapter 15 (p. 313).

Preeclampsia Syndrome

Maternal platelet function and destruction can be severely affected in women with severe preeclampsia. That said, fetal or neonatal thrombocytopenia is rarely caused by the preeclampsia syndrome even when the mother has severe thrombocytopenia. The large study of mother-infant pairs delivered at Parkland Hospital dispelled earlier reports of an association of neonatal thrombocytopenia with preeclampsia (Pritchard, 1987). Instead, neonatal thrombocytopenia was found to be associated with preterm delivery and its myriad complications (Chap. 34, p. 653).

INJURIES OF THE NEWBORN

Birth injuries can potentially complicate any delivery. Thus, although some are more likely associated with “traumatic” delivery by forceps or vacuum, others are seen with otherwise uncomplicated vaginal or cesarean delivery. In this section, some injuries are discussed in general, but specific injuries are described elsewhere in connection with their associated obstetrical complications, for example, breech delivery in Chapter 28 or multifetal gestation in Chapter 45.

Incidence

In three population studies that included more than 8 million term infants, the overall incidence of birth trauma was 20 to 26 per 1000 deliveries (Baskett, 2007; Linder, 2012; Moczygemba, 2010). Of these studies, data from Nova Scotia are shown in Table 33-4 with an overall trauma risk of 19.5 per 1000 deliveries. Only 1.6 per 1000 were due to major trauma, and these rates were highest with failed instrumented delivery and lowest with cesarean delivery without labor. Thus, most traumatic injuries were minor and had an incidence of 18 per 1000 deliveries.

Injuries associated with cesarean delivery from a Maternal-Fetal Medicine Units Network study were described by Alexander and coworkers (2006). Four hundred injuries were identified from a total of 37,100 operations—a rate of 11 per 1000 cesarean deliveries. Although skin lacerations predominated—7 per 1000—more serious injuries in these 400 infants included 88 cephalohematomas, 11 clavicular fractures, 11 facial nerve palsies, nine brachial plexopathies, and six skull fractures.

Cranial Injuries

Traumatic head injuries that are associated with labor or delivery can be *external* and obvious, such as a skull or mandibular

TABLE 33-4. Incidence of Major and Minor Birth Trauma—Nova Scotia, 1988–2001

Type of Delivery (Trauma Rate per 1000)	Number	Birth Trauma (Rate per 1000)	
		Major ^a	Minor ^b
Spontaneous (14)	88,324	1.2	13
Assisted			
Vacuum (71)	3175	3.7	67
Forceps (58)	10,478	5.2	53
Failed assisted			
Vacuum (105)	609	8.3	100
Forceps (56)	714	7.0	50
Cesarean (8.6)	16,132	0.3	8.3
Labor (12)	10,731	0.4	11.9
No labor (1.2)	5401	0.2	1.1
All (19.5)	119,432	1.6	18

^aMajor trauma = depressed skull fracture, intracranial hemorrhage, brachial plexopathy, or combination.

^bMinor trauma = linear skull fracture, other fractures, facial palsy, cephalohematoma, or combination.
Data from Baskett, 2007.

fracture; they can be *intracranial*; and in some, they are *covert*. The fetal head has considerable plasticity and can undergo appreciable molding. Rarely, severe molding can result in tearing of bridging cortical veins that empty into the sagittal sinus, internal cerebral veins, the vein of Galen, or of the tentorium itself. As a result, intracranial, subdural, and even epidural hemorrhage can be seen after an apparently uneventful vaginal delivery (Scheibl, 2012). Bleeding may also be asymptomatic. Conversely, subgaleal hemorrhages associated with instrumented delivery can be life threatening (Doumouchtis, 2008; Swanson, 2012). In rare severe head trauma cases, there is embolization of fetal brain tissue to the heart or lungs (Cox, 2009).

Intracranial Hemorrhage

Most aspects of neonatal intracranial hemorrhage are related to gestational age. Specifically, most hemorrhage in preterm neonates results from hypoxia and ischemia, whereas in term newborns, trauma is the most frequent cause. Some varieties are shown in Table 33-5. *Importantly, in some infants, a putative cause is not found.* In many cases, intracranial hemorrhage is asymptomatic. The reported incidence varies, but it is highest with operative deliveries—both vaginal and cesarean deliveries. In the study by Moczygemba and colleagues (2010), for more than 8 million singleton deliveries, the overall intracranial hemorrhage rate was approximately 0.2 per 1000 births—1 per 5000. In a study from New York City, Werner and associates (2011) cited a combined incidence in more than 120,000 nulliparous singleton operative deliveries of 0.12 percent, or about 1 in

TABLE 33-5. Major Types of Neonatal Intracranial Hemorrhage

Type	Etiology and Neuropathogenesis	Clinical Outcomes
Subdural	Trauma—tentorial, falx, or venous (sinus) laceration causing hematoma	Uncommon but potentially serious; symptom onset is variable depending on hematoma expansion, but usually < 24 hours: irritability, lethargy, and brainstem compression
Primary subarachnoid	Possibly due to trauma or hypoxia—excludes SAH associated with subdural, intraventricular, intracerebral (AVM, aneurysm), or intracerebellar hemorrhage	Common but almost always benign
Intracerebellar	Trauma and perhaps hypoxia—most cases in preterm infants	Uncommon but serious
Intraventricular	Trauma and hypoxia (no discernible cause in 25 percent)—hemorrhage usually from choroid plexus	Uncommon but serious; symptoms as for subdural hemorrhage
Miscellaneous	Trauma with epidural or intracerebral hemorrhage Hemorrhagic infarction—embolism or thrombosis in artery or vein Coagulopathies—thrombocytopenia or inherited factor deficiencies Vascular defect—aneurysm or AVM	Depends on cause

AVM = arteriovenous malformation; SAH = subarachnoid hemorrhage.
Data from Volpe, 1995.

750 procedures. The rates of intracranial hemorrhage were 1:385 with vacuum delivery; 1:515 with forceps, and 1:1210 with cesarean delivery. In another study, its incidence was nearly 1 percent following vacuum-assisted deliveries (Simonson, 2007). According to the American College of Obstetricians and Gynecologists (2012a), the incidence of intracranial hemorrhage from birth trauma has been substantively decreased by elimination of difficult operative vaginal deliveries. This was verified in a recent report of carefully conducted Kielland forceps deliveries (Burke, 2012).

The prognosis after hemorrhage depends on its location and extent, as shown in Table 33-5. For example, subdural and subarachnoid hemorrhage seldom results in neurological abnormalities, whereas large hematomas are serious. Any bleeding into the parenchyma from intraventricular or intracerebellar hemorrhage often causes serious permanent damage or death. Periventricular hemorrhage rarely causes the type of sequelae that are common in those born preterm (Chap. 34, p. 656).

Infants who have traumatic subdural or infratentorial hemorrhage tears will have neurological abnormalities from the time of birth (Volpe, 1995). Those most severely affected have stupor or coma, nuchal rigidity, and opisthotonos that worsen over minutes to hours. Some newborns who are born depressed appear to improve until about 12 hours of age, when drowsiness, apathy, feeble cry, pallor, failure to nurse, dyspnea, cyanosis, vomiting, and convulsions become evident.

Spontaneous intracranial hemorrhage has also been documented in healthy term neonates (Huang, 2004; Rutherford, 2012). In a prospective MR imaging study, Whitby and coworkers (2004) found that 6 percent of those delivered

spontaneously and 28 percent of those delivered by forceps had a subdural hemorrhage. None of these had clinical findings, and hematomas resolved by 4 weeks in all infants.

Extracranial Hematomas

These blood collections accumulate outside the calvarium and are categorized as a *cephalohematoma* or *subgaleal hemorrhage* (Fig. 33-1). From its most superficial inward, the scalp is composed of skin, subcutaneous tissue, galea aponeurotica, subgaleal space, and calvarium periosteum. The galea aponeurotica is dense fibrous tissue, whereas the subgaleal space contains loose, fibroareolar tissue. Traversing across the subgaleal space are large, valveless *emissary veins*, which connect the dural sinuses inside the skull with the superficial scalp veins. Both the galea aponeurotica and subgaleal space span across the occipital, parietal, and frontal bones. In contrast, periosteum invests each individual skull bone and does not cross suture lines.

Cephalohematomas are cranial subperiosteal hematomas. These develop from shearing forces during labor and delivery that lacerate the emissary or diploic veins. Fortunately, the densely adhered periosteum impedes rapid enlargement and limits final hematoma size. Hemorrhage can be over one or both parietal bones, but palpable edges can be appreciated as the blood reaches the limits of the periosteum. These hematomas must be differentiated from *caput succedaneum*, also shown in Figure 33-1. A cephalohematoma may not be apparent until hours after delivery, when bleeding sufficient to raise the periosteum has occurred. After it is identified, it often grows larger and persists for weeks or even months, and bleeding may be

FIGURE 33-1 Schematic of extracranial lesions in the neonate.

sufficient to cause anemia. By contrast, with caput succedaneum, swelling of the scalp causes edema that overlies the periosteum. The caput is maximal at birth, rapidly grows smaller, and usually disappears within hours or a few days. Occasionally, it becomes infected, and abscess may form (Kersten, 2008).

Cephalohematomas are common, and in the study from Nova Scotia shown in Table 33-3, these accounted for 80 percent of traumatic injuries with an incidence of 16 per 1000 (Baskett, 2007). They rarely develop in the absence of birth trauma, and an 11-percent incidence was reported in 913 term infants delivered by vacuum extraction (Simonson, 2007). In the Network study of cesarean delivery outcomes cited above, the incidence of cephalohematoma was 2.4 per 1000 operations (Alexander, 2006). Others have reported lower incidences, although cephalohematoma is more common with vacuum compared with forceps deliveries—0.8 versus 2.7 per 1000 operative deliveries (Werner, 2011).

Subgaleal hemorrhage results from laceration of one of the emissary veins, with bleeding between the galea aponeurotica and the skull periosteum. Because of its loose areolar tissue and large surface area, significant blood volumes can collect in this potential space and can extend from the neck to the orbits and laterally to the temporal fascia above the ears. Resulting hypotension can lead to significant morbidity, and cited mortality rates range from 12 to 18 percent (Chang, 2007; Kilani, 2006).

Skull Fractures

These are rare but are especially worrisome because of their association with serious intracranial hemorrhages as discussed above. Volpe (1995) considers three types of skull injuries to

be fractures—linear and depressed fractures and occipital osteodystasia. In a French study of nearly 2 million deliveries from 1990 to 2000, the incidence of skull fractures was reported to be 3.7 per 100,000 births, and 75 percent were associated with operative vaginal deliveries (Dupuis, 2005). These are occasionally seen with spontaneous or cesarean delivery such as the depressed skull fracture shown in Figure 33-2. These latter fractures are more common when the head is tightly wedged in the pelvis. In such cases, there are at least three possible causes. A fracture may result from skull compression against the sacral promontory, by hand pressure used to lift the head at cesarean delivery, or from transvaginally applied upward hand pressure by an assistant. Fractures are managed with surgical decompression, although spontaneous resolution can follow (Basaldella, 2011).

Spinal Cord Injury

Overstretching of the spinal cord and associated hemorrhage and edema are rare injuries. They are usually caused by excessive longitudinal or lateral traction of the spine or by torsion during delivery. In some cases, there is fracture or dislocation of the vertebrae. Menticoglou and associates (1995) described 15 neonates with this type of high cervical spinal cord injury and found that all of the injuries were associated with forceps rotations. Spinal cord injury also can occur during breech delivery. Ross and coworkers (2006) described C₅₋₆ vertebral dislocation associated with a Zavanelli maneuver done because of shoulder dystocia (Chap. 27, p. 544).

Peripheral Nerve Injuries

Traumatic injuries to nerves can be serious and distressing, especially if permanent. Injury can involve a single nerve, or it can affect a nerve root, plexus, or trunk (Volpe, 1995).

FIGURE 33-2 Depressed skull fracture (arrow) evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual pressure upward through the vagina.

Brachial Plexopathy

Injuries to the brachial plexus are relatively common. They are identified in 1 to 3 per 1000 term births (Baskett, 2007; Joyner, 2006; Lindqvist, 2012). In the study of more than 8 million singleton births reported by Moczygamba and colleagues (2010), the incidence of brachial nerve injury was 1.5 per 1000 vaginal deliveries and 0.17 per 1000 cesarean deliveries. Breech delivery and shoulder dystocia are risks for this trauma. However, severe plexopathy may also occur without risk factors or shoulder dystocia (Torki, 2012).

The injury with plexopathy is actually to the nerve roots that supply the brachial plexus— C_{5-8} and T_1 . With hemorrhage and edema, axonal function may be temporarily impaired, but the recovery chances are good. However, with avulsion, the prognosis is poor. In 90 percent of cases, there is damage to the C_{5-6} nerve roots causing *Erb* or *Duchenne paralysis* (Volpe, 1995). Injuries with breech delivery are normally of this type, whereas the more extensive lesions follow difficult cephalic deliveries (Ubachs, 1995). The C_{5-6} roots join to form the upper trunk of the plexus, and injury leads to paralysis of the deltoid, infraspinatus, and flexor muscles of the forearm. The affected arm is held straight and internally rotated, the elbow is extended, and the wrist and fingers flexed. Finger function usually is retained. Because lateral head traction is frequently employed to effect delivery of the shoulders in normal vertex presentations, most cases of Erb paralysis follow deliveries that do not appear difficult. Damage to the C_8 - T_1 roots supplying the lower plexus results in *Klumpke paralysis*, in which the hand is flaccid. Total involvement of all brachial plexus nerve roots results in flaccidity of the arm and hand, and with severe damage, there may also be *Horner syndrome*.

Unfortunately, as discussed in Chapter 27 (p. 541), shoulder dystocia cannot be accurately predicted. In most cases, axonal death does not occur and the prognosis is good. Lindqvist and associates (2012) reported complete recovery in 86 percent of children with C_{5-6} trauma, which was the most common injury, and in 38 percent of those with C_{5-7} damage. However, those with global C_{5-8} - T_1 injuries always had permanent disability. Surgical exploration and possible repair may improve function if there is persistent paralysis (Malessy, 2009).

Facial Paralysis

Trauma to the facial nerve commonly occurs as it emerges from the stylomastoid foramen, and this can cause facial paralysis (Fig. 33-3). The incidence, which ranges from 0.2 to 7.5 per 1000 term births, is likely influenced by the vigor with which the diagnosis is sought (Al Tawil, 2010; Moczygamba, 2010). Facial paralysis may be apparent at delivery or may develop shortly after birth. It most frequently is associated with uncomplicated vaginal delivery. However, in one series, a fourth of cases followed cesarean delivery (Alexander, 2006; Al Tawil, 2010; Moczygamba, 2010). Facial nerve damage is likely more common with low forceps (Hagadorn-Freathy, 1991; Levine, 1984). It is possible that damage is caused by pressure exerted by the posterior blade when forceps have been placed obliquely on the fetal head. In these cases, forceps marks indicate the cause of injury. Spontaneous recovery within a few days is the rule, however, permanent paralysis has been described (Al Tawil, 2010; Duval, 2009).

FIGURE 33-3 Left facial nerve injury. This was almost completely resolved two days after delivery.

Fractures

Most long-bone fractures follow difficult deliveries, however, this is not always the case. At minimum, palpation of the clavicles and long bones is indicated for all newborns after a difficult delivery. Crepitation or unusual irregularity should prompt radiographic examination.

Clavicular fractures are common, unpredictable, and unavoidable complications of normal birth. Their incidence averages 5 to 10 per 1000 live births (Linder, 2012; Moczygamba, 2010). Other than female gender, no specific risk factors—including birthweight and mode of delivery—have been identified.

Humeral fractures are infrequent, and 70 percent follow an uneventful birth (Turpenny, 1993). Others are associated with difficult delivery of the shoulders in cephalic deliveries and of an extended arm in breech deliveries. Radiographically, they are often of the greenstick type, although complete fracture with overriding bones can be seen. Sonography has also been used to confirm diagnosis (Sherr-Lurie, 2011).

Femoral fractures are relatively rare and usually are associated with vaginal breech delivery. They occasionally follow cesarean delivery, and in one report, they were bilateral (Cebesoy, 2009). Because most breech-presenting fetuses now undergo cesarean delivery, most of these fractures are associated with this mode (Alexander, 2006; Cebesoy, 2009).

Mandibular fractures have been reported, are rare, and have been reviewed by Vasconcelos and coworkers (2009). The rare cases of cervical vertebral dislocation in fetuses delivered as breech or after the Zavanelli maneuver are discussed above (Ross, 2006).

Muscle Injuries

Sternocleidomastoid muscle injury was usually seen with vaginal breech delivery (Roemer, 1954). Hematomas of the muscle or the fascial sheath may resolve slowly with cicatricial contraction. With normal neck growth, the less-elastic damaged muscle does not elongate appropriately. As a result, the head is gradually turned toward the side of the injury—*torticollis*.

Soft Tissue Injuries

Conceivably, any fetal organ or part could be injured with either vaginal or cesarean delivery. Some of these include subcapsular hepatic hematomas that presented as inguinal and scrotal hematoma. In such cases, ecchymoses of the inguinal region are termed *Stabler sign*, and those of the scrotum are termed *Bryant sign* (Heyman, 2011; Lee, 2011). Thymic gland traumatic hemorrhage in those with underlying hyperplasia or cyst has been described before, during, and after delivery (Eifinger, 2007; Saksenberg, 2001). Injuries to the sixth cranial nerve with resultant lateral rectus ocular muscle paralysis have also been reported following operative vaginal delivery (Galbraith, 1994).

Congenital Deformity Injuries

There are several injuries creating morphological defects that the fetus can sustain long before delivery. One is the amniotic band syndrome caused when a free strip of amnion forms a focal ring around an extremity or digit. Eventually, deformation or amputation may result. Occasionally, the amputated part may be found within the uterus. The genesis of such bands is debated and discussed in Chapter 6 (p. 121). A similar anomaly is a *limb-reduction defect* associated with chorionic villus sampling performed before 9 weeks' gestation as discussed in Chapter 14 (p. 300).

Various congenital postural anomalies form when a normally developed fetal structure becomes deformed by intrauterine mechanical factors. Examples of the latter include chronic oligohydramnios, restricted fetal movement imposed by an abnormally shaped or small uterine cavity, or by the presence of additional fetuses. Some mechanical deformations include talipes equinovarus (clubfoot), scoliosis, and hip dislocation (Miller, 1981). Talipes and other positional foot abnormalities are associated with membrane rupture from early amniocentesis between 11 and 13 weeks' gestation (Chap. 14, p. 299). Finally, somewhat related, hypoplastic lungs also can result from oligohydramnios (Chap. 11, p. 237).

CHAPTER 34

The Preterm Newborn

RESPIRATORY DISTRESS SYNDROME	653
AMNIOCENTESIS FOR FETAL LUNG MATURITY	655
NECROTIZING ENTEROCOLITIS	655
RETINOPATHY OF PREMATURITY	656
INTRACRANIAL HEMORRHAGE	656
CEREBRAL PALSY	657

The preterm infant is susceptible to various serious medical complications during the newborn period as well as morbidities extending later into life (Table 34-1). These complications are primarily the consequence of immature organs that result from abbreviated gestation. A less commonly cited cause of morbidity and mortality is congenital malformations, which are much more prevalent in preterm births. For example, between 2010 and 2013 at Parkland Hospital, major malformations were diagnosed in 67 per 1000 singleton births < 37 weeks' gestation. This compared with 15 per 1000 in those ≥ 38 weeks—an almost fivefold excess. The pivotal complication, however, is *respiratory distress syndrome (RDS)*. This results from immature lungs that are unable to sustain necessary oxygenation. Resulting hypoxia is an underlying associated cause of neurological damage such as cerebral palsy. In addition, hyperoxia, a side effect of RDS treatment, causes bronchopulmonary dysplasia and retinopathy of prematurity. These complications of prematurity can be placed in perspective in terms of the *human consequences*. In 2009, two thirds of all infant deaths in the United States were in the 12 percent of infants who were born < 37 weeks (Mathews, 2013).

RESPIRATORY DISTRESS SYNDROME

To provide blood gas exchange immediately following delivery, the lungs must rapidly fill with air while being cleared of fluid. Concurrently, pulmonary arterial blood flow must increase remarkably. Some of the fluid is expressed as the chest is compressed during vaginal delivery, and the remainder is absorbed through the pulmonary lymphatics. Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli. It lowers surface tension and thereby prevents lung collapse during expiration (Chap. 7, p. 142). If surfactant is inadequate, hyaline membranes form in the distal bronchioles and alveoli, and RDS develops. Although respiratory insufficiency is generally a disease of preterm neonates, it does develop in term newborns, especially with sepsis or meconium aspiration.

Clinical Course

In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by *grunting* and *nostril flaring*. Shunting of blood through nonventilated lung contributes to hypoxemia and metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The chest radiograph shows a diffuse reticulogranular infiltrate and an air-filled tracheobronchial tree—*air bronchogram*.

As discussed further in Chapter 33 (p. 637), respiratory insufficiency can also be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and malformations involving thoracic structures, such as diaphragmatic hernia. Evidence is also accruing that common mutations in surfactant protein production may cause RDS (Garmany, 2008; Shulenin, 2004).

TABLE 34-1. Complications of Prematurity

Respiratory distress syndrome (RDS, HMD)
Bronchopulmonary dysplasia (BPD)
Pneumothorax
Pneumonia/sepsis
Patent ductus arteriosus (PDA)
Necrotizing enterocolitis (NEC)
Retinopathy of prematurity (ROP)
Intraventricular hemorrhage (IVH)
Periventricular leukomalacia (PVL)
Cerebral palsy (CP)

HMD = hyaline membrane disease.

Pathology

With inadequate surfactant, alveoli are unstable, and low pressures cause collapse at end expiration. Pneumocyte nutrition is compromised by hypoxia and systemic hypotension. Partial persistence of the fetal circulation may lead to pulmonary hypertension and a relative right-to-left shunt. Eventually, alveolar cells undergo ischemic necrosis. When oxygen therapy is initiated, the pulmonary vascular bed dilates, and the shunt reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles. The epithelium underlying the membrane becomes necrotic. With hematoxylin-eosin staining, these membranes appear amorphous and eosinophilic, like hyaline cartilage. Because of this, respiratory distress in the newborn is also termed *hyaline membrane disease*.

Treatment

The most important factor influencing survival is neonatal intensive care. Although hypoxemia prompts supplemental oxygen, excess oxygen can damage the pulmonary epithelium and the retina. However, advances in mechanical ventilation technology have improved neonatal survival rates. For example, *continuous positive airway pressure (CPAP)* prevents the collapse of unstable alveoli. This allows high inspired-oxygen concentrations to be reduced, thereby minimizing its toxicity. Disadvantages include overstretch of the endothelium and epithelium, which results in barotrauma and impaired venous return (Verbrugge, 1999). *High-frequency oscillatory ventilation* may reduce the barotrauma risk by using a constant, low-distending pressure and small oscillations to promote alveolar patency. This technique allows optimal lung volume to be maintained and carbon dioxide to be cleared without damaging alveoli. Although mechanical ventilation has undoubtedly improved survival rates, it is also an important factor in the genesis of chronic lung disease—*bronchopulmonary dysplasia*.

Treatment of the ventilator-dependent neonate with *glucocorticoids* was used previously to prevent chronic lung disease. The American Academy of Pediatrics now recommends against their use because of limited benefits and increased

adverse neuropsychological effects (Watterberg, 2010). Yeh and colleagues (2004) described significantly impaired motor and cognitive function and school performance in exposed neonates. A review by Halliday and associates (2009) supports late postnatal corticosteroid treatment only for infants who could not be weaned from mechanical ventilation. In some studies, *inhaled nitric oxide* was shown to be associated with improved outcomes for neonates undergoing mechanical ventilation (Ballard, 2006; Kinsella, 2006; Mestan, 2005). Other studies showed no benefits (van Meurs, 2005). Currently, such treatment is considered investigational (Chock, 2009; Stark, 2006).

Surfactant Prophylaxis

Exogenous surfactant products can prevent RDS. They contain biological or animal surfactants such as bovine—*Survanta*, calf—*Infasurf*, porcine—*Curosurf*, or synthetic—*Exosurf*. Lucinactant—*Surfaxin R*—is a synthetic form that contains sinulpeptide KL4 to diminish lung inflammation (Zhu, 2008). In a Cochrane review, Pfister and coworkers (2007) found that animal-derived and synthetic surfactants were comparable.

Surfactant therapy has been credited with the largest drop in infant mortality rates observed in 25 years (Jobe, 1993). It has been used for *prophylaxis* of preterm, at-risk newborns and for *rescue* of those with established disease. Given together, antenatal corticosteroids and surfactant result in an even greater reduction in the overall death rate. In their review, Seger and Soll (2009) found that infants who received prophylactic surfactant had decreased risks of pneumothorax, pulmonary interstitial emphysema, bronchopulmonary dysplasia, and mortality.

Complications

Persistent hyperoxia injures the lung, especially the alveoli and capillaries. High oxygen concentrations given at high pressures can cause *bronchopulmonary dysplasia*. With this, alveolar and bronchiolar epithelial damage leads to hypoxia, hypercarbia, and chronic oxygen dependence from peribronchial and interstitial fibrosis. According to Baraldi and Filippone (2007), most cases are now seen in infants born before 30 weeks' gestation and represent a developmental disorder secondary to alveolarization injury. Severe disease and death rates are decreasing, however, long-term pulmonary dysfunction is encountered later. *Pulmonary hypertension* is another frequent complication. If hyperoxemia is sustained, the infant also is at risk of developing *retinopathy of prematurity*, formerly called *retrolental fibroplasia* (p. 656). When any of these develop, the likelihood of subsequent neurosensory impairment is substantively increased (Schmidt, 2003).

Prevention

Antenatal Corticosteroids

The National Institutes of Health (1994, 2000) concluded that a single course of antenatal corticosteroid therapy reduced respiratory distress and intraventricular hemorrhage in preterm infants born between 24 and 34 weeks (p. 657). The

American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2012) considers all women at risk for preterm birth in this gestational-age range to be potential candidates for therapy. This is discussed further in Chapter 42 (p. 850). After 34 weeks, approximately 4 percent of infants develop respiratory distress syndrome (Consortium on Safe Labor, 2010).

Amniocentesis for Fetal Lung Maturity

Delivery for fetal indications is necessary when the risks to the fetus from a hostile intrauterine environment are greater than the risk of severe neonatal problems, even if the fetus is preterm. If this degree of risk is absent and the criteria for elective delivery at term are not met, then amniocentesis and amniotic fluid analysis can be used to confirm fetal lung maturity. To accomplish this, there are several methods to determine the relative concentration of surfactant-active phospholipids in amniotic fluid. Fluid acquisition is similar to that described for second-trimester amniocentesis (Chap. 16, p. 297). With this sampling, complications requiring urgent delivery arise in up to 1 percent of procedures (American College of Obstetricians and Gynecologists, 2008). Following analysis, the probability of respiratory distress developing in a given infant depends on the test used and fetal gestational age. Importantly, administration of corticosteroids to induce pulmonary maturation has variable effects on some of these tests.

Lecithin-Sphingomyelin (L/S) Ratio. Although not used nearly as much as in the past, the labor-intensive *L/S ratio* for many years was the gold-standard test. Dipalmitoylphosphatidylcholine (DPPC), that is, lecithin—along with phosphatidylinositol and especially phosphatidylglycerol (PG)—is an important component of the surface-active layer that prevents alveolar collapse (Chap. 32, p. 624). Before 34 weeks, lecithin and sphingomyelin are present in amniotic fluid in similar concentrations. At 32 to 34 weeks, the concentration of lecithin relative to sphingomyelin begins to rise (Fig. 34-1).

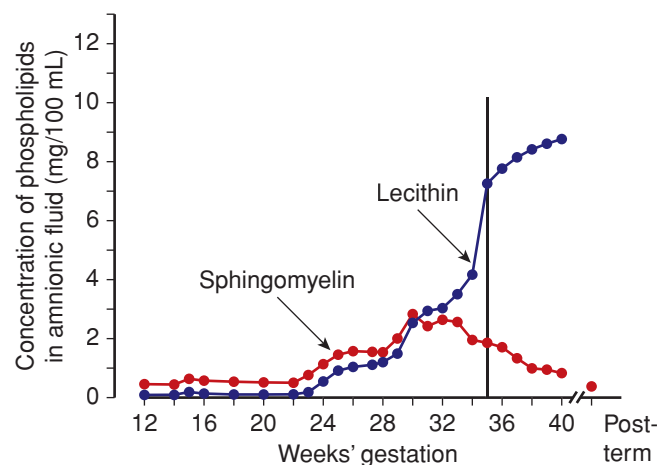

FIGURE 34-1 Changes in mean concentrations of lecithin and sphingomyelin in amniotic fluid during gestation in normal pregnancy. (Redrawn from Gluck, 1973, with permission.)

Gluck (1971) reported that the risk of neonatal respiratory distress is slight whenever the concentration of lecithin is at least twice that of sphingomyelin—the *L/S ratio*. Conversely, there is increased risk of respiratory distress when this ratio is < 2 . Because lecithin and sphingomyelin are found in blood and meconium, contamination with these substances may falsely lower a mature *L/S ratio*.

Phosphatidylglycerol. Previously, respiratory distress was thought to develop despite an *L/S ratio* > 2 in infants of women with diabetes. Some recommend that phosphatidylglycerol be documented in amniotic fluid of these women. Based on current evidence, it is unclear if either diabetes, per se, or its level of control causes false-positive phospholipid test results for fetal lung maturity (American College of Obstetricians and Gynecologists, 2008).

Fluorescence Polarization. This automated assay measures the surfactant-to-albumin ratio in uncentrifuged amniotic fluid and gives results in approximately 30 minutes. A ratio of ≥ 50 with the commercially available *TDx-FLM* test predicted fetal lung maturity in 100 percent of cases (Steinfeld, 1992). Subsequent investigators found the *TDx-FLM* to be equal or superior to the *L/S ratio*, foam stability index, or phosphatidylglycerol assessment, including testing in diabetic pregnancies (Eriksen, 1996; Karcher, 2005). The recently modified *TDx-FLM II* is used by many hospitals as their primary test of pulmonary maturity, with a threshold ratio of 55 mg/g.

Other Tests. The *foam stability* or *shake test* depends on the ability of surfactant in amniotic fluid, when mixed appropriately with ethanol, to generate stable foam at the air-liquid interface (Clements, 1972). Problems include errors caused by slight contamination and frequent false-negative test results. Alternatively, the *Lumadex-FSI test*, *fluorescent polarization (microviscometry)*, and *amniotic fluid absorbance at 650-nm wavelength* have all been used with variable success. The *lamellar body count* is a rapid, simple, and accurate method of assessing fetal lung maturity and is comparable to *TDx-FLM* and *L/S ratio* (Karcher, 2005).

NECROTIZING ENTEROCOLITIS

This newborn bowel disorder has clinical findings of abdominal distention, ileus, and bloody stools. There is usually radiological evidence of *pneumatosis intestinalis*—bowel wall gas derived from invading bacteria. Bowel perforation may prompt resection. Necrotizing enterocolitis is seen primarily in low-birthweight newborns but occasionally is encountered in mature neonates. Various hypothesized causes include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, and the feeding of cow milk and hypertonic solutions (Kliegman, 1984). All of these can ultimately lead to intestinal ischemia, and reperfusion injury likely also has a role (Czyrko, 1991). The unifying hypothesis for these pathological processes is the uncontrolled inflammatory response to bacterial colonization of the preterm intestine (Grave, 2007).

Treatment for necrotizing enterocolitis is controversial (van Vliet, 2013). A randomized trial of laparotomy versus peritoneal drainage found no difference in survival rates in preterm infants (Moss, 2006). In an observational study, however, Blakely (2006) found that death rates and neurodevelopmental outcomes assessed at 18 to 22 months were more favorable with laparotomy compared with drainage.

RETINOPATHY OF PREMATURITY

Formerly known as *retrolental fibroplasia*, by 1950, retinopathy of prematurity had become the largest single cause of blindness in this country. After the discovery that the disease resulted from hyperoxemia, its frequency decreased remarkably. The fetal retina vascularizes centrifugally from the optic nerve starting at approximately the fourth month and continues until shortly after birth. During vascularization, excessive oxygen induces severe retinal vasoconstriction with endothelial damage and vessel obliteration, especially in the temporal portion. Neovascularization results, and the new vessels penetrate the retina and extend into the vitreous. Here, they are prone to leak proteins or burst with subsequent hemorrhage. Adhesions then form, which detach the retina.

Precise levels of hyperoxemia that can be sustained without causing retinopathy are not known. Preterm birth results in a “relative” hyperoxia compared with in utero oxygen content even in infants not exposed to higher FiO_2 . To better understand the oxygen saturation threshold necessary to minimize retinopathy without increasing other adverse outcomes, the National Institute of Child Health and Human Development (NICHD) Neonatal Network performed a randomized trial of oxygenation in 1316 infants born between 24 and 27 weeks (SUPPORT Study Group, 2010). The target range of oxygen saturation was 85 to 89 percent in one arm of this trial and 91 to 95 percent in the other arm. Death before discharge occurred significantly more frequently in the lower-oxygen saturation group—20 versus 16 percent. However, severe retinopathy among survivors developed significantly less often in the lower-oxygen saturation group—8.6 versus 17.9 percent. This study generated considerable controversy as to whether the consent process was adequate for a trial with such end points (Drazen, 2013).

BRAIN DISORDERS

Central nervous system injury in preterm infants usually creates different neuroanatomical sequelae compared with that in term infants (Chap. 33, p. 639). In preterm infants, cerebral lesions detected by neuroimaging include intraventricular hemorrhage, periventricular hemorrhagic infarction, cystic periventricular leukomalacia, and diffuse white matter injury. All of these are strongly associated with adverse neurodevelopmental outcome. Locatelli and colleagues (2010) found a significantly increased incidence of neurological damage in preterm infants who had periventricular hemorrhage, periventricular leukomalacia, or both.

Cranial sonography remains the preferred approach for detecting frequently occurring brain abnormalities and acute

events. It is readily available and reliable for detecting common abnormalities and monitoring brain growth. Because cystic injuries may take 2 to 5 weeks to evolve, serial scans are obtained during this time. In infants whose findings are transient and resolve in the neonatal period, prognosis is improved compared with those whose lesions remain and evolve. At the same time, however, between 4 and 10 percent of prematurely born children may develop cerebral palsy in the absence of lesions. Put another way, 90 to 96 percent of preterm infants with cerebral palsy have cerebral lesions that are detectable using cranial sonography.

Intracranial Hemorrhage

There are four major categories of intracranial hemorrhage in the neonate (Volpe, 1995). *Subdural hemorrhage* is usually the result of trauma. *Subarachnoid hemorrhage* and *intracerebellar hemorrhage* usually result from trauma in term infants and hypoxia in preterm infants. *Periventricular-intraventricular hemorrhage* results from either trauma or asphyxia in half of term infants and has no discernible cause in a fourth. In preterm neonates, the pathogenesis of periventricular hemorrhage is multifactorial and includes hypoxic-ischemic events, anatomical factors, coagulopathy, and many others. The prognosis after hemorrhage depends on its location and extent. For example, subdural and subarachnoid hemorrhage often result in minimal, if any, neurological abnormalities. Bleeding into the parenchyma, however, can cause serious permanent damage.

Periventricular-Intraventricular Hemorrhage

When the fragile capillaries in the germinal matrix rupture, there is bleeding into surrounding tissues that may extend into the ventricular system and brain parenchyma. This type of hemorrhage is common in preterm neonates, especially those born before 32 weeks. However, it can also develop at later gestational ages and even in term neonates. Most hemorrhages develop within 72 hours of birth, but they have been observed as late as 24 days (Perlman, 1986). Because intraventricular hemorrhage usually is recognized within 3 days of delivery, its genesis is often erroneously attributed to birth events. It is important to realize that *prelabor* intraventricular hemorrhage also can occur (Achiron, 1993; Nores, 1996).

Almost half of hemorrhages are clinically silent, and most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment (Weindling, 1995). Large lesions can result in hydrocephalus or in degenerated cystic areas termed *periventricular leukomalacia* (p. 657). Importantly, the extent of periventricular leukomalacia correlates with cerebral palsy risk.

Pathology. Damage to the germinal matrix capillary network predisposes to subsequent extravasation of blood into the surrounding tissue. In preterm infants, this capillary network is especially fragile for several reasons. First, the subependymal germinal matrix provides poor support for the vessels coursing through it. Second, venous anatomy in this region causes stasis and congestion, which makes vessels susceptible to bursting with increased intravascular pressure. Third, vascular

autoregulation is impaired before 32 weeks (Matsuda, 2006; Volpe, 1987). Even if extensive hemorrhage or other complications of preterm birth do not cause death, survivors can have major neurodevelopmental handicaps. DeVries and associates (1985) attribute most long-term sequelae of intraventricular-periventricular hemorrhage to *periventricular leukomalacia*. These degenerated cystic areas develop *most* commonly as a result of ischemia and *least* commonly in direct response to hemorrhage.

Incidence and Severity. The incidence of ventricular hemorrhage depends on gestational age at birth. Approximately half of all neonates born before 34 weeks, but only 4 percent of those born at term, will have some evidence of hemorrhage (Hayden, 1985). Very-low-birthweight infants have the earliest onset of hemorrhage, the greatest likelihood of parenchymal tissue involvement, and thus the highest mortality rate (Perlman, 1986). Preterm black infants are at disparate risk for intraventricular hemorrhage (Reddick, 2008).

The severity of intraventricular hemorrhage can be assessed by neuroimaging studies. Papile and coworkers (1978) devised the most widely used grading scheme to quantify the extent of a lesion and estimate prognosis.

Grade I—hemorrhage limited to the germinal matrix

Grade II—intraventricular hemorrhage

Grade III—hemorrhage with ventricular dilatation

Grade IV—parenchymal extension of hemorrhage

Data from the Neonatal Research Network indicate that 30 percent of infants born weighing 501 to 1500 g develop intracranial hemorrhage, and 12 percent are grade III or IV (Fanaroff, 2007). Jakobi and associates (1992) showed that infants with grade I or II intraventricular hemorrhage had a greater than 90-percent survival rate and a 3-percent rate of handicap—similar to control infants without hemorrhage of the same age. The survival rate for infants with grade III or IV hemorrhage, however, was only 50 percent. Extremely-low-birthweight infants with grade I or II hemorrhage have poorer neurodevelopmental outcomes at 20 months than controls (Patra, 2006).

Contributing Factors. Events that predispose to germinal matrix hemorrhage and subsequent periventricular leukomalacia are multifactorial and complex. As noted, the preterm fetus has fragile intracranial blood vessels that make it particularly susceptible. Moreover, preterm birth is frequently associated with infection, which further predisposes to endothelial activation, platelet adherence, and thrombi (Redline, 2008). RDS and mechanical ventilation are commonly associated factors (Sarkar, 2009).

Prevention with Antenatal Corticosteroids. These agents, given at least 24 hours before delivery, appear to prevent or reduce intraventricular hemorrhage incidence and severity. A Consensus Development Conference of the National Institutes of Health (1994) concluded that such therapy reduced rates of mortality, respiratory distress, and intraventricular hemorrhage in preterm infants born between 24 and 32 weeks and that the benefits were additive with those from surfactant therapy. The consensus panel also concluded

that benefits of antenatal corticosteroid therapy probably extend to women with preterm premature membrane rupture. A second consensus statement by the National Institutes of Health (2000) recommended that repeated courses of corticosteroids should not be given. They noted that there were insufficient data to prove benefit or to document the safety of multiple courses (Chap. 42, p. 850).

Subsequently, the Maternal-Fetal Medicine Units Network reported that repeated corticosteroid courses were associated with some improved preterm neonatal outcomes, but also with reduced birthweight and increased risk for fetal-growth restriction (Wapner, 2006). Surveillance of this cohort through age 2 to 3 years found that children exposed to repeated—versus single-dose—steroid courses did not differ significantly in physical or neurocognitive measures (Wapner, 2007). It was worrisome, however, that there was a nonsignificant 5.7-fold relative risk of cerebral palsy in infants exposed to multiple steroid courses. At the same time, the 2-year follow-up of the Australasian Collaborative Trial was reported by Crowther (2007). In more than 1100 infants, the incidence of cerebral palsy was almost identical—4.2 versus 4.8 percent—in those given repeated versus single-course steroids, respectively.

Other Preventative Methods. The efficacy of *phenobarbital*, *vitamin K*, *vitamin E*, or *indomethacin* in diminishing the frequency and severity of intracranial hemorrhage, when administered either to the neonate or to the mother during labor, remains controversial (Chiswick, 1991; Hanigan, 1988; Thorp, 1995). Data from various sources suggest that *magnesium sulfate* may prevent the sequelae of periventricular hemorrhage, as discussed on page 659.

It is generally agreed that avoiding significant hypoxia both before and after preterm delivery is paramount (Low, 1995). There is presently no convincing evidence, however, that routine cesarean delivery for the preterm fetus presenting cephalic will decrease the incidence of periventricular hemorrhage. Anderson and colleagues (1992) found no significant difference in the overall frequency of hemorrhage in infants whose birthweights were below 1750 g and who were delivered without labor compared with those delivered during latent or active labor. Infants delivered of mothers in active labor, however, tended to have more grade III or IV hemorrhages.

Periventricular Leukomalacia

This pathological description refers to cystic areas deep in brain white matter that develop after hemorrhagic or ischemic infarction. Tissue ischemia leads to regional necrosis. Because brain tissue does not regenerate and the preterm neonate has minimal gliosis, these irreversibly damaged areas appear as echolucent cysts on neuroimaging studies. Generally, they require at least 2 weeks to form but may develop as long as 4 months after the initial insult. Thus, their presence at birth may help to determine the timing of a hemorrhagic event.

Cerebral Palsy

This term refers to a group of conditions that are characterized by chronic movement or posture abnormalities that are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003).

Epilepsy and mental retardation frequently accompany cerebral palsy. The cause(s) of cerebral palsy are different in preterm and term infants (Chap. 33, p. 640).

Cerebral palsy is commonly classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—as well as the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. The major types and their frequencies are:

1. *Spastic quadriplegia*, which has a strong association with mental retardation and seizure disorders—20 percent
2. *Diplegia*, which is common in preterm or low-birthweight infants—30 percent
3. *Hemiplegia*—30 percent
4. *Choreoathetoid types*—15 percent
5. *Mixed varieties* (Freeman, 1988; Rosen, 1992).

Incidence and Epidemiological Correlates

According to the Centers for Disease Control and Prevention, the prevalence of cerebral palsy in the United States was 3.1 per 1000 children in 2000 (Bhasin, 2006). Importantly, this rate either has remained essentially unchanged or has increased since the 1950s (Torfs, 1990; Winter, 2002). In some countries, the incidence has risen because advances in the care of very preterm infants have improved their survival, but not their neurological prognosis. For example, Moster and associates (2008) presented long-term follow-up of more than 900,000 births in Norway. Of nonanomalous term infants, the cerebral palsy rate was 0.1 percent compared with 9.1 percent in those born at 23 to 27 weeks. Similarly, O'Callaghan and coworkers (2011) studied the epidemiological associations of cerebral palsy and found preterm birth to be the greatest risk factor.

Intraventricular Hemorrhage

Various clinical and pathological data link severe intraventricular hemorrhage—grade III or IV—and resulting periventricular leukomalacia to cerebral palsy. As described earlier, grade I or II hemorrhages usually resolve without extensive tissue injury. Luthy (1987) reported a 16-fold increased risk of cerebral palsy for low-birthweight infants who had grade III or IV hemorrhage compared with the risk in infants who had either no or grade I or II hemorrhage.

Ischemia

Preterm infants are most susceptible to brain ischemia and periventricular leukomalacia. Before 32 weeks, the vascular anatomy of the brain is composed of two systems. One penetrates into the cortex—the *ventriculopedal system*. The other reaches down to the ventricles, but then curves to flow outward—the *ventriculofugal system* (Weindling, 1995). There are no vascular anastomoses connecting these two systems. As a result, the area between these systems, through which the pyramidal tracts pass near the lateral cerebral ventricles, is a watershed area vulnerable to ischemia. Vascular insufficiency before 32 weeks leading to ischemia would affect this watershed area first. Resulting damage of the pyramidal tracts may cause spastic diplegia. After 32 weeks, vascular flow shifts toward the cortex. Thus, hypoxic injury after this time primarily damages the cortical region.

Perinatal Infection

Periventricular leukomalacia is more strongly linked to infection and inflammation than to intraventricular hemorrhage. Zupan and colleagues (1996) studied 753 infants born between 24 and 32 weeks, 9 percent of whom developed periventricular leukomalacia. Those born before 28 weeks, those who had inflammatory events during the last days to weeks before delivery, or those who had both were at highest risk. Perlman and associates (1996) found that periventricular leukomalacia was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension. Bailis and coworkers (2008) reported that chronic—and not acute—placental inflammation was associated with leukomalacia.

Fetal infection may be the key element in the pathway between preterm birth and cerebral palsy (Burd, 2012; Leviton, 2010). In the pathway proposed in Figure 34-2, antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor and interleukins-1, -6, and -8. These in turn stimulate prostaglandin production and preterm labor (Chap. 42, p. 838). Preterm intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated damage result in massive neuronal cell death. Glutamate is released, stimulating membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendrocytes (Oka, 1993).

Many studies have shown that infection and cytokines can directly damage the immature brain. Inoculation of rabbit embryos with *Escherichia coli* causes histological damage in white matter (Yoon, 1997a). Moreover, tumor necrosis factor

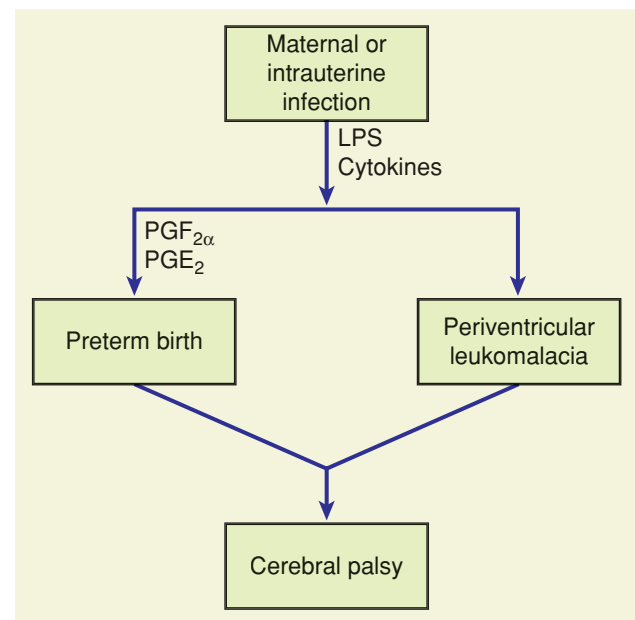

FIGURE 34-2 Schematic representation of the hypothesized pathway between maternal or intrauterine infection and preterm birth or periventricular leukomalacia. Both potentially lead to cerebral palsy. LPS = lipopolysaccharide; PG = prostaglandin.

and interleukin-6 were more frequently found in the brains of infants who died with periventricular leukomalacia (Yoon, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated (Yoon, 2000).

Andrews and colleagues (2008) provided data that raise questions regarding an increased incidence of adverse neurodevelopmental outcomes related to chorioamnionitis. In a cohort of infants born between 23 and 32 weeks, they studied several surrogate indicators and direct markers of in utero inflammation. These included clinical findings, cytokine levels, histological findings, and microbial culture results. Infants undergoing comprehensive psychoneurological testing had similar incidences of intelligence quotient (IQ) scores < 70, cerebral palsy, or both, regardless of these markers. The researchers interpreted their findings to support current practices that employ efforts to delay delivery with preterm pregnancies in the absence of overt intrauterine infection. This does not apply to preterm pregnancy in which clinical chorioamnionitis is diagnosed (Soraisham, 2009). Of 3094 singletons born < 33 weeks, 15 percent had evidence of clinical chorioamnionitis, which included foul-smelling amniotic fluid, maternal fever, uterine tenderness, fetal tachycardia, and maternal leukocytosis. Compared with noninfected infants, cases complicated by chorioamnionitis had significantly increased rates of early-onset sepsis—4.8 versus 0.9 percent—and intraventricular hemorrhage—22 versus 12 percent.

Prevention—Neuroprotection

Because epidemiological evidence suggested that maternal magnesium sulfate therapy had a fetal neuroprotective effect, three large randomized trials have been performed to investigate this hypothesis. These studies are discussed in detail in Chapter 42 (p. 854), as well as other evidence that magnesium sulfate is effective in reducing cerebral palsy in preterm infants.

CHAPTER 35

Stillbirth

DEFINITION OF FETAL MORTALITY	661
CAUSES OF FETAL DEATH	662
RISK FACTORS FOR FETAL DEATH	662
EVALUATION OF THE STILLBORN	664
PSYCHOLOGICAL ASPECTS	665
MANAGEMENT OF WOMEN WITH PRIOR STILLBIRTH	665

Fetal mortality—the intrauterine death of a fetus at any gestational age—is considered a major but often overlooked public health issue. It is estimated that there are more than 1 million fetal losses each year in the United States, and most occur before 20 weeks' gestation. Fetal mortality data from the National Vital Statistics system are usually presented for fetal deaths at 20 weeks' gestation or older (MacDorman, 2012). Using this definition, there are nearly as many fetal deaths as infant deaths (Fig. 35-1). As shown in Figure 35-2, fetal deaths rates at 20 weeks or more are gestational-age related, reaching a nadir that plateaus between approximately 27 and 33 weeks. Following this, there is a progressive rate increase.

DEFINITION OF FETAL MORTALITY

The definition of fetal death adopted by the Centers for Disease Control and Prevention National Center for Health Statistics is based on the definitions recommended by the World Health Organization (MacDorman, 2012). This definition is as follows:

Fetal death means death prior to complete expulsion or extraction from the mother of a product of human conception irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.

Reporting requirements for fetal deaths are determined by each state, and thus, requirements differ significantly (Chap. 1, p. 2). Most states require reporting of fetal deaths at 20 weeks' gestation or older or a minimum 350-g birthweight—roughly equivalent to 20 weeks—or some combination of these two. Seven states require fetal deaths before 20 weeks to be reported, and one state sets the threshold at 16 weeks. Three states require reporting of fetal deaths with birthweights 500 g or more—roughly equivalent to 22 weeks. There is substantial evidence that not all fetal deaths for which reporting is required are actually recorded (MacDorman, 2012). This is most likely at the earlier gestations of various state requirements.

The overall fetal mortality rate at 20 weeks or more for the United States has steadily declined since 1985 from 7.8 to 6.1 per 1000 total births in 2006 (MacDorman, 2012). Before this, declines were even more impressive and likely due to elimination of deaths of anomalous fetuses at later gestational ages that were “prevented” by early pregnancy terminations (Fretts, 1992).

Fetal mortality is generally divided into three periods: early, or < 20 completed weeks; intermediate, 20–27 weeks; and late, 28 weeks or more. The fetal death rate after 28 weeks has declined since 1990, whereas deaths from 20 to 27 weeks are largely unchanged (Fig. 35-3).

FIGURE 35-1 Percent distribution of fetal deaths at 20 weeks' gestation or more, and infant deaths: United States 2006. (From MacDorman, 2012.)

CAUSES OF FETAL DEATH

The Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) created the Stillbirth Collaborative Research Network to ascertain stillbirth causes in a racially and geographically diverse population in the United States. From this, the Stillbirth Collaborative Research Writing Group (2011b) ascertained stillbirths at 20 weeks or later between 2006 and 2008 in 59 tertiary care and community hospitals in five states. Standardized evaluations that included autopsy, placental histology, and testing of maternal or fetal blood/tissues—including fetal karyotyping—were performed in 500 women with 512 stillbirths. Of these, 83 percent were before labor and were considered antepartum stillbirths. Causes of stillbirth were divided into eight categories shown in Table 35-1. These categories were then classified as probable, possible, or unknown. As an example, diabetes was considered a *probable cause* if the fetus had diabetic embryopathy with lethal anomalies or the mother had diabetic ketoacidosis, but it was a *possible cause* if the mother had poor glycemic control and the fetus had abnormal growth. Overall, a probable or possible source was identified in 76 percent of cases.

FIGURE 35-3 Fetal mortality rates by period of gestation: United States, 1990–2006. (From MacDorman, 2012.)

This Network study of stillbirths is unprecedented in the United States for several reasons. It was a population-based cohort of stillbirths, all of which underwent systematic and thorough evaluation. Each cause of fetal death assigned is reasonably straightforward and comprehensible except for “placental abnormalities,” which includes “uteroplacental insufficiency” as well as a few other entities less clearly defined. This aside, the leading reasons for fetal death were obstetrical complications that primarily included abruption, multifetal gestation, and spontaneous labor or ruptured membranes before viability. The major contribution of this study was that systematic evaluation led to a likely cause in approximately three fourths of stillbirths. This rate is considerably higher than most analyses of stillbirth etiologies and serves to emphasize the importance of careful evaluations.

RISK FACTORS FOR FETAL DEATH

Factors that have been associated with an increased risk of antepartum stillbirth include advanced maternal age; African-American race; smoking; illicit drug use; maternal medical

FIGURE 35-2 Fetal mortality rate per 1000 births by single weeks of gestation: United States, 2006. (From MacDorman, 2012.)

TABLE 35-1. Causes of 512 Stillbirths in the Stillbirth Collaborative Research Network Study

Cause	Examples	Percent
Obstetrical complications	Abruption; multifetal gestation; ruptured preterm membranes at 20–24 weeks	29
Placental abnormalities	Uteroplacental insufficiency; maternal vascular disorders	24
Fetal malformations	Major structural abnormalities and/or genetic abnormalities	14
Infection	Involving the fetus or placenta	13
Umbilical cord abnormalities	Prolapse; stricture; thrombosis	10
Hypertensive disorders	Preeclampsia; chronic hypertension	9
Medical complications	Diabetes; antiphospholipid antibody syndrome	8
Undetermined	NA	24

NA = not applicable.

Percentages are rounded and total more than 100 percent because some stillbirths had more than one cause. Overall, a cause was identified in 76 percent of stillbirths.

diseases—such as overt diabetes or chronic hypertension; assisted reproductive technology; nulliparity; obesity; and previous adverse pregnancy outcomes—such as prior preterm birth or growth-restricted newborn (Reddy, 2010; Varner, 2014). There have been two major recent studies in which the investigators assessed whether it was possible to identify stillbirth risk factors either before or shortly after confirmation of pregnancy. Reddy and colleagues (2010) analyzed data from the NICHD Consortium on Safe Labor. Briefly, the pregnancy outcomes of 206,969 women delivered between 2002 and 2008 at 19 hospitals in the United States were analyzed. Shown in [Figure 35-4](#) is the distribution of stillbirths according to gestational age. Clearly, the tragedy of stillbirth occurs primarily in term pregnancies. Reddy and colleagues (2010) found individual risk factors that included race, parity, advanced maternal age, and obesity performed poorly as predictors of stillbirth at term. They concluded that these results did not support routine antenatal surveillance for any of these demographic risk factors. This is discussed further subsequently.

The second recent analysis of stillbirth risk factors was included in the Stillbirth Collaborative Research Network study described earlier. Investigators studied stillbirth prediction based on risks identified in early pregnancy. They found that pregnancy factors known at the start of pregnancy accounted for a small proportion of stillbirth risk. Except for prior stillbirth or pregnancy loss such as preterm birth or fetal-growth restriction, other risks had limited predictive value (Stillbirth Collaborative Research Network Writing Group, 2011a). The importance of prior stillbirth as a risk for recurrence has been emphasized by Sharma and associates (2006). Specifically, stillbirth risk was fivefold higher in women with a prior stillbirth, and this recurrence risk was almost tripled in African-American women. Rasmussen (2009) analyzed 864,531 births in Norway between 1967 and 2005 and reported that prior preterm birth, fetal-growth restriction, preeclampsia, and placental abruption were strongly associated with subsequent stillbirth. Shown in [Table 35-2](#) are estimates of stillbirth risk according to maternal factors including prior loss.

FIGURE 35-4 Distribution of livebirths and stillbirths in the National Institute of Child Health and Development Safe Labor Consortium according to gestational age. (From Reddy, 2010.)

TABLE 35-2. Estimated Maternal Risk Factors and Risk of Stillbirth

Condition	Prevalence (%)	Estimated Rate of Stillbirth (per 1000 births)	OR ^a
All pregnancies		6.4	1.0
Low-risk pregnancies	80	4.0–5.5	0.86
Hypertensive disorders			
Chronic hypertension	6–10	6–25	1.5–2.7
Pregnancy-induced hypertension			
Mild	5.8–7.7	9–51	1.2–4.0
Severe	1.3–3.3	12–29	1.8–4.4

EVALUATION OF THE STILLBORN

Determining the cause of fetal death aids maternal psychological adaptation to a significant loss, helps assuage the guilt that is part of grieving, permits more accurate counseling regarding recurrence risk, and may prompt therapy or intervention to prevent a similar outcome in the next pregnancy (American College of Obstetricians and Gynecologists, 2012). Identification of inherited syndromes also provides useful information for other family members.

Clinical Examination

Important tests in stillbirth evaluation are neonatal autopsy and karyotyping and examination of the placenta, cord, and membranes (Pinar, 2014). An algorithm provided by the American College of Obstetricians and Gynecologists (2012) is shown in [Figure 35-5](#). A thorough examination of the fetus, placenta, and membranes is recommended at delivery, with careful

documentation in the medical record. The details of relevant prenatal events should be provided. Photographs should be taken whenever possible, and a full radiograph of the fetus—a *fetogram*—may be performed. Magnetic resonance (MR) imaging and sonography may be especially important in providing anatomical information if parents decline a full autopsy.

Laboratory Evaluation

If autopsy and chromosomal studies are performed, up to 35 percent of stillborns are discovered to have major structural anomalies (Faye-Petersen, 1999). Approximately 20 percent have dysmorphic features or skeletal abnormalities, and 8 percent have chromosomal abnormalities (Pauli, 1994; Saller, 1995). The American College of Obstetricians and Gynecologists (2012) recommends karyotyping all stillborns. Reddy and coworkers (2012) have recently reported that microarray analysis is more likely than karyotype analysis to provide a genetic diagnosis, primarily because of its success with nonviable tissue. In the absence

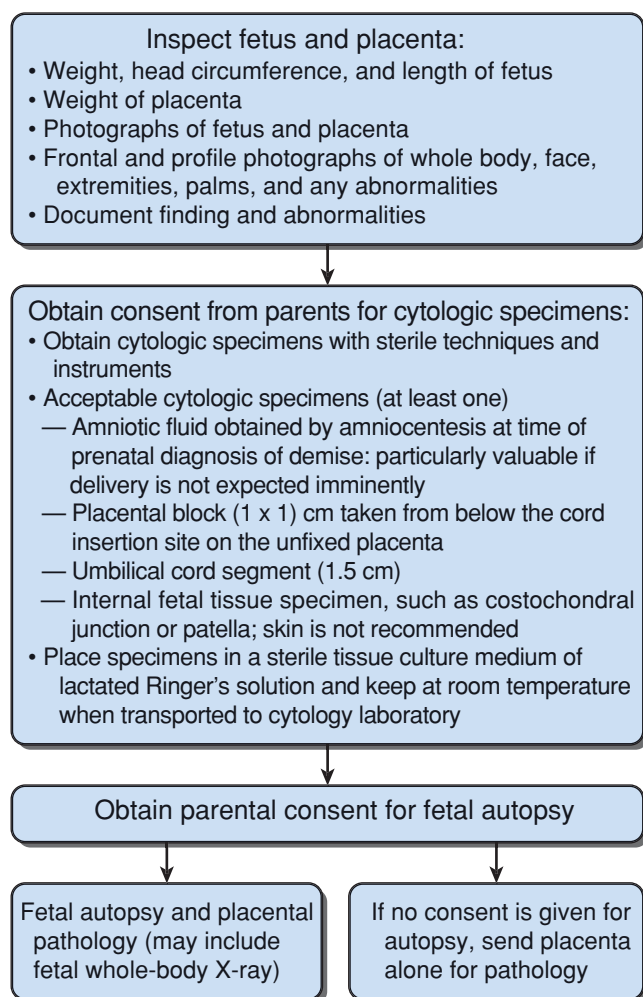

FIGURE 35-5 Flow chart for fetal and placental evaluation. (From Management of stillbirth. ACOG Practice Bulletin No. 102. American College of Obstetricians and Gynecologists. Obstet Gynecol 2009;113:748-61.

of morphological anomalies, up to 5 percent of stillborns will have a chromosomal abnormality (Korteweg, 2008).

Appropriate consent must be obtained to take fetal tissue samples, including fluid obtained postmortem by needle aspiration. A total of 3 mL of fetal blood, obtained from the umbilical cord or by cardiac puncture, is placed into a sterile, heparinized tube for cytogenetic studies. If blood cannot be obtained, the American College of Obstetricians and Gynecologists (2012) recommends at least one of the following samples: (1) a placental block measuring about 1 × 1 cm taken below the cord insertion site in the unfixed specimen; (2) umbilical cord segment approximately 1.5 cm long; or (3) internal fetal tissue specimen such as costochondral junction or patella. *Importantly, skin is no longer recommended for a tissue sample.* Tissue is washed with sterile saline before being placed in lactated Ringer solution or sterile cytogenetic medium. Placement in formalin or alcohol kills remaining viable cells and prevents cytogenetic analysis.

A full karyotype may not be possible in cases with prolonged fetal death. For example, Korteweg and associates (2008) reported that they successfully performed cytogenetic analysis in only a third of macerated fetuses. Fluorescence in situ hybridization might be used to exclude numerical abnormalities

or to document certain common deletions such as that causing DiGeorge syndrome. Maternal blood should be obtained for Kleihauer-Betke staining; for antiphospholipid antibody and lupus anticoagulant testing if indicated; and for serum glucose measurement to exclude overt diabetes (Silver, 2013).

Autopsy

Parents should be offered and encouraged to allow a full autopsy. However, valuable information can still be obtained from limited studies. Pinar and colleagues (2012) described the autopsy protocol used by the Stillbirth Collaborative Research Network. In the absence of an autopsy, a gross external examination combined with photography, radiography, MR imaging, bacterial cultures, and selective use of chromosomal and histopathological studies often can aid determination of the cause of death.

A complete autopsy is more likely to yield valuable information. An analysis of 400 consecutive fetal deaths in Wales found that autopsy altered the presumed cause of death in 13 percent and provided new information in another 26 percent (Cartledge, 1995). Other investigators have shown that autopsy results changed the recurrence risk estimates and parental counseling in 25 to 50 percent of cases (Faye-Petersen, 1999; Silver, 2007).

According to the survey by Goldenberg and coworkers (2013), most hospitals do not audit stillbirths. In other centers, however, maternal records and autopsy findings are reviewed on a monthly basis by a stillbirth committee composed of obstetricians, maternal-fetal medicine specialists, neonatologists, clinical geneticists, and perinatal pathologists. If possible, the cause of death is assigned based on available evidence. Most importantly, parents should then be contacted and offered counseling regarding the reason for death, the recurrence risk if any, and possible strategies to avoid recurrence in future pregnancies.

PSYCHOLOGICAL ASPECTS

Fetal death is psychologically traumatic for the woman and her family. Further stress results from an interval of more than 24 hours between the diagnosis of fetal death and the induction of labor, not seeing her infant for as long as she desires, and having no tokens of remembrance (Radestad, 1996). As discussed in Chapter 61 (p. 1205), the woman experiencing a stillbirth or even an early miscarriage is at increased risk for postpartum depression and should be closely monitored (Nelson, 2013). This and other significant life events increase the risks for another subsequent stillborn (Hogue, 2013).

MANAGEMENT OF WOMEN WITH PRIOR STILLBIRTH

The American College of Obstetricians and Gynecologists (2012) has provided a management outline for women with prior stillbirth (Table 35-3). Importantly, these recommendations are based primarily on limited or inconsistent scientific evidence or on expert opinions. Unfortunately, few studies

TABLE 35-3. Management of Subsequent Pregnancy after Stillbirth**Preconceptional or Initial Prenatal Visit**

Detailed medical and obstetrical history
 Evaluation and workup of previous stillbirth
 Determination of recurrence risk
 Smoking cessation
 Weight loss in obese women (preconceptional only)
 Genetic counseling if family genetic condition exists
 Diabetes screen
 Thrombophilia workup: antiphospholipid antibodies (only if specifically indicated)
 Support and reassurance

First Trimester

Dating ultrasonography
 First-trimester screen: pregnancy-associated plasma protein A, human chorionic gonadotropin, and nuchal translucency^a
 Support and reassurance

Second Trimester

Fetal ultrasonographic anatomic survey at 18–20 weeks of gestation
 Maternal serum screening (quadruple) or single-marker alpha fetoprotein if first trimester screening^a
 Support and reassurance

Third Trimester

Ultrasonographic screening for fetal-growth restriction after 28 weeks
 Kick counts starting at 28 weeks
 Antepartum fetal surveillance starting at 32 weeks or 1–2 weeks earlier than prior stillbirth
 Support and reassurance

Delivery

Elective induction at 39 weeks
 Delivery before 39 weeks only with documented fetal lung maturity by amniocentesis

^aProvides risk modification but does not alter management.

address management of such women. Those with modifiable risk factors for stillbirth such as hypertension or diabetes control require specific management strategies. According to Reddy (2007), because almost half of fetal deaths are associated with growth restriction, fetal sonographic anatomical assessment beginning at midpregnancy is recommended. This is followed by serial growth studies beginning at 28 weeks.

Weeks and associates (1995) evaluated fetal biophysical testing in 300 women whose only indication was prior stillbirth. There was only one recurrent stillbirth, and only three fetuses had abnormal testing results before 32 weeks. There was no relationship between the gestational age of the previous stillborn and the incidence or timing of abnormal test results or fetal

jeopardy in the subsequent pregnancy. These investigators concluded that antepartum surveillance should begin at 32 weeks or later in the otherwise healthy woman with a history of stillbirth. This recommendation is supported by the American College of Obstetricians and Gynecologists (2012) with the caveat that it increases the iatrogenic preterm delivery rate.

Delivery at 39 weeks is recommended by induction or by cesarean delivery for those with a contraindication to induction. This minimizes fetal mortality rates, although the degree of risk reduction may be greater for older women (Page, 2013).

MATERNAL CARE DURING THE PUERPERIUM 675

HOME CARE 678

The word *puerperium* is derived from Latin—*puer*, child + *parus*, bringing forth. Currently, it defines the time following delivery during which pregnancy-induced maternal anatomical and physiological changes return to the nonpregnant state. Its duration is understandably inexact, but is considered to be between 4 and 6 weeks. Although much less complex compared with pregnancy, the puerperium has appreciable changes, some of which may be either bothersome or worrisome for the new mother. Importantly, several complications can develop, and some are serious.

The puerperium may be a time of intense anxiety for many women. Some mothers have feelings of abandonment following delivery because of a newly aimed focus on the infant. Kanotra and colleagues (2007) analyzed challenges that women faced from 2 to 9 months following delivery. A third of these new mothers felt the need for social support, and 25 percent had concerns with breast feeding (Table 36-1).

INVOLUTION OF THE REPRODUCTIVE TRACT

Birth Canal

Return to the nonpregnant state begins soon after delivery. The vagina and its outlet gradually diminish in size but rarely regain their nulliparous dimensions. Rugae begin to reappear by the third week but are less prominent than before. The hymen is represented by several small tags of tissue, which scar to form the *myrtiform caruncles*. Vaginal epithelium begins to proliferate by 4 to 6 weeks, usually coincidental with resumed ovarian estrogen production. Lacerations or stretching of the perineum during delivery may result in vaginal outlet relaxation. Some damage to the pelvic floor may be inevitable, and parturition predisposes to urinary incontinence and pelvic organ prolapse. This is discussed in detail in Chapter 27 (p. 536).

Uterus

The massively increased uterine blood flow necessary to maintain pregnancy is made possible by significant hypertrophy and remodeling of pelvic vessels. After delivery, their caliber gradually diminishes to approximately that of the prepregnant state. Within the puerperal uterus, larger blood vessels become obliterated by hyaline changes, are gradually resorbed, and are replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

During labor, the margin of the dilated cervix, which corresponds to the external os, may be lacerated. The cervical opening contracts slowly and for a few days immediately after labor, readily admits two fingers. By the end of the first week, this opening narrows, the cervix thickens, and the endocervical canal reforms. The external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, ectocervical depressions at the site of lacerations become permanent. These changes are characteristic of a parous cervix (Fig. 36-1). The markedly attenuated lower uterine segment

TABLE 36-1. Pregnancy Risk Assessment Surveillance System—PRAMS.^a Concerns Raised by Women in the First 2–9 Months Postpartum

Concerns	Percent
Need for social support	32
Breast-feeding issues	24
Inadequate education about newborn care	21
Help with postpartum depression	10
Perceived need for extended hospital stay	8
Need for maternal insurance coverage postpartum	6

^aCenters for Disease Control and Prevention, 2012b. Data from Kanotra, 2007.

contracts and retracts, but not as forcefully as the uterine corpus. During the next few weeks, the lower segment is converted from a clearly distinct substructure large enough to accommodate the fetal head to a barely discernible uterine isthmus located between the corpus and internal os.

Cervical epithelium also undergoes considerable remodeling, and this actually may be salutary. Ahdoot and associates (1998) found that approximately half of women showed regression of high-grade dysplasia following vaginal delivery. Kaneshiro and coworkers (2005) found similar regression—about 60 percent overall—regardless of delivery mode.

Postpartum, the fundus of the contracted uterus lies slightly below the umbilicus. It consists mostly of myometrium covered by serosa and internally lined by basal decidua. The anterior and posterior walls, which lie in close apposition, are each 4 to 5 cm thick (Buhimschi, 2003). At this time, the uterus weighs approximately 1000 g. Because blood vessels are compressed by the contracted myometrium, the uterus on section appears

**FIGURE 36-1** Common appearance of nulliparous (A) and parous (B) cervixes.

ischemic compared with the reddish-purple hyperemic pregnant organ.

Myometrial involution is a truly remarkable *tour de force* of destruction or deconstruction that begins as soon as 2 days after delivery as shown in Figure 36-2. As emphasized by Hytten (1995), studies that describe the degree of decreasing uterine weight postpartum are poor quality. Best estimates are that by 1 week, the uterus weighs approximately 500 g; by 2 weeks, about 300 g; and at 4 weeks, involution is complete and the uterus weighs approximately 100 g. After each successive delivery, the uterus is usually slightly larger than before the most recent pregnancy. The total number of myocytes does not decrease appreciably—rather, their size decreases markedly.

Sonographic Findings

Uterine size dissipates rapidly in the first week (Fig. 36-3). And the uterus and endometrium return to pregravid size by 8 weeks after delivery (Belachew, 2012; Steinkeler, 2012). In a study of 42 normal women postpartum, Tekay and Jouppila (1993) identified fluid in the endometrial cavity in 78 percent at 2 weeks, 52 percent at 3 weeks, 30 percent at 4 weeks, and 10 percent at 5 weeks. Demonstrable uterine cavity contents are seen for up to 2 months following delivery. Belachew and colleagues (2012) used 3-dimensional sonography and visualized

**FIGURE 36-2** Cross sections of uteri made at the level of the involuting placental site at varying times after delivery. p.p. = postpartum. (Redrawn from Williams, 1931.)

FIGURE 36-3 Sonographic measurements of uterine involution during the first 9 days postpartum. AP = anteroposterior. (Data from Hytten, 1995.)

intracavitary tissue matter in a third on day 1, 95 percent on day 7, 87 percent on day 14, and 28 percent on day 28. By day 56, the small cavity was empty. Sohn and associates (1988) described Doppler ultrasound results showing continuously increasing uterine artery vascular resistance during the first 5 days postpartum.

Decidua and Endometrial Regeneration

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The remaining decidua has striking variations in thickness, it has an irregular jagged appearance, and it is infiltrated with blood, especially at the placental site (see Fig. 36-2).

Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic and is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. This arises from proliferation of the endometrial glandular remnants and the stroma of the interglandular connective tissue.

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium, and Sharman (1953) identified fully restored endometrium in all biopsy specimens obtained from the 16th day onward. Histological endometritis is part of the normal reparative process. Moreover, microscopic inflammatory changes characteristic of acute salpingitis are seen in almost half of women between 5 and 15 days, but these findings do not reflect infection (Andrews, 1951).

Clinical Aspects

Afterpains. In primiparous women, the uterus tends to remain tonically contracted following delivery. In multiparas, however, it often contracts vigorously at intervals and gives rise to *afterpains*, which are similar to but milder than labor contractions. These are more pronounced as parity increases and worsen when the infant suckles, likely because of oxytocin release (Holdcroft, 2003). Usually, afterpains decrease in intensity and become mild by the third day. We have encountered unusually severe and persistent afterpains in women with postpartum uterine infections.

Lochia. Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity. The discharge is termed *lochia* and contains erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red—*lochia rubra*. After 3 or 4 days, lochia becomes progressively pale in color—*lochia serosa*. After approximately the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellow-white color—*lochia alba*. The average duration of lochial discharge ranges from 24 to 36 days (Fletcher, 2012).

Placental Site Involution

Complete extrusion of the placental site takes up to 6 weeks (Williams, 1931). Immediately after delivery, the placental site is approximately palm-sized. Within hours of delivery, it normally consists of many thrombosed vessels that ultimately undergo organization (see Fig. 36-2). By the end of the second week, it is 3 to 4 cm in diameter.

Placental site involution is an exfoliation process, which is prompted in great part by undermining of the implantation site by new endometrial proliferation (Williams, 1931). Thus, involution is not simply absorption in situ. Exfoliation consists of both extension and “downgrowth” of endometrium from the margins of the placental site, as well as development of endometrial tissue from the glands and stroma left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation results from sloughing of infarcted and necrotic superficial tissues followed by a remodeling process.

Subinvolution

In some cases, uterine involution is hindered because of infection, retained placental fragments, or other causes. Such subinvolution is accompanied by varied intervals of prolonged lochia as well as irregular or excessive uterine bleeding. On bimanual examination, the uterus is larger and softer than would be expected. Ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg orally every 3 to 4 hours for 24 to 48 hours, is recommended by many, but its efficacy is questionable. Of these, only methylergonovine is currently available in the United States. If there is infection, antimicrobial therapy usually leads to a good response. In an earlier study, Wager and coworkers (1980) reported that a third of these late cases of postpartum metritis are caused by *Chlamydia trachomatis*. Empirical therapy with azithromycin or doxycycline usually prompts resolution regardless of bacterial etiology.

Another cause of subinvolution is incompletely remodeled uteroplacental arteries (Andrew, 1989; Kavalir, 2012). These noninvolved vessels are filled with thromboses and lack an endothelial lining. Perivascular trophoblasts are also identified in the vessel walls, suggesting an aberrant interaction between uterine cells and trophoblasts.

Late Postpartum Hemorrhage

The American College of Obstetricians and Gynecologists (2013b) defines *secondary postpartum hemorrhage* as bleeding 24 hours to 12 weeks after delivery. Clinically worrisome uterine

hemorrhage develops within 1 to 2 weeks in perhaps 1 percent of women. Such bleeding most often is the result of abnormal involution of the placental site. It occasionally is caused by retention of a placental fragment or by a uterine artery pseudoaneurysm. Usually, retained products undergo necrosis with fibrin deposition and may eventually form a so-called *placental polyp*. As the eschar of the polyp detaches from the myometrium, hemorrhage may be brisk. As discussed in Chapter 56 (p. 1118), delayed postpartum hemorrhage may also be caused by von Willebrand disease or other inherited coagulopathies (Lipe, 2011).

In our experiences, few women with delayed hemorrhage are found to have retained placental fragments. Thus, we and others do not routinely perform curettage (Lee, 1981). Another concern is that curettage may worsen bleeding by avulsing part of the implantation site. Thus, in a stable patient, if sonographic examination shows an empty cavity, then oxytocin, methylergometrine, or a prostaglandin analogue is given. Antimicrobials are added if uterine infection is suspected. If large clots are seen in the uterine cavity with sonography, then *gentle* suction curettage is considered. Otherwise curettage is carried out only if appreciable bleeding persists or recurs after medical management.

URINARY TRACT

Normal pregnancy-induced glomerular hyperfiltration persists on the first postpartum day but returns to prepregnancy baseline by 2 weeks (Hladunewich, 2004). Also, dilated ureters and renal pelves return to their prepregnant state during the course of 2 to 8 weeks postpartum. Because of this dilated collecting system, coupled with residual urine and bacteriuria in a traumatized bladder, urinary tract infection is a concern in the puerperium.

Bladder trauma is associated most closely with labor length and thus to some degree is a normal accompaniment of vaginal delivery. Funnell and colleagues (1954) used cystoscopy immediately postpartum and described varying degrees of submucosal hemorrhage and edema. Postpartum, the bladder has an increased capacity and a relative insensitivity to intravesical pressure. Thus, overdistention, incomplete emptying, and excessive residual urine are common. Their management is discussed on page 676.

It is unusual for urinary incontinence to manifest during the puerperium. That said, much attention has been given to the potential for subsequent development of urinary incontinence and other pelvic floor disorders in the years following delivery. A fuller discussion is found in Chapter 30 (p. 588).

PERITONEUM AND ABDOMINAL WALL

The broad and round ligaments require considerable time to recover from stretching and loosening during pregnancy. As a result of ruptured elastic fibers in the skin and prolonged distention by the pregnant uterus, the abdominal wall remains soft and flaccid. If the abdomen is unusually flabby or pendulous, an ordinary girdle is often satisfactory. An abdominal binder is at best a temporary measure. Several weeks are required for these structures to return to normal, and recovery is aided by

exercise. These may be started anytime following vaginal delivery and as soon as abdominal soreness diminishes after cesarean delivery. Silvery abdominal striae commonly develop as *striae gravidarum* (Chap. 4, p. 51). Except for these, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax. Marked separation of the rectus abdominis muscles—*dias-tasis recti*—may result.

HEMATOLOGICAL PARAMETERS AND PREGNANCY HYPERVOLEMIA

Hematological and Coagulation Changes

Marked leukocytosis and thrombocytosis may occur during and after labor. The white blood cell count sometimes reaches 30,000/ μ L, with the increase predominantly due to granulocytes. There is a relative lymphopenia and an absolute eosinopenia. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit fluctuate moderately. If they fall much below the levels present just before labor, a considerable amount of blood has been lost (Chap. 41, p. 781).

By the end of pregnancy, there are many changes in laboratory findings that assess coagulation (Kenny, 2014). These are discussed in Chapter 4 (p. 57) and listed in the Appendix (p. 1288). Many persist in the puerperium. One example is that the markedly increased levels of plasma fibrinogen are maintained at least through the first week, and hence, so is the increase in sedimentation rate.

Pregnancy-Induced Hypervolemia

When the amount of blood attained by normal pregnancy hypervolemia is lost as postpartum hemorrhage, the woman almost immediately regains her nonpregnant blood volume (Chap. 41, p. 781). If less has been lost at delivery, it appears that in most women, blood volume has nearly returned to its nonpregnant level by 1 week after delivery. Cardiac output usually remains elevated for 24 to 48 hours postpartum and declines to nonpregnant values by 10 days (Robson, 1987). Heart rate changes follow this pattern. Systemic vascular resistance and blood pressure rise (Fig. 36-4). Systemic vascular resistance remains in the lower range characteristic of pregnancy for 2 days postpartum and then begins to steadily increase to normal nonpregnant values (Hibbard, 2014).

Normal pregnancy is associated with an appreciable increase in extracellular sodium and water, and postpartum diuresis is a physiological reversal of this process. Chesley and coworkers (1959) demonstrated a decrease in sodium space of approximately 2 L during the first week postpartum. This also corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, pathological retention of fluid antepartum and its diuresis postpartum may be prodigious (Chap. 40, p. 768).

Postpartum diuresis results in relatively rapid weight loss of 2 to 3 kg, which is added to the 5 to 6 kg incurred by delivery and normal blood loss. Weight loss from pregnancy itself is likely to be maximal by the end of the second week postpartum.

FIGURE 36-4 During the early puerperium, blood pressure normally rises toward nonpregnant values. MAP = mean arterial pressure.

It follows that any residual increased weight compared with prepregnancy values probably represents fat stores that will persist. According to Schauberger and associates (1992), women approach their self-reported prepregnancy weight 6 months after delivery but still retain an average surplus of 1.4 kg (3 lb).

BREASTS AND LACTATION

Breast Anatomy and Products

Each mature mammary gland or breast is composed of 15 to 25 lobes. They are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are composed of numerous alveoli. Each alveolus is provided with a small duct that joins others to form a single larger duct for each lobe as shown in Figure 36-5. These *lactiferous ducts* open separately on the nipple, where they may be distinguished as minute but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents, described next.

After delivery, the breasts begin to secrete *colostrum*, which is a deep lemon-yellow liquid. It usually can be expressed from the nipples by the second postpartum day. Compared with mature milk, colostrum is rich in immunological components and contains more minerals and amino acids (Ballard, 2013). It also has more protein, much of which is globulin, but less sugar and fat. Secretion persists for 5 days to 2 weeks, with gradual conversion to mature milk by 4 to 6 weeks. The colostrum content of immunoglobulin A (IgA) offers the newborn protection against enteric pathogens. Other host resistance factors found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

Mature milk is a complex and dynamic biological fluid that includes fat, proteins, carbohydrates, bioactive factors, minerals, vitamins, hormones, and many cellular products. The concentrations and contents of human milk change even during a single feed and are influenced by maternal diet, as well as infant age, health, and needs. A nursing mother easily produces 600 mL of milk daily, and maternal gestational weight gain has little

FIGURE 36-5 Schematic of the alveolar and ductal system during lactation. Note the myoepithelial fibers (M) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (A) and ejected by the myoepithelial cells into the ductal system (D), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath.

impact on its quantity or quality (Institute of Medicine, 1990). Milk is isotonic with plasma, and lactose accounts for half of the osmotic pressure. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and include α -lactalbumin, β -lactoglobulin, and casein. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process. Most vitamins are found in human milk, but in variable amounts. Vitamin K is virtually absent, and thus, an intramuscular dose is given to the newborn (Chap. 33, p. 644). Vitamin D content is low—22 IU/mL. Thus, newborn supplementation is also recommended by the American Academy of Pediatrics (Wagner, 2008).

Whey is milk serum and has been shown to contain large amounts of interleukin-6 (Saito, 1991). Human milk has a whey-to-casein ratio of 60:40, considered ideal for absorption. *Prolactin* appears to be actively secreted into breast milk (Yuen, 1988). *Epidermal growth factor (EGF)* has been identified in human milk. And because it is not destroyed by gastric proteolytic enzymes, it may be absorbed to promote growth and maturation of newborn intestinal mucosa (McCleary, 1991).

Other critical components in human milk include lactoferrin, melatonin, oligosaccharides, and essential fatty acids.

■ Endocrinology of Lactation

The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus (Porter, 1974). With delivery, there is an abrupt and profound decrease in the levels of progesterone and estrogen. This decrease removes the inhibitory influence of progesterone on α -lactalbumin production and stimulates lactose synthase to increase milk lactose. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of α -lactalbumin production. Serotonin is produced in mammary epithelial cells and has a role in maintaining milk production. This may explain the decreased milk production in women taking selective serotonin-reuptake inhibitors—SSRIs (Collier, 2012).

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of nursing and emptying of milk from the breast. Prolactin is essential for lactation, and women with extensive pituitary necrosis—*Sheehan syndrome*—do not lactate (Chap. 58, p. 1163). Although plasma prolactin levels fall after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels (McNeilly, 1983). Presumably a stimulus from the breast curtails the release of dopamine, also known as prolactin-inhibiting factor, from the hypothalamus. This in turn transiently induces increased prolactin secretion.

The posterior pituitary secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts (see Fig. 36-4). Milk ejection, or *letting down*, is a reflex initiated especially by suckling, which stimulates the posterior pituitary to liberate oxytocin. The reflex may even be provoked by an infant cry and can be inhibited by maternal fright or stress.

■ Immunological Consequences of Breast Feeding

Human milk contains several protective immunological substances, including secretory IgA and growth factors. The antibodies in human milk are specifically directed against maternal environmental antigens such as against *Escherichia coli* (Iyengar, 2012). As a result, breast-fed infants are less prone to enteric infections than bottle-fed ones (Cravioto, 1991). Human milk also provides protection against rotavirus infections, a major cause of infant gastroenteritis (Newburg, 1998). Moreover, the risks of atopic dermatitis and respiratory infections are reduced (Ip, 2009). Bartick and Reinhold (2010) calculated that significant economic burdens from pediatric disease could be lessened by improved breast-feeding rates.

Much attention has been directed to the role of maternal breast-milk lymphocytes in neonatal immunological processes. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically,

milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens. These memory T cells appear to be an avenue for the neonate to benefit from the maternal immunological experience (Bertotto, 1990).

■ Nursing

Human milk is ideal food for neonates. It provides age-specific nutrients as well as immunological factors and antibacterial substances (American College of Obstetricians and Gynecologists, 2013a). Milk also contains factors that act as biological signals for promoting cellular growth and differentiation. The American Academy of Pediatrics (2012) has provided a list of dose-response benefits of nursing (Table 36-2). For both mother and infant, the benefits of breast feeding are long-term. For example, women who breast feed have a lower risk of breast and reproductive cancer, and their children have increased adult intelligence independent of a wide range of possible confounding factors (Jong, 2012; Kramer, 2008). Breast feeding is associated with decreased postpartum weight retention (Baker, 2008). In addition, rates of sudden-infant-death syndrome are significantly lower among breast-fed infants. Last, in the Nurses' Health Study, women who reported breast feeding for at least 2 cumulative years had a 23-percent lower risk of coronary heart disease (Stuebe, 2009). For all these reasons, the American Academy of Pediatrics (2012) supports the World Health Organization (2011) recommendations of exclusive breast feeding for up to 6 months, with avoidance of exposure to cow milk proteins.

The Surgeon General of the U.S. Department of Health and Human Services (2011) lists some barriers for breast feeding and suggests practical means of overcoming them. Educational initiatives that include father and peer counseling may improve these rates (Pisacane, 2005; Wolfberg, 2004). The *Baby Friendly Hospital Initiative* is an international program to increase rates of exclusive breast feeding and to extend its duration. It is based on the World Health Organization (1989) *Ten Steps to Successful Breastfeeding* (Table 36-3). Worldwide, almost 20,000 hospitals are designated as "baby-friendly." Forrester-Knauss and coworkers (2013) described successful trends toward exclusive breast feeding in Switzerland during 9 years

Summarized from the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012.

TABLE 36-3. Ten Steps to Successful Breast Feeding

1. Have a written breast-feeding policy that is regularly communicated to all health-care staff
2. Train all staff in skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breast feeding
4. Help mothers initiate breast feeding within an hour of birth
5. Show mothers how to breast feed and how to sustain lactation, even if they should be separated from their infants
6. Feed newborn infants nothing but breast milk, unless medically indicated, and under no circumstances provide breast milk substitutes, feeding bottles, or pacifiers free of charge or at low cost
7. Practice rooming-in, which allows mothers and infants to remain together 24 hours a day
8. Encourage breast feeding on demand
9. Give no artificial pacifiers to breast-feeding infants
10. Help start breast-feeding support groups and refer mothers to them

Adapted from the World Health Organization, 1989.

in which a Baby-Friendly Hospital Initiative was implemented. However, in 2011 in the United States, fewer than 10 percent of births in 43 states and the District of Columbia occurred in “baby friendly” hospitals (Centers for Disease Control and Prevention, 2012a). In a large population-based study, fewer than two thirds of term neonates were exclusively breast fed at the time of discharge (McDonald, 2012).

There are a variety of individual resources available for breast-feeding mothers that include online information from the American Academy of Pediatrics (<http://www.aap.org>) and La Leche League International (<http://www.lalecheleague.org>).

Care of Breasts

The nipples require little attention other than cleanliness and attention to skin fissures. Fissured nipples render nursing painful, and they may have a deleterious influence on milk production. These cracks also provide a portal of entry for pyogenic bacteria. Because dried milk is likely to accumulate and irritate the nipples, washing the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated or fissured, it may be necessary to use topical lanolin and a nipple shield for 24 hours or longer. If fissuring is severe, the infant should not be permitted to nurse on the affected side. Instead, the breast should be emptied regularly with a pump until the lesions are healed. Poor latching of the neonate to the breast can create such fissures. Proper technique for positioning the mother and infant during *latch-on* and nursing has been reviewed by the American College of Obstetricians and Gynecologists (2013a).

Contraindications to Breast Feeding

Nursing is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing breast cancer treatment (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012; Faupel-Badger, 2013). Breast feeding has been recognized for some time as a mode of HIV transmission and is proscribed in developed countries in which adequate nutrition is otherwise available (Chap. 65, p. 1282). Other viral infections do not contraindicate breast feeding. For example, with maternal cytomegalovirus infection, both virus and antibodies are present in breast milk. And although hepatitis B virus is excreted in milk, breast feeding is not contraindicated if hepatitis B immune globulin is given to the newborns of affected mothers. Maternal hepatitis C infection is not a contraindication because breast feeding has not been shown to transmit infection. Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing.

Drugs Secreted in Milk

Most drugs given to the mother are secreted in breast milk, although the amount ingested by the infant typically is small. Many factors influence drug excretion and include plasma concentration, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight (Rowe, 2013). The ratio of drug concentration in breast milk to that in maternal plasma is the *milk-to-plasma drug-concentration ratio*. Most drugs have a ratio of ≤ 1 , approximately 25 percent have a ratio > 1 , and about 15 percent have a ratio > 2 (Ito, 2000). Ideally, to minimize infant exposure, medication selection should favor drugs with a shorter half-life, poorer oral absorption, and lower lipid solubility. If multiple daily drug doses are required, then each is taken by the mother *after* the closest feed. Single daily-dosed drugs may be taken just before the longest infant sleep interval—usually at bedtime (Spencer, 2002).

There are only a few drugs that are absolutely contraindicated while breast feeding (Berlin, 2013; Bertino, 2012). Cytotoxic drugs may interfere with cellular metabolism and potentially cause immune suppression or neutropenia, affect growth, and, at least theoretically, increase the risk of childhood cancer. Examples include cyclophosphamide, cyclosporine, doxorubicin, methotrexate, and mycophenolate. If a medication presents a concern, then the importance of therapy should be ascertained. It should be determined whether there is a safer alternative or whether neonatal exposure can be minimized if the medication dose is taken immediately after each breast feeding (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Data on individual drugs are available through the National Institutes of Health website, LactMed, which can be found at: toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT.

Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk.

Consultation with a nuclear medicine specialist is recommended before performing a diagnostic study with these isotopes (Chap. 46, p. 934). The goal is to use a radionuclide with the shortest excretion time in breast milk. The mother should pump her breasts before the study and store enough milk in a freezer for feeding the infant. After the study, she should pump her breasts to maintain milk production but discard all milk produced during the time that radioactivity is present. This ranges from 15 hours up to 2 weeks, depending on the isotope used. Importantly, radioactive iodine concentrates and persists in the thyroid. Its special considerations are discussed in Chapter 63 (p. 1231).

Breast Engorgement

This is common in women who do not breast feed and is typified by milk leakage and breast pain. These peak 3 to 5 days after delivery (Spitz, 1998). Up to half of affected women require analgesia for breast-pain relief, and as many as 10 percent report severe pain for up to 14 days.

Evidence is insufficient to firmly support any specific treatment (Mangesi, 2010). That said, breasts can be supported with a well-fitting brassiere, breast binder, or “sports bra.” Cool packs and oral analgesics for 12 to 24 hours aid discomfort. Pharmacological or hormonal agents are not recommended to suppress lactation.

Fever caused by breast engorgement was common before the renaissance of breast feeding. In one study, Almeida and Kitay (1986) reported that 13 percent of postpartum women had fever from engorgement that ranged from 37.8 to 39°C. Fever seldom persists for longer than 4 to 16 hours. The incidence and severity of engorgement, and fever associated with it, are much lower if women breast feed. Other causes of fever, especially those due to infection, must be excluded. Of these, *mastitis* is infection of the mammary parenchyma. It is relatively common in lactating women and is discussed in Chapter 37 (p. 691).

Other Issues with Lactation

With *inverted nipples*, lactiferous ducts open directly into a depression at the center of the areola. With these depressed nipples, nursing is difficult. If the depression is not deep, milk sometimes can be made available by use of a breast pump. If instead the nipple is greatly inverted, daily attempts should be made during the last few months of pregnancy to draw or “tease” the nipple out with the fingers.

Extra breasts—*polymastia*, or extra nipples—*polythelia*, may develop along the former embryonic mammary ridge. Also termed the *milk line*, this line extends from the axilla to the groin bilaterally. In some women, there may be vulvar breast tissue (Wagner, 2013). The incidence of accessory breast tissue ranges from 0.22 to 6 percent in the general population (Loukas, 2007). These breasts may be so small as to be mistaken for pigmented moles, or if without a nipple, for lymphadenopathy or lipoma. Polymastia has no obstetrical significance, although occasionally enlargement of these accessory breasts during pregnancy or engorgement postpartum may result in discomfort and anxiety.

Galactocele is a milk duct that becomes obstructed by inspissated secretions. The amount is ordinarily limited, but an excess may form a fluctuant mass—a galactocele—that may cause pressure symptoms and have the appearance of an abscess. It may resolve spontaneously or require aspiration.

There are marked individual variations in the amount of milk secreted. Many of these are dependent not on general maternal health but on breast glandular development. Rarely, there is complete lack of mammary secretion—*agalactia*. Occasionally, mammary secretion is excessive—*polygalactia*.

MATERNAL CARE DURING THE PUERPERIUM

Hospital Care

For 2 hours after delivery, blood pressure and pulse should be taken every 15 minutes, or more frequently if indicated. Temperature is assessed every 4 hours for the first 8 hours and then at least every 8 hours subsequently (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). The amount of vaginal bleeding is monitored, and the fundus palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Uterotonics are also sometimes required. Blood may accumulate within the uterus without external bleeding. This may be detected early by uterine enlargement during fundal palpation in the first postdelivery hours. Because the likelihood of significant hemorrhage is greatest immediately postpartum, even in normal births, the uterus is closely monitored for at least 1 hour after delivery. Postpartum hemorrhage is discussed in Chapter 41 (p. 783). If regional analgesia or general anesthesia was used for labor or delivery, the mother should be observed in an appropriately equipped and staffed recovery area.

Women are out of bed within a few hours after delivery. An attendant should be present for at least the first time, in case the woman becomes syncopal. The many confirmed advantages of early ambulation include fewer bladder complications, less frequent constipation, and reduced rates of puerperal venous thromboembolism. Almost half of thromboembolic events associated with pregnancy develop in the puerperium. Jacobsen and colleagues (2008) reported that pulmonary embolism is most common in the first 6 weeks postpartum. In a recent audit of puerperal women at Parkland Hospital, the frequency of venous thromboembolism was found to be 0.008 percent after a vaginal birth and 0.04 percent following cesarean delivery. We attribute this low incidence to early ambulation. Risk factors and other measures to diminish the frequency of thromboembolism are discussed in Chapter 52 (p. 1029).

There are no dietary restrictions for women who have been delivered vaginally. Two hours after normal vaginal delivery, if there are no complications, a woman should be allowed to eat. With breast feeding, the level of calories and protein consumed during pregnancy should be increased slightly as recommended by the Food and Nutrition Board of the National Research Council (Chap. 9, p. 178). If the mother does not breast feed, dietary requirements are the same as for a nonpregnant woman. It is standard practice in our hospital to continue oral

iron supplementation for at least 3 months after delivery and to check the hematocrit at a first postpartum visit.

■ Perineal Care

The woman is instructed to cleanse the vulva from anterior to posterior—the vulva toward the anus. A cool pack applied to the perineum may help reduce edema and discomfort during the first 24 hours if there is a laceration or an episiotomy. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. Severe discomfort usually indicates a problem, such as a hematoma within the first day or so and infection after the third or fourth day (Chap. 37, p. 689 and Chap. 41, p 790). *Severe perineal, vaginal, or rectal pain always warrants careful inspection and palpation.* Beginning approximately 24 hours after delivery, moist heat as provided by warm sitz baths can be used to reduce local discomfort. Tub bathing after uncomplicated delivery is allowed. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Rarely, the cervix, and occasionally a portion of the uterine body, may protrude from the vulva following delivery. This is accompanied by variable degrees of anterior and posterior vaginal wall prolapse. Symptoms include a palpable mass at or past the introitus, voiding difficulties, or pressure. Puerperal procidentia typically improves with time as the weight of the uterus lessens with involution. As a temporizing measure in those with pronounced prolapse, the uterus can be replaced and held in position with a suitable pessary.

■ Bladder Function

In most delivery units, intravenous fluids are infused during labor and for an hour or so after delivery. Oxytocin, in doses that have an antidiuretic effect, is typically infused postpartum, and rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by local or conduction analgesia, by trauma to the bladder, by episiotomy or lacerations, or by operative vaginal delivery. Thus, urinary retention and bladder overdistention is common in the early puerperium. Ching-Chung and associates (2002) reported retention in 4 percent of women delivered vaginally. Musselwhite and coworkers (2007) reported retention in 4.7 percent of women who had labor epidural analgesia. Risk factors that increased likelihood of retention were primiparity, perineal lacerations, oxytocin-induced or -augmented labor, operative vaginal delivery, catheterization during labor, and labor duration > 10 hours.

Prevention of bladder overdistention demands observation after delivery to ensure that the bladder does not overfill and that it empties adequately with each voiding. The enlarged bladder can be palpated suprapubically, or it is evident abdominally indirectly as it elevates the fundus above the umbilicus. Van Os and Van der Linden (2006) have investigated the use of an automated sonography system to detect high bladder volumes and thus postpartum urinary retention.

If a woman has not voided within 4 hours after delivery, it is likely that she cannot. If she has trouble voiding initially,

she also is likely to have further trouble. An examination for perineal and genital-tract hematomas is made. With an overdistended bladder, an indwelling catheter should be left in place until the factors causing retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours. This prevents recurrence and allows recovery of normal bladder tone and sensation.

When the catheter is removed, it is necessary subsequently to demonstrate ability to void appropriately. If a woman cannot void after 4 hours, she should be catheterized and the urine volume measured. If more than 200 mL, the bladder is not functioning appropriately, and the catheter is left for another 24 hours. If less than 200 mL of urine is obtained, the catheter can be removed and the bladder rechecked subsequently as just described. Harris and coworkers (1977) reported that 40 percent of such women develop bacteriuria, and thus a single dose or short course of antimicrobial therapy is reasonable after the catheter is removed.

■ Pain, Mood, and Cognition

Discomfort and its causes following cesarean delivery are considered in Chapter 30 (p. 605). During the first few days after vaginal delivery, the mother may be uncomfortable because of afterpains, episiotomy and lacerations, breast engorgement, and at times, postdural puncture headache. Mild analgesics containing codeine, aspirin, or acetaminophen, preferably in combinations, are given as frequently as every 3 hours during the first few days.

It is fairly common for a mother to exhibit some degree of depressed mood a few days after delivery. Termed *postpartum blues*, this likely is the consequence of several factors that include emotional letdown that follows the excitement and fears experienced during pregnancy and delivery, discomforts of the early puerperium, fatigue from sleep deprivation, anxiety over the ability to provide appropriate infant care, and body image concerns.

In most women, effective treatment includes anticipation, recognition, and reassurance. This disorder is usually mild and self-limited to 2 to 3 days, although it sometimes lasts for up to 10 days. Should these moods persist or worsen, an evaluation for symptoms of major depression is done (Chap. 61, p. 1205). Suicidal or infanticidal ideation is dealt with emergently. Because major postpartum depression recurs in at least a fourth of women in subsequent pregnancies, some recommend pharmacological prophylaxis beginning in late pregnancy or immediately postpartum.

Last, postpartum hormonal changes in some women may affect brain function. Bannbers and colleagues (2013) compared a measure of executive function in postpartum women and controls and observed a decrease in postpartum subjects.

■ Neuromusculoskeletal Problems

Obstetrical Neuropathies

Pressure on branches of the lumbosacral nerve plexus during labor may manifest as complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as

the head descends into the pelvis. If the nerve is injured, pain may continue after delivery, and there also may be variable degrees of sensory loss or muscle paralysis. In some cases, there is footdrop, which can be secondary to injury at the level of the lumbosacral plexus, sciatic nerve, or common fibular (peroneal) nerve. Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. The common fibular nerves may be externally compressed when the legs are positioned in stirrups, especially during prolonged second-stage labor.

Obstetrical neuropathy is relatively infrequent. Wong and associates (2003) evaluated more than 6000 delivered women and found that approximately 1 percent had a confirmed nerve injury. Lateral femoral cutaneous neuropathies were the most common (24), followed by femoral neuropathies (14). A motor deficit accompanied a third of injuries. Nulliparity, prolonged second-stage labor, and pushing for a long duration in the semi-Fowler position were risk factors. The median duration of symptoms was 2 months, and the range was 2 weeks to 18 months.

Nerve injuries with cesarean delivery include the iliohypogastric and ilioinguinal nerves (Rahn, 2010). These are discussed further in Chapter 2 (p. 17).

Musculoskeletal Injuries

Pain in the pelvic girdle, hips, or lower extremities may follow stretching or tearing injuries sustained at normal or difficult delivery. Magnetic resonance (MR) imaging is often informative. One example is the piriformis muscle hematoma shown in Figure 36-6. Most injuries resolve with antiinflammatory agents and physical therapy. Rarely, there may be septic pyomyositis such as with iliopsoas muscle abscess (Nelson, 2010; Young, 2010).

Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor leads to pain and marked interference with locomotion. Estimates of the frequency of this event

FIGURE 36-6 Magnetic resonance image of a piriformis hematoma. A large inhomogeneous mass of the right piriformis muscle consistent with a hematoma (yellow cursor measurements) is compared with the normal-appearing left piriformis muscle (yellow arrow).

FIGURE 36-7 Bacterial osteitis pubis-osteomyelitis caused by *Streptococcus milleri* in a woman with symptomatic symphyseal separation.

vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis, 1932; Taylor, 1986). In our experiences, symptomatic separations are uncommon. Their onset of pain is often acute during delivery, but symptoms may manifest either antepartum or up to 48 hours postpartum (Snow, 1997). Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder. Surgery is occasionally necessary in some symphyseal separations of more than 4 cm (Kharrazi, 1997). The recurrence risk is > 50 percent in subsequent pregnancy, and Culligan and associates (2002) recommend consideration for cesarean delivery. In rare cases, fractures of the sacrum or pubic ramus are caused by even uncomplicated deliveries (Alonso-Burgos, 2007). As discussed in Chapter 58 (p. 1159), the latter are more likely with osteoporosis associated with heparin or corticosteroid therapy (Cunningham, 2005). In rare but serious cases, bacterial osteomyelitis—*osteitis pubis*—can be devastating (Fig. 36-7). Lawford and coworkers (2010) reported such a case that caused massive vulvar edema.

Immunizations

The D-negative woman who is not isoimmunized and whose infant is D-positive is given 300 µg of anti-D immune globulin shortly after delivery (Chap. 15, p. 311). Women who are not already immune to rubella or rubeola measles are excellent candidates for combined measles-mumps-rubella vaccination before discharge (Chap. 9, p. 184). Unless contraindicated, at Parkland Hospital a diphtheria-tetanus toxoid booster injection is also given to postpartum women.

Hospital Discharge

Following uncomplicated vaginal delivery, hospitalization is seldom warranted for more than 48 hours. A woman should receive instructions concerning anticipated normal physiological puerperal changes, including lochia patterns, weight loss from diuresis, and milk let-down. She also should receive instructions concerning fever, excessive vaginal bleeding, or leg

pain, swelling, or tenderness. Persistent headaches, shortness of breath, or chest pain warrant immediate concern.

Hospital stay length following labor and delivery is now regulated by federal law (Chap. 32, p. 634). Currently, the norms are hospital stays up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, 2012). Earlier hospital discharge is acceptable for appropriately selected women if they desire it.

Contraception

During the hospital stay, a concerted effort should be made to provide family planning education. Various forms of contraception are discussed throughout Chapter 38 and sterilization procedures in Chapter 39.

Women not breast feeding have return of menses usually within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently, starting soon after delivery. Ovulation occurs at a mean of 7 weeks, but ranges from 5 to 11 weeks (Perez, 1972). That said, ovulation before 28 days has been described (Hyttén, 1995). Thus, conception is possible during the artificially defined 6-week puerperium. *Women who become sexually active during the puerperium, and who do not desire to conceive, should initiate contraception.* Kelly and associates (2005) reported that by the third month postpartum, 58 percent of adolescents had resumed sexual intercourse, but only 80 percent of these were using contraception. Because of this, many recommend long-acting reversible contraceptives—LARC (Baldwin, 2013).

Women who breast feed ovulate much less frequently compared with those who do not, but there are great variations. Timing of ovulation depends on individual biological variation as well as the intensity of breast feeding. Lactating women may first menstruate as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens to determine the time of ovulation in 92 lactating women. As shown in Figure 36-8, breast feeding in general delays resumption of ovulation, although as already emphasized, it does not invariably forestall it. Other findings in their study included the following:

- 1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
- 2. Breast-feeding episodes lasting 15 minutes seven times daily delayed ovulation resumption.
- 3. Ovulation can occur without bleeding.
- 4. Bleeding can be anovulatory.
- 5. The risk of pregnancy in breast-feeding women was approximately 4 percent per year.

For the breast-feeding woman, progestin-only contraceptives—mini-pills, depot medroxyprogesterone, or progestin implants—do not affect the quality or quantity of milk. These may be initiated any time during the puerperium. Estrogen-progestin contraceptives likely reduce the quantity of breast milk, but under the proper circumstances, they too can be used

FIGURE 36-8 Cumulative proportion of breast-feeding women who ovulated during the first 70 weeks following delivery. (Data from Campbell, 1993.)

by breast-feeding women. However, these are withheld until after the first 4 weeks because of their higher thromboembolic risk in puerperal patients. These hormonal methods are summarized in Table 36-4 and are discussed in Chapter 38 (p. 695).

HOME CARE

Coitus

There are no evidence-based data concerning resumption of coitus after delivery. It seems best to use common sense (Minig, 2009). After 2 weeks, coitus may be resumed *based on desire and comfort*. Barrett and colleagues (2000) reported that almost 90 percent of 484 primiparous women resumed sexual activity by 6 months. And although 65 percent of these reported problems, only 15 percent discussed them with a health-care provider.

Intercourse too soon may be unpleasant, if not frankly painful, due to incomplete healing of the episiotomy or lacerations. Moreover, the vaginal epithelium is thin, and very little lubrication follows sexual stimulation. This is due to the hypoestrogenic state following delivery, which lasts until ovulation resumes. It may be particularly problematic in breast-feeding women who are hypoestrogenic for many months postpartum (Palmer, 2003; Wisniewski, 1991). For treatment, small amounts of topical estrogen cream can be applied daily for

several weeks to vulvar tissues. Additionally, vaginal lubricants may be used with coitus.

Late Maternal Morbidity

Taken together, major and minor maternal morbidity are surprisingly common in the months following childbirth (MacArthur, 1991). In a survey of 1249 British mothers followed for up to 18 months, 3 percent required hospital readmission within 8 weeks (Glazener, 1995; Thompson, 2002). Milder health problems during the first 8 weeks were reported by 87 percent (Table 36-5). Moreover, almost three fourths continued to have various problems for up to 18 months. Practitioners should be aware of these potential issues in their patients convalescing from birthing.

Follow-Up Care

By discharge, women who had an uncomplicated course can resume most activities, including bathing, driving, and household functions. Jimenez and Newton (1979) tabulated cross-cultural information on 202 societies from various international geographical regions. Following childbirth, most societies did not restrict work activity, and approximately half expected a return to full duties within 2 weeks. Wallace and coworkers (2013) reported that 80 percent of women who worked during pregnancy resume work by 1 year after delivery. Despite this, Tulman and Fawcett (1988) reported that only half of mothers regained their usual level of energy by 6 weeks. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the infant should be provided by the mother with ample help from the father.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012) recommend a postpartum visit between 4 and 6 weeks. This has proven quite satisfactory to identify abnormalities beyond the immediate puerperium and to initiate contraceptive practices.

TABLE 36-5. Puerperal Morbidity Reported by 8 Weeks

Morbidity	Percent ^a
Fatigue	59
Breast problems	36
Anemia	25
Backache	24
Hemorrhoids	23
Headache	22
"Blues"	21
Constipation	20
Suture breakdown	16
Vaginal discharge	15

^aAt least one symptom was reported by 87 percent of all women.

Data from Glazener, 1995.

TOXIC SHOCK SYNDROME..... 690

BREAST INFECTIONS..... 691

Puerperal complications include many of those encountered during pregnancy, but there are some that are more common at this time. Typical of these is puerperal pelvic infection—a well-known killer of postpartum women. Other infections include mastitis and breast abscesses. Thromboembolism during the short 6-week puerperium is as frequent as during all 40 antepartum weeks.

PUERPERAL INFECTIONS

Traditionally, the term *puerperal infection* describes any bacterial infection of the genital tract after delivery. These infections as well as preeclampsia and obstetrical hemorrhage form the lethal triad of maternal death causes before and during the 20th century. Fortunately, because of effective antimicrobials, maternal mortality from infection has become uncommon. Berg and associates (2010) reported results from the Pregnancy Mortality Surveillance System, which contained 4693 pregnancy-related maternal deaths in the United States from 1998 through 2005.

Infection caused 10.7 percent of pregnancy-related deaths and was the fifth leading cause. In a similar analysis of the North Carolina population from 1991 through 1999, Berg and colleagues (2005) reported that 40 percent of infection-related maternal deaths were preventable.

Puerperal Fever

A number of factors can cause fever—a temperature of 38.0°C (100.4°F) or higher—in the puerperium. *Most persistent fevers after childbirth are caused by genital tract infection.* Using this conservative definition of fever, Filker and Monif (1979) reported that only about 20 percent of women febrile within the first 24 hours after giving birth vaginally were subsequently diagnosed with pelvic infection. This was in contrast to 70 percent of those undergoing cesarean delivery. It must be emphasized that spiking fevers of 39°C or higher that develop within the first 24 hours postpartum may be associated with virulent pelvic infection caused by group A streptococcus and is discussed on page 683.

Other causes of puerperal fever include breast engorgement, urinary infections, episiotomy and abdominal incisions, perineal lacerations, and respiratory complications after cesarean delivery (Maharaj, 2007). Approximately 15 percent of women who do not breast feed develop postpartum fever from *breast engorgement*. As discussed in Chapter 36 (p. 675), the incidence of fever is lower in breast-feeding women. “Breast fever” rarely exceeds 39°C in the first few postpartum days and usually lasts < 24 hours. *Urinary infections* are uncommon postpartum because of the normal diuresis encountered then. That said, *acute pyelonephritis* has a variable clinical picture. The first sign of renal infection may be fever, followed later by costovertebral angle tenderness, nausea, and vomiting. *Atelectasis* following abdominal delivery is caused by hypoventilation and is best prevented by coughing and deep breathing on a fixed schedule following surgery. Fever associated with atelectasis is thought to follow infection by normal flora that proliferate distal to obstructing mucus plugs.

Uterine Infection

Postpartum uterine infection or puerperal sepsis has been called variously *endometritis*, *endomyometritis*, and *endoparametritis*. Because infection involves not only the decidua but also the myometrium and parametrial tissues, we prefer the inclusive term *metritis with pelvic cellulitis*.

Predisposing Factors

The route of delivery is the single most significant risk factor for the development of uterine infection (Burrows, 2004; Conroy, 2012; Koroukian, 2004). In the French Confidential Enquiry on Maternal Deaths, Deneux-Tharaux and coworkers (2006) cited a nearly 25-fold increased infection-related mortality rate with cesarean versus vaginal delivery. Rehospitalization rates for wound complications and endometritis were increased significantly in women undergoing a planned primary cesarean delivery compared with those having a planned vaginal birth (Declercq, 2007).

Vaginal Delivery. Compared with cesarean delivery, metritis following vaginal delivery is relatively infrequent. Women delivered vaginally at Parkland Hospital have a 1- to 2-percent incidence of metritis. Women at high risk for infection because of membrane rupture, prolonged labor, and multiple cervical examinations have a 5-to 6-percent frequency of metritis after vaginal delivery. If there is intrapartum chorioamnionitis, the risk of persistent uterine infection increases to 13 percent (Maberry, 1991). Finally, in one study, manual removal of the placenta, discussed in Chapter 41 (p. 784), increased the puerperal metritis rate threefold (Baksu, 2005).

Cesarean Delivery. Single-dose perioperative antimicrobial prophylaxis is recommended for all women undergoing cesarean delivery (American College of Obstetricians and Gynecologists, 2011). Such single-dose antimicrobial prophylaxis has done more to decrease the incidence and severity of postcesarean delivery infections than any other intervention in the past 30 years. Such practices decrease the puerperal pelvic infection risk by 65 to 75 percent (Smaill, 2010).

The magnitude of the risk is exemplified from reports that predate antimicrobial prophylaxis. Cunningham and associates (1978) described an overall incidence of 50 percent in women undergoing cesarean delivery at Parkland Hospital. Important risk factors for infection following surgery included prolonged labor, membrane rupture, multiple cervical examinations, and internal fetal monitoring. Women with all these factors who were not given perioperative prophylaxis had a 90-percent serious postcesarean delivery pelvic infection rate (DePalma, 1982).

Other Risk Factors. It is generally accepted that pelvic infection is more frequent in women of lower socioeconomic status (Maharaj, 2007). Except in extreme cases usually not seen in this country, it is unlikely that anemia or poor nutrition predispose to infection. *Bacterial colonization* of the lower genital tract with certain microorganisms—for example, group B streptococcus, *Chlamydia trachomatis*, *Mycoplasma hominis*,

Ureaplasma urealyticum, and *Gardnerella vaginalis*—has been associated with an increased postpartum infection risk (Andrews, 1995; Jacobsson, 2002; Watts, 1990). Other factors associated with an increased infection risk include general anesthesia, cesarean delivery for multifetal gestation, young maternal age and nulliparity, prolonged labor induction, obesity, and meconium-stained amniotic fluid (Acosta, 2012; Jazayeri, 2002; Kabiru, 2004; Leth, 2011; Siriwachirachai, 2010; Tsai, 2011).

Microbiology

Most female pelvic infections are caused by bacteria indigenous to the genital tract. Over the past 20 years, there have been reports of group A β -hemolytic streptococcus causing toxic shock-like syndrome and life-threatening infection (Aronoff, 2008; Castagnola, 2008; Nathan, 1994; Palep-Singh, 2007). Prematurely ruptured membranes are a prominent risk factor in these infections (Anteby, 1999). In reviews by Crum (2002) and Udagawa (1999) and their colleagues, women in whom group A streptococcal infection was manifested before, during, or within 12 hours of delivery had a maternal mortality rate of almost 90 percent and fetal mortality rate > 50 percent. In the past 10 years, skin and soft-tissue infections due to community-acquired methicillin-resistant *Staphylococcus aureus*—CA-MRSA—have become common (Chap. 64, p. 1251). Although this variant is not a frequent cause of puerperal metritis, it is commonly implicated in abdominal incisional infections (Anderson, 2007; Patel, 2007). Rotas and coworkers (2007) reported a woman with episiotomy cellulitis from CA-MRSA and hematogenously spread necrotizing pneumonia.

Common Pathogens. Bacteria commonly responsible for female genital tract infections are listed in Table 37-1. Generally, infections are polymicrobial, which enhances bacterial synergy. Other factors that promote virulence are hematomas and devitalized tissue. Although the cervix and vagina routinely harbor such bacteria, the uterine cavity is usually sterile before rupture of the amniotic sac. As the consequence of labor and delivery and associated manipulations, the amniotic

TABLE 37-1. Bacteria Commonly Responsible for Female Genital Infections

Aerobes
Gram-positive cocci—group A, B, and D streptococci, enterococcus, <i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i>
Gram-negative bacteria— <i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> species
Gram-variable— <i>Gardnerella vaginalis</i>
Others
<i>Mycoplasma</i> and <i>Chlamydia</i> species, <i>Neisseria gonorrhoeae</i>
Anaerobes
Cocci— <i>Peptostreptococcus</i> and <i>Peptococcus</i> species
Others— <i>Clostridium</i> , <i>Bacteroides</i> , and <i>Fusobacterium</i> species, <i>Mobiluncus</i> species

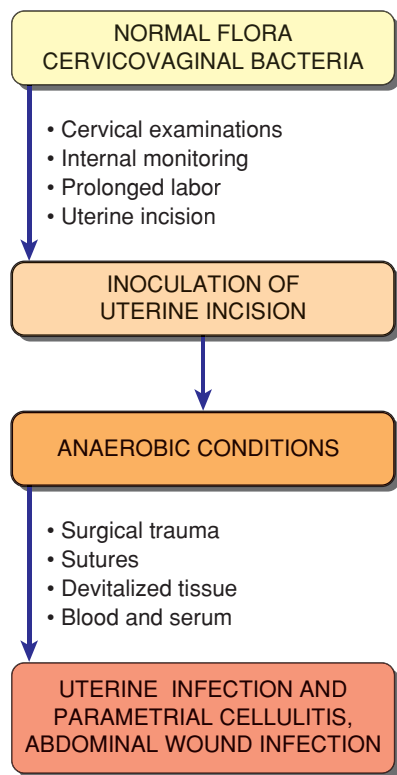

FIGURE 37-1 Pathogenesis of metritis following cesarean delivery. (Adapted from Gilstrap, 1979.)

fluid and uterus become contaminated with anaerobic and aerobic bacteria (Fig. 37-1). Intraamniotic cytokines and C-reactive protein are also markers of infection (Combs, 2013; Marchocki, 2013). In studies done before the use of antimicrobial prophylaxis, Gilstrap and Cunningham (1979) cultured amniotic fluid obtained at cesarean delivery in women in labor with membranes ruptured more than 6 hours. All had bacterial growth, and an average of 2.5 organisms was identified from each specimen. Anaerobic and aerobic organisms were identified in 63 percent, anaerobes alone in 30 percent, and aerobes alone in only 7 percent. Anaerobes included *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Aerobes included *Enterococcus* in 14 percent, group B streptococcus in 8 percent, and *Escherichia coli* in 9 percent of isolates. Sherman and coworkers (1999) later showed that bacterial isolates at cesarean delivery correlated with those taken from women with metritis at 3 days postpartum.

The role of other organisms in the etiology of these infections is unclear. Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail, 1985). Observations of Chaim and colleagues (2003) suggest that when cervical colonization of *U. urealyticum* is heavy, it may contribute to the development of metritis. Finally, Jacobsson and associates (2002) reported a threefold risk of puerperal infection in a group of Swedish women in whom bacterial vaginosis was identified in early pregnancy (Chap. 65, p. 1276).

Bacterial Cultures. Routine pretreatment genital tract cultures are of little clinical use and add significant costs. Similarly, routine

blood cultures seldom modify care. In two earlier studies done before perioperative prophylaxis was used, blood cultures were positive in 13 percent of women with postcesarean metritis at Parkland Hospital and 24 percent in those at Los Angeles County Hospital (Cunningham, 1978; DiZerega, 1979). In a later Finnish study, Kankuri and associates (2003) confirmed bacteremia in only 5 percent of almost 800 women with puerperal sepsis.

Pathogenesis and Clinical Course

Puerperal infection following vaginal delivery primarily involves the placental implantation site, decidua and adjacent myometrium, or cervicovaginal lacerations. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision (see Fig. 37-1). Bacteria that colonize the cervix and vagina gain access to amniotic fluid during labor. Postpartum, they invade devitalized uterine tissue. Parametrial cellulitis next follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. With early treatment, infection is contained within the parametrial and paravaginal tissue, but it may extend deeply into the pelvis.

Fever is the most important criterion for the diagnosis of postpartum metritis. Intuitively, the degree of fever is believed proportional to the extent of infection and sepsis syndrome. Temperatures commonly are 38 to 39°C. Chills that accompany fever suggest bacteremia or endotoxemia. Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Leukocytosis may range from 15,000 to 30,000 cells/ μ L, but recall that cesarean delivery itself increases the leukocyte count (Hartmann, 2000). Although an offensive odor may develop, many women have foul-smelling lochia without evidence for infection, and vice versa. Some other infections, notably those caused by group A β -hemolytic streptococci, may be associated with scant, odorless lochia.

Treatment

If nonsevere metritis develops following vaginal delivery, then treatment with an oral antimicrobial agent is usually sufficient. For moderate to severe infections, however, intravenous therapy with a broad-spectrum antimicrobial regimen is indicated. Improvement follows in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens. Persistent fever after this interval mandates a careful search for causes of refractory pelvic infection. These include a parametrial phlegmon—an area of intense cellulitis; an abdominal incisional or pelvic abscess or infected hematoma; and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or due to drug side effects. The woman may be discharged home after she has been afebrile for at least 24 hours, and further oral antimicrobial therapy is not needed (Dinsmoor, 1991; French, 2004).

Choice of Antimicrobials. Although therapy is empirical, initial treatment following cesarean delivery is directed against elements of the mixed flora shown in Table 37-1. For infections following vaginal delivery, as many as 90 percent of women respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage is included for infections following cesarean delivery (Table 37-2).

TABLE 37-2. Antimicrobial Regimens for Intravenous Treatment of Pelvic Infection Following Cesarean Delivery

Regimen	Comments
Clindamycin + gentamicin	"Gold standard," 90–97% efficacy, once-daily gentamicin dosing acceptable <i>plus</i> Ampicillin added to regimen with sepsis syndrome or suspected enterococcal infection
Clindamycin + aztreonam	Gentamicin substitute for renal insufficiency
Extended-spectrum penicillins	Piperacillin, piperacillin tazobactam, ampicillin/sulbactam, ticarcillin/clavulanate
Cephalosporins	Cefotetan, cefoxitin, cefotaxime
Vancomycin	Added to other regimens for suspected <i>S aureus</i> infections
Metronidazole + ampicillin + gentamicin	Metronidazole has excellent anaerobic coverage
Carbapenems	Imipenem/cilastatin, meropenem, ertapenem reserved for special indications

In 1979, DiZerega and colleagues compared the effectiveness of clindamycin plus gentamicin with that of penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the clindamycin-gentamicin regimen had a 95-percent response rate, and this regimen is still considered by most to be the standard by which others are measured (French, 2004). Because enterococcal cultures may be persistently positive despite this standard therapy, some add ampicillin to the clindamycin-gentamicin regimen, either initially or if there is no response by 48 to 72 hours (Brumfield, 2000).

Many authorities recommend that serum gentamicin levels be periodically monitored. At Parkland Hospital, we do not routinely do so if the woman has normal renal function. Once-daily dosing versus multiple-dosing with gentamicin provides adequate serum levels, and either method has similar cure rates (Livingston, 2003).

Because of potential nephrotoxicity and ototoxicity with gentamicin in the event of diminished glomerular filtration, some have recommended a combination of clindamycin and a second-generation cephalosporin to treat such women. Others recommend a combination of clindamycin and aztreonam, which is a monobactam compound with activity similar to the aminoglycosides.

The spectra of β -lactam antimicrobials include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, cefotaxime, and ceftriaxone, as well as extended-spectrum penicillins such as piperacillin, ticarcillin, and mezlocillin. β -Lactam antimicrobials are inherently safe and except for allergic reactions, are free of major toxicity. The β -lactamase inhibitors, clavulanic acid, sulbactam, and tazobactam, have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra. *Metronidazole* has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections. It is also used to treat *Clostridium difficile* colitis.

Imipenem and similar antimicrobials are in the carbapenem family. These offer broad-spectrum coverage against most organisms associated with metritis. Imipenem is used in combination with *cilastatin*, which inhibits its renal metabolism.

Preliminary findings with *ertapenem* indicated suboptimal outcomes (Brown, 2012). It seems reasonable from both a medical and an economic standpoint to reserve these drugs for serious nonobstetrical infections.

Vancomycin is a glycopeptide antimicrobial active against gram-positive bacteria. It is used in lieu of β -lactam therapy for a patient with a type 1 allergic reaction and given for suspected infections due to *Staphylococcus aureus* and to treat *C difficile* colitis (Chap. 54, p. 1074).

Perioperative Prophylaxis

As discussed, administration of antimicrobial prophylaxis at the time of cesarean delivery has remarkably reduced the postoperative pelvic and wound infection rates. Numerous studies have shown that prophylactic antimicrobials reduce the pelvic infection rate by 70 to 80 percent (Chelmow, 2001; Dinsmoor, 2009; Smaill, 2010; Witt, 2011). The observed benefit applies to both elective and nonelective cesarean delivery and also includes a reduction in abdominal incisional infection rates.

Single-dose prophylaxis with ampicillin or a first-generation cephalosporin is ideal, and both are as effective as broad-spectrum agents or a multiple-dose regimen (American College of Obstetricians and Gynecologists, 2011). Extended-spectrum prophylaxis with azithromycin added to standard single-dose prophylaxis has shown a further reduction in postcesarean metritis rates (Tita, 2008). These findings need to be verified. Women known to be colonized with methicillin-resistant *Staphylococcus aureus*—MRSA—are given vancomycin in addition to a cephalosporin (Chap. 64, p. 1251). Finally, it is controversial whether the infection rate is lowered more if the selected antimicrobial is given before the skin incision compared with after umbilical cord clamping (Baaqeel, 2012; Macones, 2012; Sun, 2013). The American College of Obstetricians and Gynecologists (2011) has concluded that the evidence favors predelivery administration. There may be additive salutary effects of preoperative vaginal cleansing with povidone-iodine rinse or application of metronidazole gel (Haas, 2013; Reid, 2011; Yildirim, 2012).

Other Methods of Prophylaxis. Several studies have evaluated the value of prenatal cervicovaginal cultures. These are

obtained in the hope of identifying pathogens that might be eradicated to decrease incidences of preterm labor, chorioamnionitis, and puerperal infections. Unfortunately, treatment of asymptomatic vaginal infections has not been shown to prevent these complications. Carey and coworkers (2000) reported no beneficial effects for women treated for asymptomatic bacterial vaginosis. Klebanoff and colleagues (2001) reported a similar postpartum infection rate in women treated for second-trimester asymptomatic *Trichomonas vaginalis* infection compared with that of placebo-treated women.

Technical maneuvers done to alter the postpartum infection rate have been studied with cesarean delivery. For example, allowing the placenta to separate spontaneously compared with removing it manually lowers the infection risk. However, changing gloves by the surgical team after placental delivery does not (Atkinson, 1996). Exteriorizing the uterus to close the hysterotomy may decrease febrile morbidity (Jacobs-Jokhan, 2004). Postdelivery mechanical lower segment and cervical dilatation have not been shown to be effective (Liabsuetrakul, 2011). No differences were found in postoperative infection rates when single- versus two-layer uterine closure was compared (Hauth, 1992). Similarly, infection rates are not appreciatively affected by closure versus nonclosure of the peritoneum (Bamigboye, 2003; Tulandi, 2003). Importantly, although closure of subcutaneous tissue in obese women does not lower the wound infection rate, it does decrease the wound separation incidence (Chelmow, 2004; Magann, 2002; Naumann, 1995). Similarly, skin closure with staples versus suture has a higher incidence of noninfectious skin separation (Mackeen, 2012; Tuuli, 2011).

Complications of Uterine and Pelvic Infections

In more than 90 percent of women, metritis responds to treatment within 48 to 72 hours. In some of the remainder, any of several complications may arise. These include wound infections, complex pelvic infections such as phlegmons or abscesses, and septic pelvic thrombophlebitis (Jaiyeoba, 2012). As with other aspects of puerperal infections, the incidence and severity of these complications are remarkably decreased by perioperative antimicrobial prophylaxis.

■ Abdominal Incisional Infections

Wound infection is a common cause of persistent fever in women treated for metritis. Other wound infection risk factors include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, hypertension, and inadequate hemostasis with hematoma formation. If prophylactic antimicrobials are given as described above, the incidence of abdominal wound infection following cesarean delivery ranges from 2 to 10 percent depending on risk factors (Andrews, 2003; Chaim, 2000).

Incisional abscesses that develop following cesarean delivery usually cause persistent fever or fever beginning about the fourth day. In many cases, antimicrobials had been given to treat pelvic infection, yet fever persisted. There is wound erythema and drainage. Although organisms that cause wound infections are generally the same as those isolated from amniotic fluid at cesarean delivery, hospital-acquired pathogens may also be causative (Emmons, 1988; Owen,

1994). Treatment includes antimicrobials, surgical drainage, and debridement of devitalized tissue. The fascia is carefully inspected to document integrity.

Local wound care is typically completed twice daily. Before each dressing change, procedural analgesia is tailored to wound size and location, and oral, intramuscular, or intravenous dosage routes are suitable. Topical lidocaine may also be added. Necrotic tissue is removed, and the wound is repacked with moist gauze. At 4 to 6 days, healthy granulation tissue is typically present, and secondary en bloc closure of the open layers can usually be accomplished (Wechter, 2005). With this closure, a polypropylene or nylon suture of appropriate gauge enters 3 cm from one wound edge. It crosses the wound to incorporate the full wound thickness and emerges 3 cm from the other wound edge. These are placed in series to close the opening. In most cases, sutures may be removed on postprocedural day 10. Wound vacuum device use is gaining popularity. However, its efficacy remains unproven in randomized trials.

Wound Dehiscence

Wound disruption or dehiscence refers to separation of the fascial layer. This is a serious complication and requires secondary closure of the incision in the operating room. McNeeley and associates (1998) reported a fascial dehiscence rate of approximately 1 per 300 operations in almost 9000 women undergoing cesarean delivery. Most disruptions manifested on about the fifth postoperative day and were accompanied by a serosanguineous discharge. Two thirds of 27 fascial dehiscences identified in this study were associated with concurrent fascial infection and tissue necrosis.

Necrotizing Fasciitis

This uncommon, severe wound infection is associated with high mortality rates. In obstetrics, necrotizing fasciitis may involve abdominal incisions, or it may complicate episiotomy or other perineal lacerations. As the name implies, there is significant tissue necrosis. Of the risk factors for fasciitis summarized by Owen and Andrews (1994), three of these—*diabetes*, *obesity*, and *hypertension*—are relatively common in pregnant women. Like pelvic infections, these wound complications usually are polymicrobial and are caused by organisms that make up the normal vaginal flora. *In some cases, however, infection is caused by a single virulent bacterial species such as group A β -hemolytic streptococcus.* Occasionally, necrotizing infections are caused by rarely encountered pathogens (Swartz, 2004).

Goepfert and coworkers (1997) reviewed their experiences with necrotizing fasciitis at the University of Alabama Birmingham Hospital. Nine cases complicated more than 5000 cesarean deliveries—frequency of 1.8 per 1000. In two women, the infection was fatal. In a report from Brigham and Women's and Massachusetts General Hospitals, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Infection may involve skin, superficial and deep subcutaneous tissues, and any of the abdominopelvic fascial layers (Fig. 37-2). In some cases, muscle is also involved—myofasciitis. Although some virulent infections, for example, from group A β -hemolytic streptococci, develop early postpartum, most of these necrotizing infections do not cause symptoms

FIGURE 37-2 Necrotizing fasciitis involving the abdominal wall and Pfannenstiel incision. The skin rapidly became dusky and gangrenous, and pus is seen exuding from the left angle of the incision. Extensive debridement and supportive therapy were lifesaving.

until 3 to 5 days after delivery. Clinical findings vary, and it is frequently difficult to differentiate more innocuous superficial wound infections from an ominous deep fascial one. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving. We aggressively pursue early exploration. Certainly, if myofasciitis progresses, the woman may become ill from septicemia. Profound hemoconcentration from capillary leakage with circulatory failure commonly occurs, and death may soon follow as described in Chapter 47 (p. 947).

Early diagnosis, surgical debridement, antimicrobials, and intensive care are paramount to successfully treat necrotizing soft-tissue infections (Gallup, 2004; Urschel, 1999). Surgery includes extensive debridement of all infected tissue, leaving wide margins of healthy bleeding tissue. This may include extensive abdominal or vulvar debridement with unroofing and excision of abdominal, thigh, or buttock fascia. Death is virtually universal without surgical treatment, and rates approach 50 percent even if extensive debridement is performed. With extensive resection, synthetic mesh may ultimately be required later to close the fascial incision (Gallup, 2004; McNeeley, 1998).

Adnexal Abscesses and Peritonitis

An *ovarian abscess* rarely develops in the puerperium. These are presumably caused by bacterial invasion through a rent in the ovarian capsule (Wetchler,

1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery. Rupture is common, and peritonitis may be severe.

Peritonitis is infrequent following cesarean delivery. It is almost invariably preceded by metritis. It most often is caused by uterine incisional necrosis and dehiscence, but it may be due to a ruptured adnexal abscess or an inadvertent bowel injury at cesarean delivery. Peritonitis is rarely encountered after vaginal delivery, and many such cases are due to virulent strains of group A β -hemolytic streptococci or similar organisms.

Importantly in postpartum women, abdominal rigidity may not be prominent with puerperal peritonitis because of abdominal wall laxity from pregnancy. Pain may be severe, but frequently, the first symptoms of peritonitis are those of *adynamic ileus*. Marked bowel distention may develop, and these findings are unusual after uncomplicated cesarean delivery. If the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone usually suffices. Conversely, peritonitis caused by uterine incisional necrosis as discussed subsequently, or from bowel perforation, must be treated promptly with surgical intervention.

Parametrial Phlegmon

For some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intensive and forms an area of induration—a *phlegmon*—within the leaves of the broad ligament (Fig. 37-3). These infections should be considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (Brown, 1999; DePalma, 1982).

Phlegmons are usually unilateral, and they frequently are limited to the parametrium at the base of the broad ligament. If the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of

FIGURE 37-3 Right-sided parametrial phlegmon: cellulitis causes induration in the parametrium adjacent to the hysterotomy incision. Induration extends to the pelvis sidewall and on bimanual pelvic examination, a phlegmon is palpable as a firm, three-dimensional mass.

FIGURE 37-4 Necrotic hysterotomy infection. Severe cellulitis of the uterine incision resulted in dehiscence with subsequent leakage into the peritoneal cavity. Hysterectomy was required for sufficient debridement of necrotic tissue.

extension is laterally along the broad ligament, with a tendency to extend to the pelvic sidewall. Occasionally, posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix. In most women with a phlegmon, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. Typically, fever resolves in 5 to 7 days, but in some cases, it persists longer. Absorption of the induration may require several days to weeks.

In some women, severe cellulitis of the uterine incision may lead to necrosis and separation (Treszezamsky, 2011). Extrusion of purulent material as shown in [Figure 37-4](#) leads to intraabdominal abscess formation and peritonitis as described above. Surgery is reserved for women in whom uterine incisional necrosis is suspected because of ileus and peritonitis. For most, hysterectomy and surgical debridement are needed and are predictably difficult because the cervix and lower uterine segment are involved with an intense inflammatory process that extends to the pelvic sidewall. The adnexa are seldom involved, and one or both ovaries can usually be conserved. There is often appreciable blood loss, and transfusion may be necessary.

Imaging Studies

Persistent puerperal infections can be evaluated using computed tomography (CT) or magnetic resonance (MR) imaging. Brown and associates (1991) used CT imaging in 74 women in whom pelvic infection was refractory to 5 days of antimicrobial therapy. They found at least one abnormal radiological finding in 75 percent of these women, and in most, these were nonsurgical. Maldjian and coworkers (1999) used MR imaging in 50 women with persistent fever and found a bladder flap hematoma in two thirds. In three women, parametrial edema was seen, and another two had a pelvic hematoma. In most cases, imaging can be used to dissuade surgical exploration.

Uterine incisional dehiscence such as shown in [Figure 37-4](#) is sometimes suspected based on CT scanning images. Another

FIGURE 37-5 Pelvic computed tomography scan showing necrosis of the uterine incision with gas in the myometrium (arrows). There is also a large right-sided parametrial abscess (a).

example is shown in [Figure 37-5](#). These findings must be interpreted within the clinical context because apparent uterine incisional defects thought to represent edema can be seen even after uncomplicated cesarean delivery (Twickler, 1991).

Occasionally, a parametrial phlegmon suppurates, forming a fluctuant broad ligament mass that may point above the inguinal ligament. These abscesses may dissect anteriorly as shown in [Figure 37-5](#) and be amenable to CT-directed needle drainage. Occasionally they dissect posteriorly to the rectovaginal septum, where surgical drainage is easily effected by colpotomy incision. A *psoas abscess* is rare, and despite antimicrobial therapy, percutaneous drainage may be required (Shahabi, 2002; Swanson, 2008).

Septic Pelvic Thrombophlebitis

This was a frequent complication in the preantibiotic era. Collins and colleagues (1951) described suppurative thrombophlebitis in 70 women cared for from 1937 through 1946 at Charity Hospital in New Orleans. Septic embolization was common and caused a third of maternal deaths during that period. With the advent of antimicrobial therapy, the mortality rate and need for surgical therapy for these infections diminished.

Septic phlebitis arises as an extension along venous routes and may cause thrombosis as shown in [Figure 37-6](#). Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus and therefore the placental implantation site. The experiences of Witlin and Sibai (1995) and Brown and coworkers (1999) suggest that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses ([Fig. 37-7](#)). In a fourth of women, the clot extends into the inferior vena cava and occasionally to the renal vein.

The incidence of septic phlebitis has varied in several reports. In a 5-year survey of 45,000 women who were delivered at Parkland Hospital, Brown and associates (1999) found an incidence of septic pelvic thrombophlebitis of 1 per 9000 following

FIGURE 37-6 Septic pelvic thrombophlebitis: uterine and parametrial infection may extend to any pelvic vessel as well as the inferior vena cava. The clot in the right common iliac vein extends from the uterine and internal iliac veins and into the inferior vena cava. The ovarian vein septic thrombosis extends halfway to the vena cava.

vaginal delivery and 1 per 800 with cesarean delivery. The overall incidence of 1 per 3000 deliveries was similar to the 1 per 2000 reported by Dunnihoo and colleagues (1991). In a cohort of 16,650 women undergoing primary cesarean delivery, Rouse and coworkers (2004) reported an incidence of 1 per 400 cesarean deliveries. Incidences approximated 1 per 175 surgeries if there was antecedent chorioamnionitis but only 1 per 500 if there was no intrapartum infection.

FIGURE 37-7 Ovarian vein thrombosis. Pelvic computed tomography scan shows enlargement of the right ovarian venous plexus with low density of the various lumens (arrows). The clotted vessels were easily palpable in this thin woman who had delivered vaginally 3 days earlier and was being treated with antimicrobials for metritis.

Women with septic thrombophlebitis usually have symptomatic improvement with antimicrobial treatment, however, they continue to have fever. Although there occasionally is pain in one or both lower quadrants, patients are usually asymptomatic except for chills. Diagnosis can be confirmed by either pelvic CT or MR imaging (Klima, 2008; Sheffield, 2001). Using either, Brown and colleagues (1999) found that 20 percent of 69 women with metritis who had fever despite ≥ 5 days of appropriate antimicrobial therapy had septic pelvic thrombophlebitis.

It has been disproven that intravenous heparin causes fever to dissipate with septic phlebitis (Brown, 1986; Witlin, 1995). And although Garcia and coworkers (2006) and Klima and Snyder (2008) advocate heparin therapy, we do not recommend anticoagulation. In a randomized study of 14 women by Brown and associates (1999), the addition of heparin to antimicrobial therapy

for septic pelvic thrombophlebitis did not hasten recovery or improve outcome. Certainly, there is no evidence for long-term anticoagulation as given for non-infection-related venous thromboembolism.

Perineal Infections

Episiotomy infections are not common because the operation is performed much less frequently now than in the past (American College of Obstetricians and Gynecologists, 2013). Reasons for this are discussed further in Chapter 27 (p. 550). In an older study, Owen and Hauth (1990) described only 10 episiotomy infections in 20,000 women delivered at the University of Alabama at Birmingham. With infection, dehiscence is a concern. Ramin and colleagues (1992) reported an episiotomy dehiscence rate of 0.5 percent at Parkland Hospital—80 percent of these were infected. In a more recent study, Uygur and associates (2004) reported a 1-percent dehiscence rate and attributed two thirds to infection. There are no data to suggest that dehiscence is related to faulty repair.

Infection of a fourth-degree laceration can be more serious. Goldaber and coworkers (1993) described 390 women with a fourth-degree laceration, of whom 5.4 percent had morbidity. In these women, 2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent only infection. Stock and associates (2013) reported wound complications in 7.3 percent of women with anal sphincter injuries. They further observed that intrapartum antimicrobials were protective against infection. Although life-threatening septic shock is rare, it may still occur as a result of an infected episiotomy (Soltesz,

1999). Occasionally also, necrotizing fasciitis develops as discussed on page 686.

Pathogenesis and Clinical Course

Episiotomy dehiscence is most commonly associated with infection as discussed above. Other factors include coagulation disorders, smoking, and human papillomavirus infection (Ramin, 1994). Local pain and dysuria, with or without urinary retention, are common symptoms. Ramin and colleagues (1992), evaluating a series of 34 women with episiotomy dehiscence, reported that the most common findings were pain in 65 percent, purulent discharge in 65 percent, and fever in 44 percent. In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate.

Vaginal lacerations may become infected directly or by extension from the perineum. The mucosa becomes red and swollen and may then become necrotic and slough. Parametrial extension may result in lymphangitis.

Cervical lacerations are common but seldom are noticeably infected, which may manifest as metritis. Deep lacerations which extend directly into the tissue at the base of the broad ligament may become infected and cause lymphangitis, parametritis, and bacteremia.

Treatment

Infected episiotomies are managed like other infected surgical wounds. Drainage is established, and in many cases, sutures are removed and the infected wound debrided. In women with obvious cellulitis but no purulence, close observation and broad-spectrum antimicrobial therapy alone may be appropriate. With dehiscence, local wound care is continued along with intravenous antimicrobials. Hauth and colleagues (1986) were the first to advocate early repair after infection subsided, and other studies have confirmed the efficacy of this approach. Hankins and coworkers (1990) described early repair of episiotomy dehiscence in 31 women with an average duration of 6 days from dehiscence to episiotomy repair. All but two had a successful repair. Each of the two women with failures developed a pinpoint rectovaginal fistula that was treated successfully with a small rectal flap. With episiotomy dehiscence due to infection, Ramin and coworkers (1992) reported successful early repair in 32 of 34 women (94 percent), and Uygur and colleagues (2004) noted a similarly high percentage. Rarely, intestinal diversion may be required to allow healing (Rose, 2005).

Early Repair of Infected Episiotomy

Before performing early repair, diligent preparation is essential as outlined in Table 37-3. The surgical wound must be properly cleaned and cleared of infection. Once the surface of the episiotomy wound is free of infection and exudate and covered by pink granulation tissue, secondary repair can be accomplished. The tissue must be adequately mobilized, with special attention to identify and mobilize the anal sphincter muscle. Secondary closure of the episiotomy is accomplished in layers, as described for primary episiotomy closure (Chap. 27, p. 551). Postoperative care includes local wound care, low-residue diet, stool softeners, and nothing per vagina or rectum until healed.

TABLE 37-3. Preoperative Protocol for Early Repair of Episiotomy Dehiscence

Open wound, remove sutures, begin intravenous antimicrobials
Wound care
Sitz bath several times daily or hydrotherapy
Adequate analgesia or anesthesia—regional analgesia or general anesthesia may be necessary for the first few debridements
Scrub wound twice daily with a povidone-iodine solution
Debride necrotic tissue
Closure when afebrile and with pink, healthy granulation tissue
Bowel preparation for fourth-degree repairs

Toxic Shock Syndrome

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. There is usually fever, headache, mental confusion, diffuse macular erythematous rash, subcutaneous edema, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may follow in rapid sequence. During recovery, the rash-covered areas undergo desquamation. For some time, *Staphylococcus aureus* was recovered from almost all afflicted persons. Specifically, a staphylococcal exotoxin, termed *toxic shock syndrome toxin-1* (TSST-1) was found to cause the clinical manifestations by provoking profound endothelial injury. A very small amount of TSST-1 has been shown to activate 5 to 30 percent of T cells to create a “cytokine storm” as described by Que (2005) and Heying (2007) and their coworkers.

During the 1990s, sporadic reports of virulent group A β -hemolytic streptococcal infection began to appear. Heavy colonization or infection is complicated in some cases by *streptococcal toxic shock syndrome*, which is produced when pyrogenic exotoxin is elaborated. Serotypes M1 and M3 are particularly virulent (Beres, 2004; Okumura, 2004). Finally almost identical findings of toxic shock were reported by Robbie and associates (2000) in women with *Clostridium sor-dellii* colonization.

Thus, in some cases of toxic shock syndrome, infection is not apparent and colonization of a mucosal surface is the presumed source. Ten to 20 percent of pregnant women have vaginal colonization with *S aureus*. Thus, it is not surprising that the disease develops in postpartum women when there is luxuriant bacterial growth vaginally (Chen, 2006; Guerinot, 1982).

Delayed diagnosis and treatment may be associated with maternal mortality (Schummer, 2002). Crum and colleagues (2002) described a neonatal death following antenatal toxic shock syndrome. Principal therapy is supportive, while allowing reversal of capillary endothelial injury (Chap. 47, p. 947). Antimicrobial therapy that includes staphylococcal and streptococcal coverage is given. With evidence of pelvic infection,

antimicrobial therapy must also include agents used for polymicrobial infections. Women with these infections may require extensive wound debridement and possibly hysterectomy. Because the toxin is so potent, the mortality rate is correspondingly high (Hotchkiss, 2003).

BREAST INFECTIONS

Parenchymal infection of the mammary glands is a rare antepartum complication but is estimated to develop in up to a third of breast-feeding women (Barbosa-Cesnik, 2003). Excluding breast engorgement, in our experiences, as well as that of Lee and associates (2010), the incidence of mastitis is much lower and probably approximates 1 percent. There is no evidence that any of several prophylactic measures prevent breast infection (Crepinsek, 2012). Risk factors include difficulties in nursing and mothers with outside employment (Branch-Elliman, 2012). Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and as a rule, not until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes inflammation. Symptoms include chills or actual rigors, which are soon followed by fever and tachycardia. There is severe pain, and the breast(s) becomes hard and red (Fig. 37-8). Approximately 10 percent of women with mastitis develop an abscess. Detection of fluctuation may be difficult, and sonography is usually diagnostic as also shown in Figure 37-8.

Etiology

Staphylococcus aureus, especially its methicillin-resistant strain, is the most commonly isolated organism. Matheson and coworkers (1988) reported it in 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of organisms that cause mastitis is almost always the infant's nose and throat. Bacteria enter the breast through the nipple at the site of a fissure or small abrasion. The infecting organism can usually be cultured from milk. Toxic shock syndrome from mastitis caused by *S aureus* has been reported (Demey, 1989; Fujiwara, 2001).

At times, suppurative mastitis reaches epidemic levels among nursing mothers. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant staphylococcus. A contemporaneous example is community-acquired methicillin-resistant *S aureus* (CA-MRSA), which has rapidly become the most commonly isolated staphylococcal species in some areas (Klevens, 2007; Pallin, 2008). At Parkland Hospital from 2000 to 2004, Laibl and associates (2005) reported that a fourth of CA-MRSA isolates were from pregnant or postpartum women with puerperal mastitis. Hospital-acquired MRSA may cause mastitis when the infant becomes colonized after contact with nursery personnel who are colonized (Centers for Disease Control and Prevention, 2006). Stafford and colleagues (2008) found a higher incidence of subsequent abscess in those with CA-MRSA-associated mastitis. In one study of puerperal breast abscesses, 63 percent were due to methicillin-resistant strains (Berens, 2010).

FIGURE 37-8 Puerperal mastitis with breast abscess. **A.** Photograph shows indurated, erythematous skin overlying area of right-sided breast infection. **B.** Sonographic picture of this 5-cm abscess. (Images contributed by Dr. Emily Adhikari.)

Management

Provided that appropriate therapy for mastitis is started before suppuration begins, the infection usually resolves within 48 hours. As discussed, abscess formation is more common with *S aureus* infection (Matheson, 1988). Most recommend that milk be expressed from the affected breast onto a swab and cultured before therapy is begun. Bacterial identification and antimicrobial sensitivities provide information mandatory for a successful program of nosocomial infection surveillance (Lee, 2010).

The initial antimicrobial choice is influenced by the current experience with staphylococcal infections at the institution. Although most are community-acquired organisms, as discussed above, these frequently include CA-MRSA. Dicloxacillin, 500 mg orally four times daily, may be started empirically. Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococci or if resistant organisms are suspected while awaiting the culture results, then vancomycin or another anti-MRSA antimicrobial should be given. Even though clinical

response may be prompt, treatment should be continued for 10 to 14 days.

Marshall and coworkers (1975) demonstrated the importance of continued breast feeding. They reported that of 65 women with mastitis, the only three who developed abscesses were among the 15 women who quit breast feeding. Vigorous milk expression may be sufficient treatment alone (Thomsen, 1984). Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the milk taste but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

In resource-poor countries, breast feeding in women infected with the human immunodeficiency virus (HIV) is not contraindicated. In the setting of mastitis or breast abscess, it is recommended to stop feeding from the infected breast. This is because HIV RNA levels increase in affected breast milk. These levels return to baseline after symptoms resolve (Semrau, 2013).

Breast Abscess

In a population-based study of nearly 1.5 million Swedish women, the incidence of breast abscess was 0.1 percent (Kvist, 2005). An abscess should be suspected when defervescence does not follow within 48 to 72 hours of mastitis treatment or when a mass is palpable. Again, sonographic imaging is valuable (see Fig. 37-8). Breast abscesses can be quite large, and in one case report, 2 liters of pus was drained (Martic, 2012). Traditional therapy is surgical drainage, which usually requires general anesthesia. The incision should be made corresponding to Langer skin lines for a cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of fluctuation is usually sufficient. Multiple abscesses, however, require several incisions and disruption of loculations. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack.

A more recently used technique that is less invasive is sonographically guided needle aspiration using local analgesia. This has an 80- to 90-percent success rate (O'Hara, 1996; Schwarz, 2001). In a randomized trial, Naem and colleagues (2012) compared surgical drainage and aspiration. They found aspiration resulted in quicker healing at 8 weeks, 77 versus 93 percent, respectively.

CHAPTER 38

Contraception

INTRAUTERINE DEVICES	696
PROGESTIN IMPLANTS	703
PROGESTIN-ONLY CONTRACEPTIVES GROUP	704
HORMONAL CONTRACEPTIVES	705
BARRIER METHODS	712
FERTILITY AWARENESS-BASED METHODS	713
SPERMICIDES	713
EMERGENCY CONTRACEPTION	714
PUERPERAL CONTRACEPTION	715

Half of all pregnancies each year in the United States are unintended (Finer, 2011). These may follow contraceptive method failure or stem from lack of contraceptive use. Specifically, 10 percent of sexually active American women not pursuing pregnancy did not use any birth control method (Jones, 2012). And, for sexually active fertile women not using contraception, pregnancy rates approach 90 percent at 1 year.

For those seeking contraception, various effective contraceptive methods are available. Preferences of United States women are shown in [Table 38-1](#). With these methods, wide variations are seen between estimated failure rates of perfect and typical use during the first year. Similarly, the World Health Organization (WHO) has grouped methods according to effectiveness tiers that reflect these failure rates ([Table 38-2](#)). Implants and intrauterine devices are found in the top tier. They are effective in lowering unintended pregnancy rates and are considered long-acting reversible contraception (LARC) (Winner, 2012).

The American College of Obstetricians and Gynecologists (2013c) recognizes these efficacy tiers and the high unintended pregnancy rate. Thus, the College recommends that clinicians provide counseling on *all* options and encourages highly effective LARC for all appropriate candidates.

Unfortunately, no contraceptive method is completely without side effects. That said, an important tenet is that contraception usually poses less risk than pregnancy. During appropriate method selection, underlying patient health conditions should be known. Some disorders or the medications used for their treatment can increase the risk of some contraceptives. The WHO (2010) has provided evidence-based guidelines, termed *Medical Eligibility Criteria*, for the use of all highly effective reversible contraceptive methods by women with various health conditions. Individual countries have subsequently modified these. The *United States Medical Eligibility Criteria (US MEC)* was published in the United States by the Centers for Disease Control and Prevention (CDC) (2010b), and its use is encouraged by the American College of Obstetricians and Gynecologists (2011b). Shown on page 698, the CDC (2011, 2012) has since added updates to reflect changes for women at high risk for human immunodeficiency virus (HIV) infection and for women in the puerperium. The US MEC guidelines and these updates, as well as a free smart-phone application of the guidelines, are available at the CDC website: <http://www.cdc.gov/reproductivehealth/UnintendedPregnancy/USMEC.htm>.

In the US MEC, reversible contraceptive methods are organized into six groups by their similarity: combination hormonal contraceptives (CHCs), progestin-only pills (POPs), depot medroxyprogesterone acetate (DMPA), implants, levonorgestrel-releasing intrauterine system (LNG-IUS), and copper intrauterine devices (Cu-IUDs). For a given health condition, each method is categorized 1 through 4. The score describes a method's safety profile for a typical woman with that condition:

TABLE 38-1. Method Use among Women in the United States

Method	Percentage
Female sterilization	16.5
Male sterilization	6.2
Combination pill	17.1
Progestin-only pill	0.4
Implants or patch	0.9
DMPA	2.3
Vaginal ring	1.3
Intrauterine devices	3.5
Male condom	10.2
Periodic abstinence	
Calendar method	0.6
Natural family planning ^a	0.1
Withdrawal	3.2
Other methods ^b	0.3
Not using contraception ^c	37.8

^aMethods using physiological changes to signal ovulation.
^bIncludes diaphragm, female condom, cervical cap, contraceptive sponge, spermicides, and emergency contraception.
^cIncludes those seeking pregnancy, surgically sterilized for noncontraceptive reasons, sexually inactive, pregnant or puerperal, and those who are sexually active but not using contraception.
DMPA = depot medroxyprogesterone acetate.
Data from Jones, 2012.

(1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, and (4) method poses an unacceptably high health risk.

Alternatively, depending on the underlying disorder or patient desire, male or female sterilization may be a preferred or recommended permanent contraceptive method. These options are fully discussed in Chapter 39 (p. 720).

LONG-ACTING REVERSIBLE CONTRACEPTION: INTRAUTERINE DEVICES

These are the most commonly used method of reversible contraception worldwide, and in the United States, nearly 4 percent of women select this method (d’Arcanques, 2007; Jones, 2012). Fortunately, contraindications to IUD use are few.

Intrauterine devices (IUDs) that are *chemically inert* are composed of nonabsorbable materials. The three IUDs currently approved for use in the United States are *chemically active* and have continuous elution of copper or a progestin. Of these, there are two different levonorgestrel-releasing intrauterine systems—*Mirena* and *Skyla* (Fig. 38-1). Each releases the progestin into the uterus at a relatively constant rate, which reduces systemic effects. Their T-shaped radiopaque frames have a stem wrapped with a cylinder reservoir that contains the levonorgestrel. There are two trailing brown strings attached

TABLE 38-2. Contraceptive Failure Rates During the First Year of Method Use in Women in the United States

Method ^a	Perfect Use	Typical Use
Top Tier: Most Effective		
Intrauterine devices		
Levonorgestrel system	0.2	0.2
T 380A copper	0.6	0.8
Levonorgestrel implants	0.05	0.05
Female sterilization	0.5	0.5
Male sterilization	0.1	0.15
Second Tier: Very Effective		
Combination pill	0.3	9
Vaginal ring	0.3	9
Patch	0.3	9
DMPA	0.2	6
Progestin-only pill	0.3	9
Third Tier: Effective		
Condom		
Male	2	18
Female	5	21
Diaphragm with spermicides	6	12
Fertility-awareness		24
Standard days	5	
Two day	4	
Ovulation	3	
Symptothermal	0.4	
Fourth Tier: Least Effective		
Spermicides	18	28
Sponge		
Parous women	20	24
Nulliparous women	9	12
No WHO Category		
Withdrawal	4	22
No contraception	85	85

^aMethods organized according to tiers of efficacy by World Health Organization (WHO), Johns Hopkins Bloomberg School of Public Health, 2007.
DMPA = depot medroxyprogesterone acetate.
Data from Trussell, 2011a.

to the stem (Bayer Healthcare Pharmaceuticals, 2013a,b). *Mirena* is currently approved for 5 years of use following insertion, however, some evidence supports its efficacy for 7 years (Thonneau, 2008). *Skyla* is approved for 3 years of use. It has slightly smaller overall dimensions than its counterpart and was sized to more appropriately fit a nulliparous uterus (Gemzell-Danielsson, 2012). It can also be differentiated from *Mirena* visually and sonographically by a silver ring near the junction of the device’s stem and arms.

The third device is the T 380A IUD, named *ParaGard*. It has a polyethylene and barium sulfate T-shaped frame wound with copper, and two strings extend from the stem base. Originally

FIGURE 38-1 Intrauterine devices (IUDs). **A.** ParaGard T 380A copper IUD. **B.** Mirena levonorgestrel-releasing intrauterine system.

blue, the strings are now white. It is currently approved for 10 years of use following insertion (Teva Women's Health, 2011).

In addition to these three currently marketed, women may retain discontinued brands of IUD. A *Lippes Loop* has two "S" shapes stacked one on the other. The *Dalkon Shield* has a crab form, whereas a *Copper 7* mirrors that number. *Progestasert* is an early T-shaped progestin-releasing IUD. Last, various metal-eluting ring-shaped devices are common in Asia.

Contraceptive Action

All these IUDs are effective. Failure rates are well below 1 percent and similar overall to those of tubal sterilization (American College of Obstetricians and Gynecologists, 2013a; Thonneau, 2008; Trussell, 2011b). Their mechanisms have not been precisely defined, but prevention of fertilization is now favored. Within the uterus, an intense local endometrial inflammatory response is induced, especially by copper-containing devices. Cellular and humoral components of this inflammation are expressed in endometrial tissue and in fluid filling the uterine cavity and fallopian tubes. These lead to decreased sperm and egg viability (Ortiz, 2007). Also, in the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. The endometrium is transformed into a hostile site for implantation. With the copper IUD specifically, copper levels increase in the cervical mucus of users and decrease sperm motility and viability (Jecht, 1973). With the LNG-IUS, in addition to an inflammatory reaction, long-term progestin release leads to endometrial atrophy, which hinders normal implantation. Moreover, progestins create scant viscous cervical mucus that obstructs sperm motility. The LNG-IUS may also inconsistently release sufficient progestin to inhibit ovulation, although this is a lesser effect than its local actions.

Method-Specific Adverse Effects

Several method-specific complications may follow IUD insertion and include uterine perforation, device expulsion, menstrual changes, infection, and miscarriage if pregnancy occurs. Also, in the past, IUDs were perceived to increase the risk of ectopic pregnancy. However, this has been clarified. Specifically, IUDs are so effective as contraceptives that they lower the abso-

lute number of ectopic pregnancies by half compared with the rate in noncontracepting women (World Health Organization, 1985, 1987). But, the IUD mechanisms of action are more effective in preventing *intrauterine* implantation. Thus, if an IUD fails, a higher proportion of pregnancies are likely to be ectopic (Backman, 2004; Furlong, 2002).

Perforation

During uterine sounding or IUD insertion, the uterus may be perforated, which is identified by the tool traveling further than the expected uterine length based on initial bimanual examination. Rates approximate 1 per 1000 insertions, and risks include puerperal insertion, lactation, provider inexperience, and extremes of uterine flexion (Harrison-Woolrych, 2003). Although devices may migrate spontaneously into and through the uterine wall, most perforations occur, or at least begin, at the time of insertion.

With the more common fundal perforation, bleeding typically is minimal due to myometrial contraction around the site. If no brisk or persistent bleeding is noted from the os following instrument removal, then patient observation alone is reasonable. Rarely, lateral perforations may lead to uterine artery laceration and brisk bleeding, which may prompt laparoscopy or laparotomy for control. Following any perforation, although this is not firmly evidence-based, a single dose of broad-spectrum antibiotic may mitigate infection.

Lost Device

Expulsion of an IUD from the uterus is most common during the first month. Thus, women should be examined approximately 1 month following IUD insertion, usually after menses, to identify the tails trailing from the cervix. Following this, a woman should be instructed to palpate the strings each month after menses.

If the tail of an IUD cannot be visualized, the device may have been expelled, may have perforated the uterus, or may be malpositioned. Some have found that IUD perforation, rotation, or embedding may cause pain or bleeding (Benacerraf, 2009; Moschos, 2011). Alternatively, the device may be normally positioned with its tail folded within the endocervical canal or uterine cavity. To investigate, after excluding pregnancy, a cytological brush can be twirled within the endocervical canal to entangle the strings and bring them gently into the vagina. If unsuccessful, the uterine cavity is probed gently with a Randall stone clamp or with a specialized rod with a terminal hook to retrieve the strings.

It should never be assumed that the device has been expelled unless it was seen. Thus, if tails are not visible and the device is not felt by gentle probing of the uterine cavity, transvaginal sonography can be used to ascertain if the device is within the uterus. Although traditional sonography will document IUD position adequately in most cases, three-dimensional sonography offers improved visualization, especially with the levonorgestrel-releasing IUD (Moschos, 2011). If sonography is inconclusive or if no device is seen, then a plain radiograph of the abdominopelvis is taken. Computed tomography (CT) scanning or less commonly, magnetic resonance (MR) imaging is an alternative (Boortz, 2012). It is safe to perform MR imaging at 1.5 and 3 Tesla (T) with an IUD in place (Pasquale, 1997; Zieman, 2007).

TABLE 38-3. Contraindications and Cautions with Specific Contraceptive Methods

Condition	CHC ^a	POP	DMPA	Implants	LNG-IUS	Cu-IUD

^aCombination hormone contraception (CHC) group includes pills, vaginal ring, and patch.

^bAssociated risks that increase category score include: age ≥ 35 , transfusion at delivery, BMI ≥ 30 , postpartum hemorrhage, cesarean delivery, smoking, preeclampsia.

^cSmoking ≥ 15 cigarettes/day increases risk category to 4 in this age group.

^dRisk category score is modified by associated risk factors and disease severity.

^eOral agents only. Ring and patch are category 1.

^fBenign hepatic adenoma or hepatocellular cancer.

^gThese include phenytoin, barbiturates, carbamazepine, oxcarbazepine, primidone, topiramate.

^hIn those methods under Start/Continue columns, the first US MEC number refers to whether a method may be initiated in an affected patient. For patients who initially develop the condition while using a specific method, the second number refers to risks for continuing that method.

ⁱPrior to evaluation.

^jThose on chronic corticosteroids and at risk for bone fracture.

AIDS = acquired immunodeficiency syndrome; APA = antiphospholipid antibodies; ARV = antiretroviral; BP = blood pressure; CHTN = chronic hypertension; Cu-IUD = copper intrauterine device; DM = diabetes mellitus; DMPA = depot medroxyprogesterone acetate; GC/CT = gonorrhea/chlamydial infection; GTD = gestational trophoblastic disease; ISHD = ischemic heart disease; LNG-IUS = levonorgestrel-releasing intrauterine system; PI = protease inhibitor; PID = pelvic inflammatory disease; POP = progestin-only pills; SLE = system lupus erythematosus.

Adapted from Centers for Disease Control and Prevention, 2010b, 2011, 2013.

A device may penetrate the muscular uterine wall to varying degrees. Those with a predominantly intrauterine location are typically managed by hysteroscopic IUD removal. In contrast, devices that have nearly or completely perforated through the uterine wall are more easily removed laparoscopically. Chemically inert devices usually are removed easily from the peritoneal cavity. An extrauterine copper-bearing device, however, frequently induces an intense local inflammatory reaction and adhesions. Thus, copper IUDs may be more firmly adhered. Laparotomy may be necessary, and bowel preparation is considered. Perforations of large and small bowel and bladder and bowel fistulas have been reported remote from insertion (Lyon, 2012; Mascarenhas, 2012; Zeino, 2011).

Menstrual Changes

Women who choose the copper IUD should be informed that dysmenorrhea and menorrhagia may develop. These are often treated with nonsteroidal antiinflammatory drugs (NSAIDs) (Grimes, 2006). Heavy bleeding may cause iron deficiency anemia, for which oral iron salts are given (Hassan, 1999).

With the LNG-IUS, women are counseled to expect irregular spotting for up to 6 months after placement, and thereafter to expect monthly menses to be lighter or even absent (Bayer HealthCare Pharmaceuticals, 2013a). Specifically, the Mirena device is associated with progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnerdag, 1999). This is often associated with improved dysmenorrhea.

Infection

The device-related infection risk is increased only during the first 20 days following insertion (Farley, 1992). Of those who develop an infection during this time, most usually have an unrecognized coexistent cervical infection. Accordingly, women at risk for sexually transmitted diseases (STDs) should be screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2010a; Sufrin, 2012). That said, device insertion need not be delayed while awaiting *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or PAP screening results in asymptomatic women. If these bacteria are found and the patient is without symptoms, then the IUD may remain and treatment prescribed as detailed in Chapter 65 (p. 1269). Importantly, routine antimicrobial prophylaxis before insertion is not recommended (Grimes, 2001; Walsh, 1998). Moreover, the American Heart Association does not recommend infective endocarditis prophylaxis with insertion (Wilson, 2007).

After these first 3 weeks, infection risk is not increased in IUD users who would otherwise be at low risk of STDs. Correspondingly, IUDs appear to cause little, if any, increase in the risk of infertility in these low-risk patients (Hubacher, 2001). For these reasons, the American College of Obstetricians and Gynecologists (2011a, 2012a) recommends that women at low risk for STDs, including adolescents, are good candidates for IUDs (Table 38-3). The IUD is also safe and effective in HIV-infected women and may be used in others who are immunosuppressed (Centers for Disease Control and Prevention, 2012).

If infection does develop, it may take several forms and typically requires broad-spectrum antimicrobials. *Septic*

abortion mandates immediate uterine evacuation in addition to antimicrobials. Pelvic inflammatory disease (PID) without abscess is treated with systemic antibiotics. There are theoretical concerns that a coexistent IUD might worsen the infection or delay resolution. Although a provider may choose to remove an IUD in this setting, some evidence also supports allowing a device to remain during treatment in those hospitalized with mild or moderate PID (Centers for Disease Control and Prevention, 2010b; Tepper, 2013). Last, *tuboovarian abscess* may develop with PID and is treated aggressively with intravenous broad-spectrum antibiotics and IUD removal.

In addition to these infections, *Actinomyces israelii* is a gram-positive, slow-growing, anaerobic indigenous vaginal bacterium that rarely causes infection with abscess formation (Persson, 1984). Some have found it more frequently in the vaginal flora or on the Pap smears of IUD users (Curtis, 1981; Fiorino, 1996). Current recommendations advise that an asymptomatic woman may retain her IUD and does not require antibiotic treatment (American College of Obstetricians and Gynecologists, 2013c; Lippes, 1999; Westhoff, 2007a). However, if signs or symptoms of infection develop in women who harbor *Actinomyces* species, then the device should be removed and antimicrobial therapy instituted. Early findings with infection include fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge. *Actinomyces* species are sensitive to antimicrobials with gram-positive coverage, notably the penicillins.

Pregnancy with an IUD

For women who become pregnant while using an IUD, ectopic pregnancy should be excluded (Chap. 19, p. 379). With intrauterine pregnancy, until approximately 14 weeks' gestation, the tail may be visible through the cervix, and if seen, it should be grasped and the IUD removed by gentle outward traction. This action reduces complications such as subsequent abortion, chorioamnionitis, and preterm birth (Brahmi, 2012; Kim, 2010). Tatum and coworkers (1976) reported an abortion rate of 54 percent with the device left in place compared with a rate of 25 percent if it was promptly removed.

If the tail is not visible, attempts to locate and remove the device may result in abortion. However, some practitioners have successfully used sonography to assist in device removal in cases without visible strings (Schiesser, 2004). After fetal viability is reached, it is unclear whether it is better to remove an IUD whose string is visible and accessible or to leave it in place. There is no evidence that fetal malformations are increased with a device in place (Tatum, 1976).

Second-trimester miscarriage with an IUD in place is more likely to be infected (Vessey, 1974). Sepsis may be fulminant and fatal. Pregnant women with a device in utero who demonstrate any evidence of pelvic infection are treated with intensive antimicrobial therapy and prompt uterine evacuation. Because of these risks, a woman should be given the option of early pregnancy termination if the device cannot be removed early in pregnancy. Last, in women who give birth with a device in place, appropriate steps should be taken at delivery to identify and remove the IUD.

Insertion

Timing

Immediately following miscarriage, surgical abortion, or delivery, an IUD may be inserted in the absence of infection. Also, Shimoni and colleagues (2011) describe “immediate” insertion 1 week after medical abortion. The risk of IUD expulsion is slightly higher if it is placed immediately following any of these recent pregnancies. That said, the advantages of preventing future unplanned pregnancies appear to outweigh this (Bednarek, 2011; Chen, 2010; Grimes, 2010a; Steenland, 2011).

Insertion techniques depend on uterine size. After first-trimester evacuation, the IUD can be placed using the manufacturer's standard instructions. If the uterine cavity is larger, the IUD can be placed using ring forceps with sonographic guidance (Stuart, 2012). Immediately following vaginal or cesarean delivery, an IUD can be placed by hand or with an instrument (Grimes, 2010b). To reduce expulsion rates and to minimize the perforation risk, some may choose to wait for complete involution—at least 6 weeks after delivery. Women delivered at Parkland Hospital are seen 3 weeks postpartum, and IUDs are inserted 6 weeks postpartum or sooner if involution is complete.

For placement not related to pregnancy, insertion near the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, may be easier and at the same time may exclude early pregnancy. But, insertion is not limited to this time. For the woman who is sure she is not pregnant and does not want to be pregnant, insertion is done at any time.

Technique

Before insertion, several procedural steps are carried out. Any contraindications are identified. If there are none, the woman is counseled and written consent obtained. An oral NSAID, with or without codeine, can be used to allay cramps (Karabayirli, 2012). Strong evidence does not support an advantage to supplemental misoprostol, intrauterine or cervical canal instillation of lidocaine, or paracervical blockade to lessen insertional pain (McNicholas, 2012; Nelson, 2013; Swenson, 2012). Bimanual pelvic examination is performed to identify uterine position and size. Abnormalities are evaluated, as they may contraindicate insertion. Mucopurulent cervicitis or significant vaginitis should be appropriately treated and resolved before IUD insertion.

The cervical surface is cleansed with an antiseptic solution, and sterile instruments and a sterile IUD should be used. A tenaculum is placed on the cervical lip, and the canal and uterine cavity are straightened by applying gentle traction. The uterus is then sounded to identify the direction and depth of the uterine cavity. Specific steps of ParaGard and Mirena insertion are shown in [Figures 38-2](#) and [38-3](#) and outlined in their respective package inserts.

Following insertion, only the threads should be visible trailing from the cervix. These are trimmed to allow 3 to 4 cm to protrude into the vagina, and their length is recorded. If there is suspicion that the device is not positioned correctly, then placement should be confirmed, using sonography if necessary.

FIGURE 38-2 Insertion of the *Mirena* intrauterine system. Initially, threads from behind the slider are first released to hang freely. The slider found on the handle should be positioned at the top of the handle nearest the device. The IUD arms are oriented horizontally. A flange on the outside of the inserter tube is positioned from the IUD tip to reflect the depth found with uterine sounding. **A.** As both free threads are pulled, the *Mirena* IUD is drawn into the inserter tube. The threads are then tightly fixed from below into the handle's cleft. In these depictions, the inserter tube has been foreshortened. The inserter tube is gently inserted into the uterus until the flange lies 1.5 to 2 cm from the external cervical os to allow the arms to open. **B.** While holding the inserter steady, the IUD arms are released by pulling the slider back to reach the raised horizontal mark on the handle, but no further. **C.** The inserter is then gently guided into the uterine cavity until its flange touches the cervix. **D.** The device is released by holding the inserter firmly in position and pulling the slider down all the way. The threads will be released automatically from the cleft. The inserter may then be removed, and IUD strings trimmed.

FIGURE 38-3 Insertion of *ParaGard T 380A*. The uterus is sounded, and the IUD is loaded into its inserter tube not more than 5 minutes before insertion. A blue plastic flange on the outside of the inserter tube is positioned from the IUD tip to reflect uterine depth. The IUD arms should lie in the same plane as the flat portion of the oblong blue flange. **A.** The inserter tube, with the IUD loaded, is passed into the endometrial cavity. A long, solid, white inserter rod abuts the base of the IUD. When the blue flange contacts the cervix, insertion stops. **B.** To release the IUD arms, the solid white rod within the inserter tube is held steady, while the inserter tube is withdrawn no more than 1 cm. **C.** The inserter tube, not the inserter rod, is then carefully moved upward toward the top of the uterus until slight resistance is felt. At no time during insertion is the inserter rod advanced forward. **D.** First, the solid white rod and then the inserter tube are withdrawn individually. At completion, only the threads should be visible protruding from the cervix. These are trimmed to allow 3 to 4 cm to extend into the vagina.

If the IUD is not positioned completely within the uterus, it is removed and replaced with a new device. An expelled or partially expelled device should not be reinserted.

LONG-ACTING REVERSIBLE CONTRACEPTION: PROGESTIN IMPLANTS

Etonogestrel Implant

Contraception can be provided by thin, pliable progestin-containing cylinders that are implanted subdermally and release hormone over many years. One of these, *Implanon* is a single-rod implant with 68 mg of etonogestrel covered by an ethylene vinyl acetate copolymer cover. The implant is placed subdermally on the medial surface of the upper arm 8 to 10 cm from the elbow in the biceps groove and is aligned with the long axis of the arm. It may be used as contraception for 3 years and then replaced at the same site or in the opposite arm (Merck, 2012a).

Implanon is not radiopaque, and a misplaced implant may be identified with sonography using a 10- to 15-MHz linear array transducer (Shulman, 2006). In some cases, MR imaging may be required if supplemental information is needed despite sonography (Correia, 2012). To improve radiologic detection, the manufacturer developed *Nexplanon*, which is similarly shaped and pharmacologically identical to *Implanon* but is radiopaque. Additionally, the *Nexplanon* inserter device is designed to assist with subdermal placement and avert deeper insertions. Both implants are highly effective, and the mechanism of action for progestin-only products is described on page 704 (Croxatto, 1998; Mommers, 2012). Although still approved by the Food and Drug Administration (FDA), *Implanon* is no longer distributed by the manufacturer.

Levonorgestrel Implants

The first progestin implants contained levonorgestrel, and systems are still available outside the United States. *Jadelle*, originally named *Norplant-2*, provides levonorgestrel and contraception for 5 years through two subdermally implanted Silastic rods. After this time, rods may be removed and if desired, new rods inserted at the same site (Bayer Schering Pharma Oy, 2010). *Jadelle* is approved by the FDA, however, it is not marketed or distributed in the United States (Population Council, 2013). Sino-implant II is a two-rod implant with the same amount (150 mg) of levonorgestrel and same mechanism of action as *Jadelle* but provides 4 years of contraception (Shanghai Dahua Pharmaceutical, 2012). Sino-implant II is manufactured in China and approved for use by several countries in Asia and Africa.

Both implant systems are highly effective, and the mechanism of action for progestin-only products is described on page 704. Like the etonogestrel implant, these systems are placed subdermally on the inner arm approximately 8 cm from the elbow and have similar removal steps. Implants vary regarding their insertion technique, and manufacturer instructions should be consulted.

The forerunner of these implants was the *Norplant System*, which provided levonorgestrel in six Silastic rods implanted subdermally. The manufacturer stopped distributing the system in 2002.

Method-Specific Adverse Effects

Risks that are specific to implants stem mainly from malpositioning. First, branches of the medial antebrachial cutaneous nerve can be injured if the implant or insertion needle is placed too deeply or if exploration for a lost implant is aggressive. Clinically, numbness and paresthesia over the anteromedial aspect of the forearm are noted (Brown, 2012; Wechselberger, 2006). Second, nonpalpable devices are not uncommon and may require radiological imaging for localization as described earlier. If imaging fails to locate an *Implanon* or *Nexplanon* implant, etonogestrel blood level determination can be used to verify that the implant is in situ.

Insertion

Timing

For those not currently using hormonal contraception, the etonogestrel implant is ideally inserted within 5 days of menses onset. If inserted later in the cycle, then alternative contraception is recommended for 7 days following placement. With levonorgestrel-releasing implants, contraception is established within 24 hours if inserted within the first 7 days of the menstrual cycle (Sivin, 1997; Steiner, 2010). For transitioning methods, an implant is placed on the day of the first placebo COC pill; on the day that the next DMPA injection would be due; or within 24 hours of taking the last POP (Merck, 2012a). Related to pregnancy, an implant may be inserted before discharge following delivery, miscarriage, or abortion.

Nexplanon Insertion Technique

With the patient lying down, her nondominant arm, forearm, and hand are outstretched on the bed with the inner aspects of each exposed upward, and the elbow is flexed. The insertion site is marked with a sterile pen 8 to 10 cm proximal to the medial condyle of the humerus. A second mark is placed 4 centimeters proximally and delineates the final path of the implant. The *Nexplanon* is inserted using sterile technique. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected beneath the skin along the planned insertion path. The implant is then placed as shown in [Figure 38-4](#). After placement, both patient and provider should palpate and identify both ends of the 4-cm implant. To minimize bruising at the site, a pressure bandage is created around the arm and is removed the following day.

With sterile implant removal, the proximal end of the implant is depressed with a finger to allow the distal end to bulge toward the skin. After anesthetizing the skin over this bulge, the skin is incised 2 mm toward the elbow along the long axis of the arm. The proximal butt of the implant is then pushed toward this incision. Once visible, the distal implant is grasped with a hemostat and removed. If present, superficial

FIGURE 38-4 Nexplanon insertion. A sterile pen marks the insertion site, which is 8 to 10 cm proximal to the medial humeral condyle. A second mark is placed 4 cm proximally along the arm's long axis. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected along the planned insertion path. **A.** The insertion device is grasped at its gripper bubbles found on either side, and the needle cap is removed outward. The device can be seen within the needle bore. The needle bevel then pierces the skin at a 30-degree angle. **B.** Once the complete bevel is subcutaneous, the needle is quickly angled downward to lie horizontally. **C.** Importantly, the skin is tented upward by the needle as the needle is slowly advanced horizontally and subdermally. **D.** Once the needle is completely inserted, the lever on the top of the device is pulled backward toward the operator. This retracts the needle and thereby deposits the implant. The device is then lifted away from the skin. After placement, both patient and operator should palpate the 4-cm implant.

adhesions surrounding an implant may be dissected away with hemostat tips placed into the incision.

PROGESTIN-ONLY CONTRACEPTIVE GROUP

■ Actions and Side Effects

Progestin-only contraceptives include the implants just described, pills, and injectables. As their primary contraceptive action, these progestins suppress luteinizing hormone (LH) and in turn block ovulation. As other effects, cervical mucus is thickened to retard sperm passage, and atrophy renders the endometrium unfavorable for implantation. Fertility is restored rapidly following cessation of progestin-only contraception, with the exception of DMPA as described on page 711 (Mansour, 2011).

For all progestin-only methods, irregular uterine bleeding is a distinct disadvantage. It may manifest as metrorrhagia or menorrhagia and is the most frequently reported adverse event leading to method discontinuation. Often, counseling and reassurance regarding this effect is sufficient. Particularly troublesome bleeding may be improved by one to two cycles of COCs, by a 1- to 3-week course of estrogen alone, or by a short course of NSAIDs combined with the established method. Fortunately, with prolonged use, progestins induce endometrial atrophy, which leads to sustained amenorrhea. And, for the well-counseled patient, this is often an advantage.

Most progestin-only contraceptive methods do not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, and blood pressure (Dorflinger, 2002). Moreover, these have not been shown to increase the risk for thromboembolism, stroke, or cardiovascular disease (Mantha, 2012; World Health Organization, 1998). However, as described on page 711, the increased low-density lipoprotein (LDL) cholesterol and decreased high-density lipoprotein (HDL) cholesterol levels seen with DMPA may be less desirable if there are cardiac or vascular risks.

Progestin-only methods do not impair milk production and are an excellent choice for lactating women. There are no increased risks of genital tract or breast neoplasia (Wilailak, 2012; World Health Organization, 1991a,b, 1992). Weight gain and bone mineral density loss are not prominent side effects of this contraceptive group, except for DMPA, as noted on page 711 (Funk, 2005; Lopez, 2011). Functional ovarian cysts develop with a greater frequency in women using progestin-only agents, although they do not usually necessitate intervention (Brache, 2002; European Society of Human Reproduction and Embryology, 2001). Last, an association between depression and DMPA or POPs is unclear (Civic, 2000; Svendal, 2012; Westhoff, 1995). Women with depression may be prescribed these methods, but surveillance following initiation is reasonable.

■ Contraindications to Progestin-Only Contraceptives

These methods are ideal for most women, but contraindications and cautions are associated with a few conditions. Current breast cancer and pregnancy are the only two absolute contraindications. However, conditions for which limited and cautious use should be considered are listed in Table 38-3.

There are a few instances in which manufacturer restrictions differ from the US MEC. First, manufacturer prescribing information lists thrombosis or thromboembolic disorders as contraindications (Merck, 2012a; Pfizer, 2012). However, for individuals with these disorders, US MEC considers progestin-containing methods category 2. Second, for many progestin products, manufacturers note prior ectopic pregnancy as a contraindication. This is secondary to progesterone's effect to slow fallopian tube motility and thereby delay fertilized egg transport to the endometrial cavity. But again, US MEC considers progestin injectables and implants category 1, and progestin-only pills are category 2 for those with prior ectopic pregnancy.

VERY EFFECTIVE CONTRACEPTION: HORMONAL CONTRACEPTIVES

These currently are available in forms that contain both estrogen and progestin or contain only progestin. Progestin-only injectables and pills are considered very effective, yet second-tier agents, due to the need for increased patient compliance. Similarly, products containing both estrogen and progestin, often termed combination hormonal contraception (CHC), are considered in this tier. These may be supplied as pills, transvaginal rings, or transdermal patches.

Combination Hormonal Contraceptives Mechanism of Action

The contraceptive actions of CHCs are multiple, but the most important effect is suppression of hypothalamic gonadotropin-releasing factors. This in turn blocks pituitary secretion of follicle-stimulating hormone (FSH) and LH to inhibit ovulation. The progestin component provides ovulation prevention by suppressing LH; they thicken cervical mucus and thereby retard sperm passage; and they render the endometrium unfavorable for implantation. Estrogen blocks ovulation by suppressing FSH release. It also stabilizes the endometrium, which prevents intermenstrual bleeding—also known as *breakthrough bleeding*. The net effect is an extremely effective yet highly reversible method (Mansour, 2011).

Combination Oral Contraceptive Pills

Composition

Combination oral contraceptive pills are the most frequently used birth control method in the United States. In a 2006 to 2010 survey, 17 percent of US women were using these (Jones, 2012). COCs are marketed in an almost bewildering variety (Table 38-4). Most are also available as generics, and the FDA (2013) confirms the bioequivalence of COC generics. The American College of Obstetricians and Gynecologists (2013b) supports the use of either branded or generic preparations.

Pharmacologically, ethinyl estradiol is the most common estrogen present in COC formulations in the United States. Less frequently, mestranol or estradiol valerate is used. Unwanted effects most often attributed to the estrogen component include breast tenderness, fluid retention, weight gain, nausea, and headache.

COCs also contain one of several progestins that are structurally related to progesterone, testosterone, or spironolactone. Thus, these progestins bind variably to progesterone, androgen, estrogen, glucocorticoid, and mineralocorticoid receptors. These affinities explain many pill-related side effects and are often used to compare one progestin with another.

Most progestins used in COCs are related to testosterone and may impart androgenic side effects such as acne and adverse HDL and LDL levels. To avoid these effects, progestins more structurally similar to the progesterone molecule have been developed. Medroxyprogesterone acetate is one example, but it is mainly used in a progestin-only injectable form. Another, norgestrel acetate, is used in a COC approved outside the

United States. Despite these pharmacological differences, the true advantage of one progestin over another is less apparent clinically (Lawrie, 2011; Moreau, 2007).

Another progestin, drospirenone, is structurally similar to spironolactone. The doses used in currently marketed COCs have effects similar to 25 mg of this diuretic hormone (Seeger, 2007). Drospirenone displays antiandrogenic activity, provides an antialdosterone action to minimize water retention, and has antimineralocorticoid properties that may, in theory, cause potassium retention and hyperkalemia (Krattenmacher, 2000). Thus, it is avoided in women with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, serum potassium level monitoring is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention. These include NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists, heparin, aldosterone antagonists, and potassium-sparing diuretics (Bayer HealthCare Pharmaceuticals, 2012).

Since the development of COCs, their estrogen and progestin content has dropped remarkably to minimize adverse effects. Currently, the lowest acceptable dose is limited by the ability to prevent pregnancy and to avoid unacceptable breakthrough bleeding. Thus, the daily estrogen content varies from 10 to 50 µg of ethinyl estradiol, and most contain 35 µg or less.

With COCs termed *monophasic pills*, the progestin dose remains constant throughout the cycle. In others, the dose frequently is varied, and terms *biphasic*, *triphasic*, or *quadriphasic pill* are used depending on the number of dose changes within the cycle. In some formulations, the estrogen dose also varies. In general, phasic pills were developed to reduce the total progestin content per cycle without sacrificing contraceptive efficacy or cycle control. The theoretical advantage of a lower total progesterone dose per cycle has not been borne out clinically (Moreau, 2007). Cycle control also appears to be comparable among mono- through triphasic pills (van Vliet, 2006, 2011a,b).

Administration

Hormones are taken daily for a specified time (21 to 81 days) and then replaced by placebo for a specified time (4 to 7 days), which is called the “pill-free interval.” During these pill-free days, withdrawal bleeding is expected.

With the trend to lower estrogen doses to minimize side effects, there is concern for follicular development and ovulation. To counter this, the active-pill duration in some formulations is extended to 24 days. And, these 24/4 regimens do appear to reduce ovulation and breakthrough bleeding rates (Fels, 2013).

Alternatively, longer durations of active hormone, designed to minimize the number of withdrawal episodes, have been introduced (Edelman, 2006). These extended-cycle products produce a 13-week cycle, that is, 12 weeks of hormone use, followed by a week for withdrawal menses. The product *Amethyst* provides continuous active hormone pills for 365 days each year. Such extended or continuous regimens may be especially suited for women with significant menstrual symptoms.

EE = ethinyl estradiol; EV = estradiol valerate; LC = levomefolate calcium; Mes = mestranol.

^aAdministered for 21 days, variations listed in parentheses.

^b0.451 mg of levomefolate calcium, which is a form of folic acid, is found in each pill.

^cContains or is available in formulas that contain 75-mg doses of ferrous fumarate within the placebo pills.

^d12 weeks of active pills, 1 week of inert pills.

^e12 weeks of active pills, 1 week of ethinyl estradiol only.

^fOne pill every day, 365 days each year.

Compiled from US Food and Drug Administration, 2013.

For general initiation, women should ideally begin COCs on the first day of a menstrual cycle. In such cases, a supplementary contraceptive method is unnecessary. With the more traditional “Sunday start,” women begin pills on the first Sunday that follows menses onset, and an additional method is needed for 1 week to prevent conception. If menses begin on a Sunday, then pills are begun that day and no supplementary method is required. Alternatively, with the “Quick Start” method, COCs are started on any day, commonly the day prescribed, regardless of cycle timing. An additional method is used during the first week. This latter approach improves short-term compliance (Westhoff, 2002, 2007b). If the woman is already pregnant during Quick Start initiation, COCs are not teratogenic (Lammer, 1986; Rothman, 1978; Savolainen, 1981). Similarly, same-day initiation can be implemented with the contraceptive vaginal ring or patch (Murthy, 2005; Schafer, 2006).

For maximum efficiency, pills should be taken at the same time each day. If one dose is missed, contraception is likely not diminished with higher-dose monophasic COCs. Doubling the next dose will minimize breakthrough bleeding and maintain the pill schedule. If several doses are missed or if lower-dose pills are used, the pill may be stopped, and an effective barrier technique used until menses. The pill may then be restarted. Alternatively, a new pack can be started immediately following identification of missed pills, and a barrier method used for 1 week. If there is no withdrawal bleeding, the woman should continue her pills but seek attention to exclude pregnancy.

With initiation of COCs, spotting or bleeding is common. It does not reflect contraceptive failure and typically resolves within one to three cycles. If unscheduled bleeding persists, those with bleeding during the first part of a pill pack may

benefit from an increase in the pill’s estrogen dose, whereas those with bleeding during the second part may improve with a higher progestin dose (Nelson, 2011).

■ **Method-Specific Effects**

Altered Drug Efficacy

Combination oral contraceptives interfere with the actions of some drugs. In such cases, doses can be adjusted as shown in Table 38-5. Conversely, some drugs decrease the COC effectiveness. Three groups are notable: the antitubercular drugs rifampin and rifabutin; efavirenz and ritonavir-boosted protease inhibitors, which are used to treat HIV infection; and enzyme-inducing anticonvulsants, which include phenytoin (Dilantin), carbamazepine (Tegretol), oxcarbazepine (Trileptal), barbiturates, primidone (Mysoline), and topiramate (Topamax) (Gaffield, 2011; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). With these, a method other than COCs is preferable. However, if a COC is selected for concurrent use with an agent from these three groups, then a preparation containing a minimum of 30 µg ethinyl estradiol should be chosen.

In obese women, COCs are highly effective (Lopez, 2010). That said, some but not all studies point to a potential increased pregnancy risk with COC use due to lowered hormone bioavailability (Brunner, 2005; Holt, 2002, 2005; Westhoff, 2010). With the transdermal patch method, however, there is stronger evidence that obesity may alter pharmacokinetics and lower efficacy (p. 701).

Metabolic Changes

Although their effects on carbohydrate metabolism are considered clinically insignificant, COCs do have notable effects on lipid and protein synthesis. In general, COCs increase serum levels of triglycerides and total cholesterol. Estrogen decreases LDL cholesterol concentrations but increases HDL and very-low density (VLDL) cholesterol levels. Some progestins cause the reverse. Despite this, the clinical consequences of these perturbations have almost certainly been overstated. Oral contraceptives are not atherogenic, and their impact on lipids is inconsequential for most women (Wallach, 2000). But in women with dyslipidemias, the American College of Obstetricians and Gynecologists

TABLE 38-5. Drugs Whose Effectiveness Is Influenced by Combination Oral Contraceptives

Interacting Drug	Documentation	Management
Analgesics		
Acetaminophen	Adequate	Larger doses of analgesic may be required
Aspirin	Probable	Larger doses of analgesic may be required
Meperidine	Suspected	Smaller doses of analgesic may be required
Morphine	Probable	Larger doses of analgesic may be required
Anticoagulants		
Dicumarol, warfarin	Controversial	
Anticonvulsant		
Lamotrigine monotherapy	Adequate	Avoid
Antidepressants		
Imipramine	Suspected	Decrease dosage about a third
Tranquilizers		
Diazepam, alprazolam	Suspected	Decrease dose
Temazepam	Possible	May need to increase dose
Other benzodiazepines	Suspected	Observe for increased effect
Anti-inflammatories		
Corticosteroids	Adequate	Watch for potentiation of effects, decrease dose accordingly
Bronchodilators		
Aminophylline, caffeine, theophylline	Adequate	Reduce starting dose by a third
Antihypertensives		
Cyclopenthiazine	Adequate	Increase dose
Metoprolol	Suspected	May need to lower dose
Antibiotics		
Troleandomycin	Suspected liver damage	Avoid
Cyclosporine	Possible	May use smaller dose

Modified from Gaffield, 2011; Wallach, 2000.

(2013e) recommends assessment of lipid levels following COC initiation. Moreover, for women with LDL cholesterol levels > 160 mg/dL or for those with multiple additional risk factors for cardiovascular disease, alternative contraceptive methods are recommended.

With COCs, protein metabolism is affected, and estrogens prompt increased hepatic production of various globulins. First, fibrinogen and many of the clotting factor levels are increased in direct proportion to estrogen dose and may lead to thrombosis (Comp, 1996). Angiotensinogen production is also augmented by COCs, and its conversion by renin to angiotensin I may be associated with “pill-induced hypertension” discussed subsequently. Last, COCs increase sex-hormone binding globulin (SHBG) levels, which decrease bioavailable testosterone concentrations and improve androgenic side effects.

Regarding carbohydrate metabolism, there are fortunately limited effects with current low-dose formulations in women who do not have diabetes (Lopez, 2012a). And, the risk of developing diabetes is not increased (Kim, 2002). Moreover, COCs may be used in nonsmoking, diabetic women younger than 35 years who have no associated vascular disease (American College of Obstetricians and Gynecologists, 2013e). Last, studies have not supported a connection between COCs and weight gain (Gallo, 2011).

Other metabolic changes, often qualitatively similar to those of pregnancy, have been identified in women taking oral contraceptives. For example, total plasma thyroxine (T_4) and thyroid-binding proteins are elevated. These pregnancy-like effects should be considered when evaluating laboratory tests in women using COCs.

Cardiovascular Effects

Despite increased plasma angiotensinogen (renin substrate) levels, most women using low-dose COCs formulations rarely develop clinically significant hypertension (Chasan-Taber, 1996). However, it is common practice for patients to return 8 to 12 weeks after COC initiation for evaluation of blood pressure and other symptoms.

During initial contraception selection, a history of gestational hypertension does not preclude subsequent COC use. Also, COCs are permissible in women with well-controlled uncomplicated hypertension who are nonsmokers, otherwise healthy, and younger than 35 (American College of Obstetricians and Gynecologists, 2013e). In contrast, severe forms of hypertension, especially those with end-organ involvement, usually preclude COC use.

For women with prior stroke, COCs should not be considered due to risks for repeat events. The risk for a first stroke is substantially increased in women who have hypertension, who smoke, or who have migraine headaches with visual aura or other focal neurological changes *and* use oral contraceptives (MacClellan, 2007). However, for nonsmoking women younger than 35, the risk of ischemic and hemorrhagic strokes is extremely low, and method benefits considerably outweigh risks (World Health Organization, 1996, 1998). Moreover, because of this low risk, the American College of Obstetricians and Gynecologists (2013e) notes that COCs may be considered for women with migraines that lack focal neurological signs if they are otherwise healthy, normotensive nonsmokers younger than 35 years.

For women with prior myocardial infarction, COCs should not be considered. Also, in women with multiple cardiovascular risk factors, which include smoking, hypertension, older age, and diabetes, the risk for myocardial infarction outweighs the benefits of this method. However, for those without these risks, low-dose oral contraceptives are not associated with an increased risk of myocardial infarction (Margolis, 2007; World Health Organization, 1997).

It has long been known that the risk of deep-vein thrombosis and pulmonary embolism is increased in women who use COCs (Stadel, 1981). These clearly are estrogen-dose related, and rates have substantively decreased with lower-dose formulations containing 10 to 35 μ g of ethinyl estradiol. The incidence of venous thromboembolism (VTE) with COC use is only 3 to 4 per 10,000 woman-years and is lower than the incidence of 5 to 6 per 10,000 woman-years estimated for pregnancy (Chap. 52, p. 1028) (Mishell, 2000). The enhanced risk of VTE appears to decrease rapidly once COCs are stopped. And because these complications are increased in women smokers older than 35 years, COCs are not recommended for this population (Craft, 1989).

Those most at risk for VTE include women with thrombophilias (Comp, 1996). Other clinical factors that increase the risk of VTE with COC use are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Pomp, 2007, 2008). Moreover, COC use during the month before a major operative procedure appears to double the risk for postoperative VTE (Robinson, 1991). Thus, the American College of Obstetricians and Gynecologists (2013d) recommends balancing the risks of VTE with those of unintended pregnancy during the 4 to 6 weeks required to reverse the thrombogenic effects of COCs before surgery. In the early puerperium, VTE risks are also increased, and COCs are not recommended for women within the first 4 weeks after delivery. For all women, an increased VTE risk with drospirenone-containing COCs has been shown in two studies. Accordingly, the FDA has encouraged an assessment of benefits and VTE risks in users of these pills (Food and Drug Administration, 2011; Jick, 2011; Parkin, 2011).

Neoplasia

Fortunately, most studies indicate that overall, COCs are not associated with an increased risk of cancer (Hannaford, 2007). In fact, a protective effect against ovarian and endometrial cancer has been shown (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Tsilidis, 2011). Protection from these cancers decreases, however, as time from pill use lengthens (Tworoger, 2007). In contrast, the relative risk of cervical dysplasia and cervical cancer is increased in current COC users, but this declines after use is discontinued. Following 10 or more years, risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007).

Although COC use in the past was linked to development of hepatic *focal nodular hyperplasia* and *benign hepatic adenoma*, large studies do not support this (Heinemann, 1998). Moreover, there is also no evidence for increased risk of hepatocellular cancer (Maheshwari, 2007). For women with known tumors, COCs may be used in those with focal

nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009b). Rates of colorectal cancer appear to be reduced in ever users (Bosetti, 2009; Kabat, 2008).

It is unclear whether COCs contribute to the development of breast cancer, and major studies show no risk or a small risk among current users, which drops with time following cessation (Collaborative Group on Hormonal Factors in Breast Cancer, 1996; Marchbanks, 2002). In women who are carriers of the *BRCA1* or *BRCA2* gene mutation, risks for breast cancer are not increased by COC use (Brohet, 2007; Iodice, 2010). With regard to benign breast disease, COCs appear to lower rates (Vessey, 2007).

Other Effects

As summarized in Table 38-6, many noncontraceptive benefits are associated with COC use (American College of Obstetricians and Gynecologists, 2012c). And indeed, COCs may be used for these effects, even in those without contraceptive needs.

Low-dose estrogen formulations are not associated with depression or premenstrual mood changes and may actually improve the latter (Joffe, 2007). This is especially true with the drospirenone-containing COCs. Several studies have shown symptom improvement in women with premenstrual dysphoric disorder (PMDD) who use the drospirenone-containing COC *Yaz* (Lopez, 2012b; Pearlstein, 2005; Yonkers, 2005). And, the FDA has approved indications for this pill to include treatment of PMDD and moderate acne vulgaris for women requesting oral contraception.

Cholestasis and cholestatic jaundice are uncommon, but they resolve when COCs are discontinued. For women who have active hepatitis, COCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking COCs. Use of progestin-only contraception in these women is not restricted. Moreover, there is no reason to withhold COCs from women who have recovered. With cirrhosis, mild compensated disease does not limit the use of COCs or progestin-only methods. However, in those with severe decompensated disease, all hormonal methods should be avoided (Kapp, 2009a).

TABLE 38-6. Some Benefits of Combined Estrogen Plus Progestin Oral Contraceptives
Increased bone density
Reduced menstrual blood loss and anemia
Decreased risk of ectopic pregnancy
Improved dysmenorrhea from endometriosis
Fewer premenstrual complaints
Decreased risk of endometrial and ovarian cancer
Reduction in various benign breast diseases
Inhibition of hirsutism progression
Improvement of acne
Prevention of atherogenesis
Decreased incidence and severity of acute salpingitis
Decreased activity of rheumatoid arthritis

The progestin component of COCs reduces serum free testosterone levels and inhibits 5 α -reductase to limit conversion of testosterone to its active metabolite, dihydrotestosterone. The estrogen component increases SHBG production and also lowers circulating androgen levels. The expected results of these actions are to improve androgenic conditions such as acne and hirsutism.

Hyperpigmentation of the face and forehead—chloasma—is more likely in women who demonstrated such a change during pregnancy. This is less common with low-dose estrogen formulations. Cervical mucorrhea, likely due to cervical ectopy, is common in response to the estrogen component of COCs (Critchlow, 1995). Although previously used for treating functional ovarian cysts, low-dose COC formulations have no effects related to cyst resolution or prevention (European Society of Human Reproduction and Embryology, 2001; Grimes, 2011).

Transdermal Patch

The *Ortho Evra* patch is another combination hormonal contraceptive formulation. It has an inner layer containing an adhesive and hormone matrix, and a water-resistant outer layer. Thus, women can wear the patch in bathtubs, showers, swimming pools, saunas, and whirlpools without decreased efficacy. The patch may be applied to buttocks, upper outer arm, lower abdomen, or upper torso, but the breasts are avoided. Because the hormones are combined with the adhesive, improper skin adherence will lower hormone absorption and efficacy. Therefore, if a patch is so poorly adhered that it requires reinforcement with tape, it should be replaced.

Initiation of the patch is the same as for COCs, and a new patch is applied weekly for 3 weeks, followed by a patch-free week to allow withdrawal bleeding. Although a patch is ideally worn no longer than 7 days, hormone levels remain in an effective range for up to 9 days. This affords a 2-day window for patch change delays (Abrams, 2001).

In general, the transdermal patch and vaginal ring produce metabolic changes, side effects, and efficacy rates comparable to those with COC pills. However, the patch has been associated with a higher VTE risk in some but not other studies (Cole, 2007; Jick, 2010; Lidegaard, 2012). And despite this lack of convincing association, the FDA (2008) ordered labeling for the patch to state that users *may* be at increased risk for developing VTE. Obesity—90 kg or greater—may be associated with an increased risk for patch contraceptive failure (Zieman, 2002). Last, application-site reaction and breast tenderness are more frequent during initial cycles in patch wearers (Urdl, 2005).

Transvaginal Ring

The *NuvaRing* is yet another form of combination hormonal contraception and is a flexible intravaginal ring. Constructed of ethinyl vinyl acetate, the ring measures 54 mm in diameter and 4 mm in cross section (Fig. 38-5). During insertion, the ring is compressed and threaded into the vagina, but no specific final intravaginal position is required. Its core releases ethinyl estradiol and the progestin etonogestrel, which are absorbed across the vaginal epithelium. Before being dispensed, the

FIGURE 38-5 NuvaRing: estrogen-progestin—releasing vaginal contraceptive ring.

rings are refrigerated, and once dispensed, their shelf life is 4 months. The ring is placed within 5 days of menses onset and after 3 weeks of use, is removed for 1 week to allow withdrawal bleeding. Contraception will still be afforded if a ring is left in place for a fourth week (Merck, 2012b).

Patient satisfaction is high with this method, although vaginitis, ring-related events, and leukorrhea are more common (Oddsson, 2005). Despite this, no deleterious affect on vaginal flora or on lower reproductive-tract or endometrial epithelia has been found (Bulten, 2005; Veres, 2004). Approximately 70 percent of partners feel the ring during intercourse (Dieben, 2002). If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours to maintain efficacy.

■ Injectable Progestin Contraceptives

Both intramuscular depot medroxyprogesterone acetate (Depo-Provera), 150 mg every 3 months, and norethisterone enanthate, 200 mg every 2 months, are injectable progestin contraceptives that have been effectively used worldwide for years. Available in the United States, DMPA is injected into the deltoid or gluteus muscle, but massage is avoided to ensure that the drug is released slowly. Alternatively, a subcutaneous version, *depo-subQ provera 104*, is also available and is injected into the subcutaneous tissue of the anterior thigh or abdomen every 3 months.

DMPA is an effective method, and as with other progestin-only methods, contraception is provided by ovulation inhibition, increased cervical mucus viscosity, and creation of an endometrium unfavorable for ovum implantation. Initial injection is given within the first 5 days following menses onset. Therapeutic serum levels sufficient to exert a consistent contraceptive effect are observed by 24 hours. Thus, no additional contraceptive method is required with initiation within this window. Alternatively, limited data support a “Quick Start” or initiation of DMPA regardless of cycle day. If so implemented, investigators recommend an initial negative pregnancy test result before injection, a supplemental contraceptive method

during the 7 days following injection, and a second pregnancy test after 3 to 6 weeks to identify an early pregnancy (Rickert, 2007; Sneed, 2005). Fortunately, pregnancies conceived during DMPA use are not associated with an increased risk of fetal malformation (Katz, 1985). For women who present for intramuscular DMPA reinjection more than 13 weeks or subcutaneous DMPA reinjection more than 14 weeks after the prior dose, the manufacturer recommends exclusion of pregnancy before reinjection (Pfizer, 2010, 2012).

Actions and Side Effects

Injected progestins offer the convenience of a 3-month dosing schedule, contraceptive effectiveness comparable with or better than COCs, and minimal to no lactation impairment. Iron deficiency anemia is less likely in long-term users because of amenorrhea, which develops in up to 50 percent after 1 year and in 80 percent after 5 years.

Similar to other progestin-only contraceptive, irregular menstrual bleeding is common, and a fourth of women discontinued DMPA in the first year because of this (Cromer, 1994). Unique to DMPA, prolonged anovulation can follow discontinuation, which results in delayed fertility resumption. After injections are stopped, one fourth of patients do not resume regular menses for up to 1 year (Gardner, 1970). Accordingly, DMPA may not be ideal for women who plan to use birth control only briefly before attempting conception.

As with other progestins, DMPA has not been associated with cardiovascular events or stroke in otherwise healthy women. However, in those with severe hypertension, an increased risk of stroke has been found in DMPA users (World Health Organization, 1998). Moreover, the US MEC expresses concerns regarding hypoestrogenic effects and reduced HDL levels from DMPA in women with vascular disease or multiple risks for cardiovascular disease.

Weight gain is generally attributed to DMPA, and these increases are comparable between the two depot forms (Bahamondes, 2001; Nault, 2013; Westhoff, 2007c). In long-term users, loss of bone mineral density is also a potential problem (Petitti, 2000; Scholes, 1999). In 2004, the FDA added a black box warning to DMPA labeling, which notes that this concern is probably most relevant for adolescents, who are building bone mass, and perimenopausal women, who will soon have increased bone loss during menopause. That said, it is the opinion of the World Health Organization (1998) and American College of Obstetricians and Gynecologists (2008) that DMPA should not be restricted in those high-risk groups. And, it seems prudent to reevaluate overall risks and benefits during extended use (d’Arcangues, 2006).

It is somewhat reassuring that bone loss appears to be reversible after discontinuation of therapy but is still not complete after 18 to 24 months (Clark, 2006; Gai, 2011; Scholes, 2002).

■ Progestin-Only Pills

So-called *mini-pills* are progestin-only contraceptives that are taken daily. These contraceptives have not achieved widespread popularity and are used by only 0.4 percent of American

women (Hall, 2012). Unlike COCs, they do not reliably inhibit ovulation. Rather, their effectiveness depends more on cervical mucus thickening and endometrial atrophy. Because mucus changes are not sustained longer than 24 hours, mini-pills should be taken at the same time every day to be maximally effective. If a progestin-only pill is taken even 4 hours late, a supplemental form of contraception must be used for the next 48 hours. Progestin-only pills are contraindicated in women with known breast cancer or pregnancy. Other cautions are listed in Table 38-3.

EFFECTIVE CONTRACEPTION: BARRIER METHODS

Male Condom

For many years, male and female condoms, vaginal diaphragms, and periodic abstinence have been used for contraception with variable success (see Table 38-2). The contraceptive efficacy of the male condom is enhanced appreciably by a reservoir tip and probably by the addition of a spermicide. Such agents, as well as those used for lubrication, should be water-based because oil-based products destroy latex condoms and diaphragms.

When used properly, condoms provide considerable but not absolute protection against a broad range of STDs. These include gonorrhea, syphilis, trichomoniasis, and HIV, herpetic, and chlamydial infections.

For individuals sensitive to latex, condoms made from lamb intestines are effective, but they do not provide infection protection. Fortunately, nonallergenic condoms have been developed that are made of polyurethane or of synthetic elastomers. Polyurethane condoms are effective against STDs but have a higher breakage and slippage rate than latex condoms (Gallo, 2006).

Female Condom

The only female condom available is marketed as the *FC2 Female Condom*. It is a synthetic nitrile sheath with one flexible polyurethane ring at each end. Its open ring remains outside the vagina, whereas its closed internal ring is fitted under the symphysis like a diaphragm (Fig. 38-6). The female condom can be used with both water-based and oil-based lubricants. Male condoms should not be used concurrently because simultaneous use may cause friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills. As an added value, in vitro tests have shown the female condom to be impermeable to HIV and other STDs.

Diaphragm Plus Spermicide

The diaphragm consists of a circular latex dome of various diameters supported by a circumferential latex-covered metal spring. It is effective when used in combination with spermicidal jelly or cream. The spermicide is applied into the dome cup and along the rim. The device is then positioned so that the cup faces the cervix and so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. In this fashion, the centrally placed spermicide is held against the cervix. When appropriately positioned, one rim is lodged deep in the posterior vaginal fornix, and the opposite rim fits behind the inner surface of the symphysis and immediately below the urethra (Fig. 38-7). If a diaphragm is too small, it will not remain in place. If it is too large, it is uncomfortable when forced into position. A coexistent cystocele or uterine prolapse typically leads to instability and expulsion. Because size and spring flexibility must be individualized, the diaphragm is available only by prescription.

FIGURE 38-6 FC2 Female Condom insertion and positioning. **A.** The inner ring is squeezed for insertion. The sheath is inserted similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

FIGURE 38-7 A diaphragm in place creates a physical barrier between the vagina and cervix.

With use, the diaphragm and spermicide can be inserted hours before intercourse, but if more than 6 hours elapse, additional spermicide should be placed in the upper vagina for maximum protection and be reapplied before each coital episode. The diaphragm should not be removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the next morning, to minimize this rare event. Diaphragm use is associated with a slightly increased rate of urinary infections, presumably from urethral irritation by the ring under the symphysis.

Cervical Cap

FemCap is currently the only available cervical cap in the United States. Made of silicone rubber, it has a sailor-cap shape with a dome that covers the cervix and a flared brim, which allows the cap to be held in place by the muscular walls of the upper vagina. Available in 22-, 26-, and 30-mm sizes, it should be used with a spermicide applied once at insertion to both sides of the dome cup. For contraception, it should remain in place for 6 hours following coitus and may remain for up to 48 hours. Even with proper fitting and correct use, pregnancy rates with this method are higher than with the diaphragm (Gallo, 2002; Mauck, 1999).

Fertility Awareness-Based Methods

All of these family planning methods attempt to identify the fertile days each cycle and advise sexual abstinence during these days. However, their limited efficacy is shown in Table 38-2. Common forms of these fertility awareness-based (FAB) methods include Standard Days, Calendar Rhythm, Temperature Rhythm, Cervical Mucus, and Symptothermal Methods.

The *Standard Days Method* counsels women to avoid unprotected intercourse during cycle days 8 through 19. For

successful use, women must have regular monthly cycles of 26 to 32 days. Those who use this method can mark a calendar or can use *Cycle-Beads*, which is a ring of counting beads, to keep track of their days.

The *Calendar Rhythm Method* requires counting the number of days in the shortest and longest menstrual cycle during a 6- to 12-month span. From the shortest cycle, 18 days are subtracted to calculate the first fertile day. From the longest cycle, 11 days are subtracted to identify the last fertile day. This is problematic because ovulation most often occurs 14 days before the onset of the next menses. Because this is not necessarily 14 days after the onset of the last menses, the calendar rhythm method is not reliable.

The *Temperature Rhythm Method* relies on slight changes—sustained 0.4°F increases—in the basal body temperature that usually occur just before ovulation. This method is much more likely to be successful if during each menstrual cycle, intercourse is avoided until well after the ovulatory temperature rise. For this method to be most effective, the woman must abstain from intercourse from the first day of menses through the third day after the temperature increase.

The *Cervical Mucus Method*, also called the Two-Day Method or Billings Method, relies on awareness of vaginal “dryness” and “wetness.” These reflect changes in the amount and quality of cervical mucus at different times in the menstrual cycle. With the Billings Method, abstinence is required from the beginning of menses until 4 days after slippery mucus is identified. With the Two-Day method, intercourse is considered safe if a woman did not note mucus on the day of planned intercourse or the day prior.

The *Symptothermal Method* combines changes in cervical mucus—onset of fertile period; changes in basal body temperature—end of fertile period; and calculations to estimate the time of ovulation. This method is more complex to learn and apply, but it does not appreciably improve efficacy.

LESS EFFECTIVE CONTRACEPTION: SPERMICIDES

These contraceptives are marketed variously as creams, jellies, suppositories, films, and aerosol foam. They are especially useful for women who need temporary protection, for example, during the first week after starting COCs. Most can be purchased without a prescription.

Typically, spermicides function by providing a physical barrier to sperm penetration and a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Although these are spermicidal, they do not provide STD protection. Ideally, spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal effectiveness is usually no more than 1 hour, and thereafter, they must be reinserted before repeat intercourse. Douching should be avoided for at least 6 hours after coitus.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, they are considered a less effective method (see Table 38-2). Fortunately, if pregnancy does occur, they are not considered teratogenic (Briggs, 2011).

FIGURE 38-8 *Today* sponges. The sponge is moistened with tap water and gently squeezed to create light suds. It is then positioned with the dimple directly against the cervix. The fabric loop trails within the vagina and can be hooked with a finger to later extract the sponge.

Contraceptive Sponge

The *Today* contraceptive sponge is an over-the-counter, one-size-fits-all device. The nonoxynol-9–impregnated polyurethane disc is 2.5 cm thick and 5.5 cm wide and has a dimple on one side and satin loop on the other (Fig. 38-8). The sponge can be inserted up to 24 hours prior to intercourse, and while in place, it provides contraception regardless of coital frequency. It should remain in place for 6 hours after intercourse. Pregnancy is prevented primarily by the spermicide nonoxynol-9 and to a lesser extent, by covering the cervix and absorbing semen.

Although the sponge is possibly more convenient than the diaphragm or condom, it is less effective than either (Kuyoh,

2003). Most common causes for discontinuance are pregnancy, irritation, discomfort, or vaginitis (Beckman, 1989). Although toxic shock syndrome (TSS) has been reported with the contraceptive sponge, it is rare, and evidence suggests that the sponge may actually limit production of the responsible staphylococcal exotoxin (Remington, 1987). Still, it is recommended that the sponge not be used during menses or the puerperium.

EMERGENCY CONTRACEPTION

Many women present for contraceptive care following unprotected sexual intercourse. In this situation, several emergency contraception (EC) regimens substantially decrease the likelihood of an unwanted pregnancy when used correctly. Current methods include COCs, POPs, progesterone antagonists, and copper-containing IUDs (Table 38-7). Patients can obtain information regarding emergency contraception by calling 1-888-NOT-2-LATE or accessing The Emergency Contraception Website: <http://not-2-late.com>.

Hormonal Emergency Contraception

Also known as the *Yuzpe method*, one EC method provides a minimum of 100 µg of ethinyl estradiol and 0.5 mg of levonorgestrel in each of two doses. As shown in Table 38-7, a sufficient dose may be achieved by two or more pills. The first dose is taken ideally within 72 hours of intercourse but may be given up to 120 hours. The initial dose is followed 12 hours later by a second equivalent dose.

With progestin-only regimens, 1.5 mg of levonorgestrel is taken, either as a single, one-time 1.5-mg dose or as two tablets, each containing 0.75 mg levonorgestrel. With these regimens, the first dose is ideally taken within 72 hours of unprotected coitus but may be given up to 120 hours. With the two-pill

TABLE 38-7. Methods Available for Use as Emergency Contraception

Method	Formulation	Pills per Dose	Number of Doses ^a
Progestin-Only Pill			
Plan B, Next Choice	0.75 mg levonorgestrel	1	2
Plan B One-Step, Next Choice One Dose	150 mg levonorgestrel	1	1
PRM Pill			
Ella	30 mg ulipristal acetate	1	1
COC Pills^{b,c}			
Ogestrel	0.05 mg EE + 0.5 mg norgestrel	2	2
Lo/Ovral, Low-Ogestrel	0.03 mg EE + 0.3 mg norgestrel	4	2
Enpresse (orange), Trivora (pink)	0.03 mg EE + 0.125 mg levonorgestrel	4	2
Nordette, Seasonale	0.03 mg EE + 0.15 mg levonorgestrel	4	2
Aviane, LoSeasonique (orange)	0.02 mg EE + 0.1 mg levonorgestrel	5	2
Copper-Containing IUD			
Paragard T 380A			

^aDoses taken 12 hours apart.

^bOther COC brands with formulations identical to those above may also be used (see Table 38-4).

^cUse of an antiemetic agent before taking the medication will lessen the risk of nausea, which is a common side effect. COC = combination oral contraceptive; EE = ethinyl estradiol; PRM = progesterone-receptor modulator.

regimen, the second dose follows 12 hours later, although a 24-hour interval between the doses is also effective (Ngai, 2005).

One progesterone-receptor modulator currently available for EC is ulipristal acetate and is marketed as *Ella*. It is taken as a single 30-mg tablet up to 120 hours after unprotected intercourse (Brache, 2010; Watson, 2010).

The major mechanism with all hormonal regimens is inhibition or delay of ovulation. Emergency hormonal contraceptive regimens are more effective the sooner they are taken and decrease the risk of pregnancy by up to 94 percent (American College of Obstetricians and Gynecologists, 2012b). Although highly effective, if EC fails to prevent pregnancy or is mistimed, no associations with major congenital malformation or pregnancy complications have been noted with estrogen- or progestin-containing regimens. Data regarding ulipristal acetate in this setting are limited.

With EC administration, nausea and vomiting can be a significant side effect (Gemzell-Danielsson, 2013). Accordingly, an oral antiemetic may be prescribed at least 1 hour before each dose. If a woman vomits within 2 hours of a dose, the dose must be repeated.

Copper-Containing Intrauterine Devices

For women who are candidates, copper IUD insertion is an effective EC method and provides an effective 10-year method of contraception (Cheng, 2012). If an IUD is placed up to 5 days after unprotected coitus, the failure rate approximates only 0.1 percent (Fasoli, 1989; Wu, 2010).

PUERPERAL CONTRACEPTION

For mothers who are nursing exclusively, ovulation during the first 10 weeks after delivery is unlikely. Nursing, however, is not a reliable method of family planning for women whose infants are on a daytime-only feeding schedule. Moreover, waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation. Certainly, after the first menses, contraception is essential unless the woman desires pregnancy.

For nursing mothers, progestin-only contraceptives are the preferred choice in most cases. In addition, IUDs have been recommended for the lactating sexually active woman. Estrogen-progestin contraceptives may reduce both the rate and the duration of milk production, although data are limited (Truitt, 2010). Moreover, very small quantities of the hormones are excreted in breast milk, but no adverse effects on infants have been reported (World Health Organization, 1988). Thus, in many cases, the benefits from pregnancy prevention by the use of COCs after the first 4 puerperal weeks would appear to outweigh the risks in selected patients. Immediate postpartum COC initiation is avoided due to VTE risks (Centers for Disease Control and Prevention, 2011).

CHAPTER 39

Sterilization

FEMALE STERILIZATION 720

PUERPERAL TUBAL STERILIZATION 720

NONPUERPERAL TUBAL STERILIZATION 721

LONG-TERM COMPLICATIONS 721

TRANSCERVICAL STERILIZATION 722

MALE STERILIZATION 723

Sterilization is a popular choice of contraception for millions of men and women. This procedure is indicated in those requesting sterilization and who clearly understand its permanence as well as its difficult and often unsuccessful reversal. The American College of Obstetricians and Gynecologists (2009, 2013) recommends that all persons considering sterilization should also be counseled regarding alternative contraceptive choices.

FEMALE STERILIZATION

Almost a fourth of all women using contraception in the United States from 2006 through 2008 chose a form of sterilization (Mosher, 2010). And, for women aged 35 to 44 years, surgical sterilization was their most commonly reported form of birth control (Brunner Huber, 2009).

Female sterilization is usually accomplished by occlusion or division of the fallopian tubes. *Puerperal sterilization* procedures performed in conjunction with cesarean or vaginal delivery follow approximately 8 percent of all live births in the United States (Chan, 2010). *Nonpuerperal tubal sterilization* is done at a time unrelated to recent pregnancy and is also termed interval sterilization. These latter procedures are usually accomplished via laparoscopy as outpatient surgery. Hysteroscopic or mini-laparotomy approaches to occlusion are also available.

Puerperal Tubal Sterilization

For several days after delivery, the uterine fundus lies at the level of the umbilicus, and fallopian tubes are accessible directly beneath the abdominal wall. Moreover, abdominal laxity allows easy repositioning of the incision over each uterine cornu. Thus, puerperal sterilization is technically simple, and hospitalization need not be prolonged.

Some prefer to perform sterilization immediately following delivery, although others wait for 12 to 24 hours. At Parkland Hospital, puerperal tubal ligation is performed in the obstetrical surgical suite the morning after delivery. This minimizes hospital stay but lowers the likelihood that postpartum hemorrhage would complicate recovery following surgery. In addition, the status of the newborn can be better ascertained before surgery.

Various techniques are now used to disrupt tubal patency. In general, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and peritoneal regrowth. Commonly used methods of interval sterilization include the Parkland, Pomeroy, and modified Pomeroy techniques (American College of Obstetricians and Gynecologists, 2013). Irving and Uchida techniques or Kroener fimbriectomy are rarely used because they involve increased dissection, operative time, and chance of mesosalpingeal injury. With fimbriectomy, unfavorably high failure rates stem from recanalization of the proximal tubal segment (Pati, 2000).

Surgical Technique

If scheduled for the first postpartum day, puerperal sterilization is typically completed using spinal analgesia. If done more proximate to delivery, the same epidural catheter used for labor analgesia can be used for sterilization analgesia. General anesthesia may be less desirable due to residual pregnancy-related airway changes (Bucklin, 2003).

The bladder is emptied before surgery. A small infraumbilical incision is made. Adequate exposure is critical, and Army-Navy

or appendiceal retractors are usually suitable. For obese women, a slightly larger incision and narrow Deaver retractors may be required. If bowel or omentum is obstructing, then Trendelenburg position may be helpful. Digitally packing with a single, moist, fanned-out piece of surgical gauze may also be used, but a hemostat should always be attached to the distal end to avert its retention. It is sometimes helpful to tilt the entire table to the opposite side of the tube being exposed.

The fallopian tube is identified and grasped at its midportion with a Babcock clamp, and the distal fimbria confirmed. This prevents confusing the round ligament with the midportion of the tube. A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. Therefore, identification and isolation of the distal tube prior to ligation is necessary. Whenever the tube is inadvertently dropped, it is mandatory to repeat this identification procedure. Surgical steps for ligation are outlined in [Figures 39-1](#) and [39-2](#).

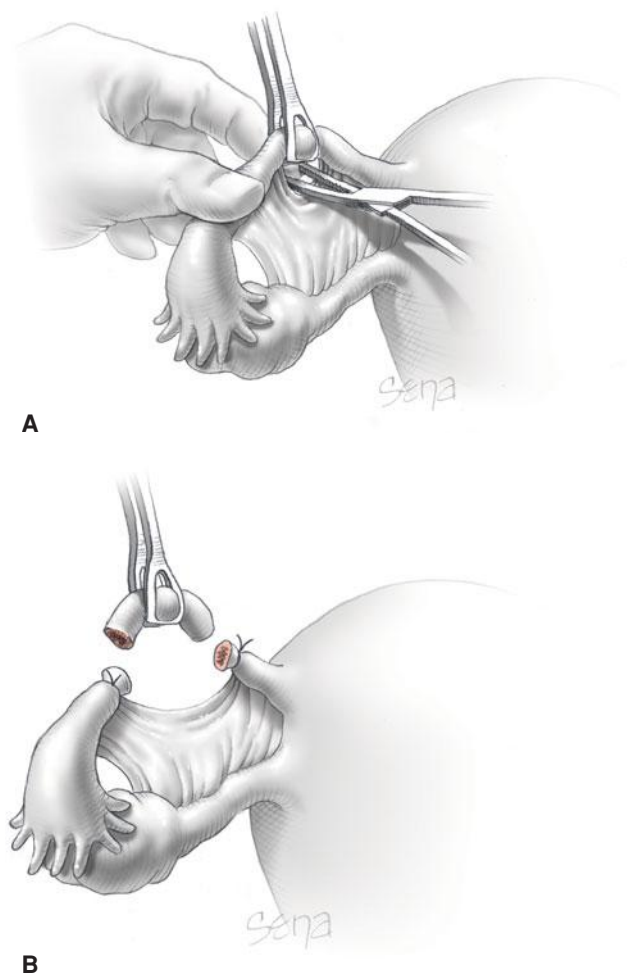

FIGURE 39-1 Parkland method. **A.** An avascular site in the mesosalpinx adjacent to the fallopian tube is perforated with a small hemostat. The jaws are opened to separate the fallopian tube from the adjacent mesosalpinx for approximately 2.5 cm. **B.** The freed fallopian tube is ligated proximally and distally with 0-chromic suture. The intervening segment of approximately 2 cm is excised, and the excision site is inspected for hemostasis. This method was designed to avoid the initial intimate proximity of the cut ends of the fallopian tube inherent with the Pomeroy procedure. (From Word, 2012, with permission.)

FIGURE 39-2 Pomeroy method. During ligation of a midsegment tubal loop, plain catgut is used to ensure prompt absorption of the ligature and subsequent separation of the severed tubal ends. (From Word, 2012, with permission.)

After surgery, diet is given as tolerated. Ileus is infrequent and should prompt concern for bowel injury, albeit rare. Most women have an uncomplicated course and are discharged on the first postoperative day.

Nonpuerperal (Interval) Surgical Tubal Sterilization

These techniques and other modifications basically consist of (1) ligation and resection at laparotomy as described earlier for puerperal sterilization; (2) application of permanent rings, clips, or inserts to the fallopian tubes by laparoscopy or hysteroscopy; or (3) electrocoagulation of a tubal segment, usually through a laparoscope. A detailed description and illustration of these can be found in *Williams Gynecology, 2nd edition* (Thompson, 2012).

In the United States, a laparoscopic approach to interval tubal sterilization is the most common. The procedure is frequently performed in an ambulatory surgical setting under general anesthesia. In almost all cases, the woman can be discharged within several hours. Minilaparotomy using a 3-cm suprapubic incision is also popular, especially in resource-poor countries (Kulier, 2004). Although not commonly used, the peritoneal cavity can be entered through the posterior vaginal fornix—colpotomy or culdotomy—to perform tubal interruption. Major morbidity is rare with either minilaparotomy or laparoscopy.

Long-Term Complications

Contraceptive Failure

Pregnancy following sterilization is uncommon. The Collaborative Review of Sterilization (CREST) study followed 10,863 women who had undergone tubal sterilization from 1978 through 1986

(Peterson, 1996). The cumulative failure rate for the various tubal procedures was 18.5 per 1000 or approximately 0.5 percent. The study found puerperal sterilization to be highly effective. The 5-year failure rate was 5 per 1000, and for 12 years, it was 7 per 1000.

Puerperal sterilization fails for two major reasons. First, surgical errors occur and include transection of the round ligament or only partial transection of the tube. For this reason, both tubal segments are submitted for pathological confirmation. Second, a fistulous tract or spontaneous reanastomosis may form between the severed tubal stumps.

Interval tubal sterilization may fail for several reasons. First, it may be due to equipment failure such as a defective current for electrosurgery or an insufficiently occlusive clip (Belot, 2008). Second, failure may result from fistula formation, especially with electrosurgical procedures, or the fallopian tube may undergo spontaneous reanastomosis. A third possibility is that the woman may have been already pregnant at the time of surgery—a so-called luteal phase pregnancy. To limit this possibility, surgery may ideally be performed during the follicular phase, and an effective contraceptive method used before surgery. Last, in some cases, no reason is found. Importantly, Soderstrom (1985) found that most sterilization failures were not preventable.

Approximately 30 percent of pregnancies that follow a failed tubal sterilization procedure are ectopic. This rate rises to 50 percent for those following a bipolar coagulation procedure (McCausland, 1980; Peterson, 1997). Thus, any symptoms of pregnancy in a woman after tubal sterilization must be investigated, and an ectopic pregnancy excluded.

Other Effects

Ovarian and breast cancer risks are either decreased or unaffected following sterilization (Ness, 2011; Press, 2011). Women who have undergone tubal sterilization are highly unlikely to subsequently have salpingitis (Levgur, 2000). An almost twofold increased incidence of functional ovarian cysts follows tubal sterilization (Holt, 2003). Several investigators have evaluated the risk of menorrhagia and intermenstrual bleeding following tubal sterilization, and most have found no association (DeStefano, 1985; Peterson, 2000; Shy, 1992).

Less objective but important psychological sequelae of sterilization have also been evaluated. In the CREST study, Costello (2002) found that tubal ligation did not change sexual interest or pleasure in 80 percent of women. In most of the 20 percent of women who did report a change, positive effects were 10 to 15 times more likely.

Invariably, a number of women express regrets regarding sterilization, and this is especially true if performed at a younger age (Curtis, 2006; Kelekçi, 2005). In the CREST study, Jamieson (2002) reported that 7 percent of women who had undergone tubal ligation had regrets by 5 years. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

Reversal of Tubal Sterilization

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed by either surgery or by

assisted reproductive techniques. Both approaches are technically difficult, expensive, and not always successful. Pregnancy rates following surgical reanastomosis are higher in younger women, in those with significant tubal length remaining, and in those with isthmic-to-isthmic repairs (American Society for Reproductive Medicine, 2012). With surgical reversals, pregnancy rates vary from 45 to 85 percent (Trussell, 2003; Van Voorhis, 2000). Almost 10 percent of women who became pregnant following reversal of tubal sterilization have an ectopic pregnancy.

Salpingectomy and Hysterectomy

Newer evidence suggests that the fallopian tube may be the origin of pelvic serous carcinomas, especially those of the ovary. With this knowledge, the Society of Gynecologic Oncologists (2013) has issued a practice statement recommending salpingectomy to lower cancer risks. Specifically, for women at average risk of ovarian cancer, risk-reducing salpingectomy should be discussed and considered with patients at the time of abdominal or pelvic surgery, with hysterectomy, or in lieu of tubal ligation. Initial steps of salpingectomy are shown in [Figure 39-3](#). Further illustration and discussion of surgical steps are outlined in *Williams Gynecology, 2nd edition* (Word, 2012).

In the absence of uterine or other pelvic disease, hysterectomy solely for sterilization at the time of cesarean delivery, early in the puerperium, or even remote from pregnancy is difficult to justify. It carries significantly increased surgical morbidity compared with tubal sterilization (Jamieson, 2000; Nieboer, 2009).

Transcervical Sterilization

Intratubal Devices

There are several devices that are inserted via hysteroscopy to occlude the proximal fallopian tubes. These interval sterilization options include *Essure*, a microinsert that has a fine stainless-steel inner coil enclosed in polyester fibers and an

FIGURE 39-3 With salpingectomy, the mesosalpinx is sequentially clamped, cut, and ligated. (From Word, 2012, with permission.)

FIGURE 39-4 Essure microinsert placement hysteroscopically and ingrowth of tissue. (From Thompson, 2012, with permission.)

expandable outer coil of Nitinol—a nickel and titanium alloy (Fig. 39-4). The outer coil expands after placement, allowing the inner fibers also to expand. These synthetic fibers incite a chronic inflammatory response to prompt local tissue ingrowth that leads to complete tubal lumen occlusion (Valle, 2000).

For hysteroscopic placement, sedation, paracervical block, or both may be used, and in-office insertion is often selected. Devices cannot be placed in all women, and some do not tolerate the procedure awake (Duffy, 2005). Bilateral placement is achieved in 95 to 98 percent of cases (Anderson, 2011; Cooper, 2003; Miño, 2007). Rarely, intractable pelvic pain following insertion may require Essure removal (Beckwith, 2008; Lannon, 2007).

Because complete tubal blockage is not 100 percent, it must be confirmed by hysterosalpingography (HSG) 3 months following surgery (American College of Obstetricians and Gynecologists, 2012). With such confirmation, efficacy rates for these devices reach 98 to 99 percent (Anderson, 2011; Smith, 2010). Failures following transcervical sterilization include noncompliance with HSG or its misinterpretation, conception before insertion, insert expulsion, migration of one or both of the inserts, uterine perforation, and method failure (Levy, 2007; Veersema, 2010). Although data are limited to small case series, pregnancies conceived with Essure in place do not appear to be at increased risk from the device (Galen, 2011; Mijatovic, 2012; Veersema, 2013).

The other insert, *Adiana*, also stimulates tissue ingrowth for tubal occlusion using a cylindrical, 1.5 × 3.5 mm, nonabsorbent silicone elastomer matrix. However, for financial reasons, production of this device has now been discontinued by the manufacturer (Hologic, 2012).

Intratubal Chemical Methods

Although none is currently available in the United States, several chemical substances are used to cause sclerosis or obstruction of the tubal ostia (Abbott, 2007; Ogburn, 2007). Placement of quinacrine pellets into the uterine fundus with an IUD-type inserter

method has been used worldwide in more than 100,000 women. The World Health Organization has lifted its ban on quinacrine use because studies have shown no evidence of carcinogenesis (Lippes, 2002). The major drawbacks are 1-, 5-, and 10-year cumulative pregnancy rates of 3, 10, and 12 percent, respectively (Sokal, 2008a,b, 2010).

MALE STERILIZATION

Currently, up to a half million men in the United States undergo vasectomy each year (Barone, 2006; Magnani, 1999). Through a small incision, the vas deferens lumen is disrupted to block the passage of sperm from the testes (Fig. 39-5). Alternatively, the no-scalpel method accomplishes this through a needle puncture in the scrotum. The latter method is associated with fewer minor surgical complications than the traditional incision technique, but each is equally effective (Cook, 2007).

Vasectomy is safer than tubal sterilization because it is less invasive and is performed with local analgesia (American College of Obstetricians and Gynecologists, 2013). In a review to compare the two, Hendrix and associates (1999) found that, compared with vasectomy, female tubal sterilization has a 20-fold increased complication rate, a 10- to 37-fold failure rate, and costs three times as much.

One disadvantage is that sterilization following vasectomy is not immediate. Complete release of sperm stored in the reproductive tract beyond the interrupted vas deferens takes approximately 3 months or 20 ejaculations. Although guidelines vary regarding the number and timing of postprocedural semen analyses, many investigators suggest that collection of only one azoospermic semen analysis at 3 months is sufficient evidence of sterility (Bodiwala, 2007; Griffin, 2005). During the period before azoospermia is documented, another form of contraception should be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures but only 11.4 per 1000 at 2, 3, and 5 years (Jamieson, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete occlusion of the vas deferens, or recanalization (Awsare, 2005; Deneux-Tharaux, 2004).

FIGURE 39-5 Anatomy of male reproductive system showing procedure for vasectomy.

Long-Term Effects

Other than regrets, long-term consequences are rare. A major one is troublesome chronic scrotal pain, which develops in up to 15 percent of men (Leslie, 2007; Manikandan, 2004). Previous concerns for atherogenesis, immune-complex mediated disease, testicular cancer, and prostate cancer have been allayed (Bernal-Delgado, 1998; Giovannucci, 1992; Goldacre, 1983; Møller, 1994).

Restoration of Fertility

Reanastomosis of the vas deferens can be completed most effectively using microsurgical techniques. Conception rates following reversal are adversely affected by longer duration from vasectomy, poor sperm quality found at reversal, and type of reversal procedure required (American Society for Reproductive Medicine, 2008).

OBSTETRICAL COMPLICATIONS

CHAPTER 40

Hypertensive Disorders

TERMINOLOGY AND DIAGNOSIS 728

INCIDENCE AND RISK FACTORS 731

ETIOPATHOGENESIS 731

PATHOPHYSIOLOGY 736

PREDICTION AND PREVENTION 746

MANAGEMENT 749

LONG-TERM CONSEQUENCES 769

How pregnancy incites or aggravates hypertension remains unsolved despite decades of intensive research. Indeed, hypertensive disorders remain among the most significant and intriguing unsolved problems in obstetrics.

Hypertensive disorders complicate 5 to 10 percent of all pregnancies, and together they are one member of the deadly triad—along with hemorrhage and infection—that contributes greatly to maternal morbidity and mortality. Of these disorders, the *preeclampsia syndrome*, either alone or superimposed on chronic hypertension, is the most dangerous. As subsequently discussed, new-onset hypertension during pregnancy—termed *gestational hypertension*—is followed by signs and symptoms of preeclampsia almost half the time, and preeclampsia is identified in 3.9 percent of all pregnancies (Martin, 2012).

The World Health Organization (WHO) systematically reviews maternal mortality worldwide, and in developed countries, 16 percent of maternal deaths were reported to be due to hypertensive disorders (Khan, 2006). This proportion is greater than three other leading causes that include hemorrhage—13 percent, abortion—8 percent, and sepsis—2 percent. In the United States from 1998 to 2005, Berg and colleagues (2010) reported that 12.3 percent of 4693 pregnancy-related maternal deaths

were caused by preeclampsia or eclampsia. The rate was similar to that of 10 percent for maternal deaths in France from 2003 through 2007 (Saucedo, 2013). Importantly, more than half of these hypertension-related deaths were preventable (Berg, 2005).

TERMINOLOGY AND DIAGNOSIS

In this country for the past two decades, pregnancy hypertension was considered using the terminology and classification promulgated by the Working Group of the National High Blood Pressure Education Program—NHBPEP (2000). To update these, a Task Force was appointed by President James Martin for the American College of Obstetricians and Gynecologists (2013b) to provide evidence-based recommendations for clinical practice. The basic classification was retained, as it describes four types of hypertensive disease:

- 1. Gestational hypertension—evidence for the preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum
- 2. Preeclampsia and eclampsia syndrome
- 3. Chronic hypertension of any etiology
- 4. Preeclampsia superimposed on chronic hypertension.

Importantly, this classification differentiates the preeclampsia syndrome from other hypertensive disorders because it is potentially more ominous. This concept aids interpretation of studies that address the etiology, pathogenesis, and clinical management of pregnancy-related hypertensive disorders.

■ Diagnosis of Hypertensive Disorders

Hypertension is diagnosed empirically when appropriately taken blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. Korotkoff phase V is used to define diastolic pressure. Previously, incremental increases of 30 mm Hg systolic or 15 mm Hg diastolic from midpregnancy blood pressure values had

TABLE 40-1. Diagnostic Criteria for Pregnancy-Associated Hypertension

Condition	Criteria Required
Gestational hypertension	BP > 140/90 mmHg after 20 weeks in previously normotensive women
Preeclampsia—Hypertension and:	
Proteinuria	<ul style="list-style-type: none"> • ≥ 300 mg/24h, or • Protein: creatinine ratio ≥ 0.3 or • Dipstick 1+ persistent^a
	or
Thrombocytopenia	• Platelets < 100,000/ μ L
Renal insufficiency	• Creatinine > 1.1 mg/dL or doubling of baseline ^b
Liver involvement	• Serum transaminase levels ^c twice normal
Cerebral symptoms	• Headache, visual disturbances, convulsions
Pulmonary edema	—

^aRecommended only if sole available test.

^bNo prior renal disease.

^cAST (aspartate aminotransferase) or ALT (alanine aminotransferase).

Modified from the American College of Obstetricians and Gynecologists, 2013b.

also been used as diagnostic criteria, even when absolute values were < 140/90 mm Hg. These incremental changes are no longer recommended criteria because evidence shows that such women are not likely to experience increased adverse pregnancy outcomes (Levine, 2000; North, 1999). That said, women who have a rise in pressure of 30 mm Hg systolic or 15 mm Hg diastolic should be observed more closely because eclamptic seizures develop in some of these women whose blood pressures have stayed < 140/90 mm Hg (Alexander, 2006). A sudden rise in mean arterial pressure later in pregnancy—also known as “delta hypertension”—may also signify preeclampsia even if blood pressure is < 140/90 mm Hg (Macdonald-Wallis, 2012; Volvaard, 2007).

Concept of “Delta Hypertension”

The systolic and diastolic blood pressure levels of 140/90 mm Hg have been arbitrarily used since the 1950s to define

“hypertension” in nonpregnant individuals. As discussed in detail in Chapter 50 (p. 1000), these levels were selected by insurance companies for a group of middle-aged men. It seems more realistic to define normal-range blood pressures that fall between an upper and lower limit for blood pressure measurements for a particular population—such as young, healthy, pregnant women. A schematic example is shown in [Figure 40-1](#) using arbitrary blood pressure readings. Data curves for both women show blood pressure measurements near the 25th percentile until 32 weeks. These begin to rise in patient B, who by term has substantively increased blood pressures. However, her pressures are still < 140/90 mm Hg, and thus she is considered to be “normotensive.” We termed this rather acute increase in blood pressure as “delta hypertension.” As discussed later, some of these women will develop eclamptic seizures or HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome while still normotensive.

FIGURE 40-1 Schematic shows normal reference ranges for blood pressure changes across pregnancy. Patient A (blue) has blood pressures near the 20th percentile throughout pregnancy. Patient B (red) has a similar pattern with pressures at about the 25th percentile until about 36 weeks when blood pressure begins to increase. By term, it is substantively higher and in the 75th percentile, but she is still considered “normotensive.”

Gestational Hypertension

This diagnosis is made in women whose blood pressures reach 140/90 mm Hg or greater for the first time after midpregnancy, but in whom *proteinuria is not identified* ([Table 40-1](#)). Almost half of these women subsequently develop preeclampsia syndrome, which includes findings such as headaches or epigastric pain, proteinuria, and thrombocytopenia. Even so, when blood pressure increases appreciably, it is dangerous to both mother and fetus to ignore this rise only because proteinuria has not yet developed. As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria can be detected. Finally, gestational hypertension is reclassified by some as *transient hypertension* if evidence for preeclampsia does not develop and the blood pressure returns to normal by 12 weeks postpartum.

Preeclampsia Syndrome

As emphasized throughout this chapter, *preeclampsia is best described as a pregnancy-specific syndrome that can affect virtually every organ system*. And, although preeclampsia is much more than

simply gestational hypertension with proteinuria, appearance of proteinuria remains an important diagnostic criterion. Thus, proteinuria is an *objective* marker and reflects the system-wide endothelial leak, which characterizes the preeclampsia syndrome.

Abnormal protein excretion is arbitrarily defined by 24-hour urinary excretion exceeding 300 mg; a urine protein:creatinine ratio ≥ 0.3 ; or persistent 30 mg/dL (1+ dipstick) protein in random urine samples (Lindheimer, 2008a). None of these values is sacrosanct, and urine concentrations vary widely during the day, as do dipstick readings. Thus, assessment may show a dipstick value of 1+ to 2+ from concentrated urine specimens from women who excrete < 300 mg/day. As discussed on page 740, it is likely that determination of a spot urine:creatinine ratio is a suitable replacement for a 24-hour urine measurement (Chap. 4, p. 65).

It is now appreciated that overt proteinuria may not be a feature in some women with the preeclampsia syndrome (Sibai, 2009). Because of this, the Task Force (2013) suggested other diagnostic criteria, which are shown in Table 40-1. Evidence of multiorgan involvement may include thrombocytopenia, renal dysfunction, hepatocellular necrosis (“liver dysfunction”), central nervous system perturbations, or pulmonary edema.

Indicators of Preeclampsia Severity

The markers listed in Table 40-1 are also used to classify preeclampsia syndrome severity. Although many use a dichotomous “mild” and “severe” classification, the Task Force (2013) discourages the use of “mild preeclampsia.” It is problematic that there are criteria for the diagnosis of “severe” preeclampsia, but the default classification is either implied or specifically termed as “mild,” “less severe,” or “nonsevere” (Alexander, 2003; Lindheimer, 2008b). There are no generally agreed-on criteria for “moderate” preeclampsia—an elusive third category. We use the criteria listed in Table 40-2, which are categorized as “severe” versus “nonsevere.” Importantly, while it is pragmatic that nonsevere classifications include “moderate” and “mild,” these have not been specifically defined.

Some symptoms are considered to be ominous. *Headaches* or *visual disturbances* such as *scotomata* can be premonitory symptoms of eclampsia. *Epigastric or right upper quadrant pain* frequently accompanies hepatocellular necrosis, ischemia, and edema that ostensibly stretches Glisson capsule. This characteristic pain is frequently accompanied by elevated serum hepatic transaminase levels. Finally, *thrombocytopenia* is also characteristic of worsening preeclampsia as it signifies platelet activation and aggregation as well as microangiopathic hemolysis. Other factors indicative of severe preeclampsia include renal or cardiac involvement and obvious fetal-growth restriction, which also attests to its duration.

As will be discussed, the more profound these signs and symptoms, the less likely they can be temporized, and the more likely delivery will be required. *A caveat is that differentiation between nonsevere and severe gestational hypertension or preeclampsia can be misleading because what might be apparently mild disease may progress rapidly to severe disease.*

Eclampsia

In a woman with preeclampsia, a convulsion that cannot be attributed to another cause is termed *eclampsia*. The seizures are generalized and may appear before, during, or after labor. The proportion who do not develop seizures until after 48 hours post-

TABLE 40-2. Indicators of Severity of Gestational Hypertensive Disorders^a

Abnormality	Nonsevere ^b	Severe
Diastolic BP	< 110 mm Hg	≥ 110 mm Hg
Systolic BP	< 160 mm Hg	≥ 160 mm Hg
Proteinuria ^c	None to positive	None to positive
Headache	Absent	Present
Visual disturbances	Absent	Present
Upper abdominal pain	Absent	Present
Oliguria	Absent	Present
Convulsion (eclampsia)	Absent	Present

BP = blood pressure.

partum approximates 10 percent (Sibai, 2005). In some reports, up to a fourth of eclamptic seizures develop beyond 48 hours postpartum (Chames, 2002). Our experiences from Parkland Hospital, however, are that delayed postpartum eclampsia continues to occur in about 10 percent of cases—similar to what we first reported more than 20 years ago (Alexander, 2006; Brown, 1987). This lower percentage was also found in 222 women with eclampsia from The Netherlands (Zwart, 2008).

Preeclampsia Superimposed on Chronic Hypertension

Regardless of its cause, any chronic hypertensive disorder predisposes a woman to develop superimposed preeclampsia syndrome. Chronic underlying hypertension is diagnosed in women with documented blood pressures $\geq 140/90$ mm Hg before pregnancy or before 20 weeks’ gestation, or both. Hypertensive disorders can create difficult problems with diagnosis and management in women who are not first seen until after midpregnancy. This is because blood pressure normally decreases during the second and early third trimesters in both normotensive and chronically hypertensive women (Chap. 50, p. 1003). Thus, a woman with previously undiagnosed chronic vascular disease who is seen before 20 weeks frequently has blood pressures within the normal range. During the third trimester, however, as blood pressures return to their originally hypertensive levels, it may be difficult to determine whether hypertension is chronic or induced by pregnancy. Even a careful search for evidence of

preexisting end-organ damage may be futile, as many of these women have mild disease and no evidence of ventricular hypertrophy, retinal vascular changes, or renal dysfunction.

In some women with chronic hypertension, their blood pressure increases to obviously abnormal levels, and this is typically after 24 weeks. If new-onset or worsening baseline hypertension is accompanied by new-onset proteinuria or other findings listed in Table 40-1, then superimposed preeclampsia is diagnosed. Compared with “pure” preeclampsia, superimposed preeclampsia commonly develops earlier in pregnancy. It also tends to be more severe and often is accompanied by fetal-growth restriction. The same criteria shown in Table 40-2 are also used to further characterize severity of superimposed preeclampsia.

INCIDENCE AND RISK FACTORS

Preeclampsia Syndrome

Young and nulliparous women are particularly vulnerable to developing preeclampsia, whereas older women are at greater risk for chronic hypertension with superimposed preeclampsia. The incidence is markedly influenced by race and ethnicity—and thus by genetic predisposition. By way of example, in nearly 2400 nulliparas enrolled in a Maternal-Fetal Medicine Units (MFMU) Network study, the incidence of preeclampsia was 5 percent in white, 9 percent in Hispanic, and 11 percent in African-American women (Myatt, 2012a,b).

Other factors include environmental, socioeconomic, and even seasonal influences (Lawlor, 2005; Palmer, 1999; Spencer, 2009). With consideration for these vicissitudes, in several worldwide studies reviewed by Staff and coworkers (2014), the incidence of preeclampsia in nulliparous populations ranged from 3 to 10 percent. The incidence of preeclampsia in multiparas is also variable but is less than that for nulliparas. Specifically, population studies from Australia, Canada, Denmark, Norway, Scotland, Sweden, and Massachusetts indicate an incidence of 1.4 to 4 percent (Roberts, 2011).

There are several other risk factors associated with preeclampsia. These include obesity, multifetal gestation, maternal age, hyperhomocysteinemia, and metabolic syndrome (Conde-Agudelo, 2000; Scholten, 2013; Walker, 2000). The relationship between maternal weight and the risk of preeclampsia is progressive. It increases from 4.3 percent for women with a body mass index (BMI) < 20 kg/m² to 13.3 percent in those with a BMI > 35 kg/m² (Fig. 48-5, p. 966). In women with a twin gestation compared with those with singletons, the incidence of gestational hypertension—13 versus 6 percent, and the incidence of preeclampsia—13 versus 5 percent, are both significantly increased (Sibai, 2000). It is interesting that this latter incidence is unrelated to zygosity (Maxwell, 2001).

Although smoking during pregnancy causes various adverse pregnancy outcomes, ironically, it has consistently been associated with a *reduced risk* for hypertension during pregnancy (Bainbridge, 2005; Zhang, 1999). Kraus and associates (2013) posit that this is because smoking upregulates placental adrenomedullin expression, which regulates volume homeostasis.

Women with preeclampsia in the first pregnancy are at greater risk in a second pregnancy compared with women normotensive during their first pregnancy (McDonald, 2009). And conversely,

in the woman who was normotensive during her first pregnancy, the incidence of preeclampsia in a subsequent pregnancy is much lower than for a first pregnancy. In a population-based retrospective cohort analysis, Getahun and colleagues (2007) studied almost 137,000 second pregnancies in such women. The incidence for preeclampsia in secundigravida white women was 1.8 percent compared with 3 percent in African-American women.

Eclampsia

Presumably because it is somewhat preventable by adequate prenatal care, the incidence of eclampsia has decreased over the years in areas where health care is more readily available. In countries with adequate resources, its incidence averages 1 in 2000 deliveries. Ventura and associates (2000) estimated that the incidence in the United States in 1998 was 1 in 3250 births. According to the Royal College of Obstetricians and Gynaecologists (2006), it approximates 1 in 2000 in the United Kingdom. Akkawi and coworkers (2009) reported it to be 1 in 2500 in Dublin, Andersgaard and associates (2006) as 1 per 2000 for Scandinavia, and Zwart and colleagues (2008) as 1 per 1600 for The Netherlands.

ETIOPATHOGENESIS

Any satisfactory theory concerning the etiology and pathogenesis of preeclampsia must account for the observation that gestational hypertensive disorders are more likely to develop in women with the following characteristics:

- Are exposed to chorionic villi for the first time
- Are exposed to a superabundance of chorionic villi, as with twins or hydatidiform mole
- Have preexisting conditions of endothelial cell activation or inflammation such as diabetes or renal or cardiovascular disease
- Are genetically predisposed to hypertension developing during pregnancy.

A fetus is not a requisite for preeclampsia to develop. And, although chorionic villi are essential, they need not be intra-uterine. For example, Worley and associates (2008) reported a 30-percent incidence in women with an extrauterine pregnancy exceeding 18 weeks' gestation. Regardless of precipitating etiology, the cascade of events leading to the preeclampsia syndrome is characterized by abnormalities that result in vascular endothelial damage with resultant vasospasm, transudation of plasma, and ischemic and thrombotic sequelae.

Phenotypic Expression of Preeclampsia Syndrome

The preeclampsia syndrome is widely variable in its clinical phenotypic expression. There are at least two major subtypes differentiated by whether or not remodeling of uterine spiral arterioles by endovascular trophoblastic invasion is defective. This concept has given rise to the “two-stage disorder” theory of preeclampsia etiopathogenesis. Ness and Roberts (1996) consider that the two-stage disorder includes “maternal and placental preeclampsia.” According to Redman and coworkers (2014), stage 1 is caused by faulty endovascular trophoblastic remodeling that downstream causes the stage 2 clinical syndrome. Importantly, stage 2 is susceptible to modification by preexisting maternal conditions that

are manifest by endothelial cell activation or inflammation. Such conditions include cardiovascular or renal disease, diabetes, obesity, immunological disorders, or hereditary influences.

Such compartmentalization is artificial, and it seems logical to us that preeclampsia syndrome presents clinically as a spectrum of worsening disease. Moreover, evidence is accruing that many “isoforms” exist as discussed below. Examples include differences in maternal and fetal characteristics, placental findings, and hemodynamic findings (Phillips, 2010; Valensise, 2008; van der Merwe, 2010).

Etiology

Writings describing eclampsia have been traced as far back as 2200 BC (Lindheimer, 2014). And, an imposing number of mechanisms have been proposed to explain its cause. Those currently considered important include:

1. Placental implantation with abnormal trophoblastic invasion of uterine vessels
2. Immunological maladaptive tolerance between maternal, paternal (placental), and fetal tissues
3. Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy
4. Genetic factors including inherited predisposing genes and epigenetic influences.

Abnormal Trophoblastic Invasion

Normal implantation is characterized by extensive remodeling of the spiral arterioles within the decidua basalis as shown schematically in Figure 40-2 (Chap. 5, p. 93). Endovascular trophoblasts replace the vascular endothelial and muscular linings to enlarge the vessel diameter. The veins are invaded only superficially. In some cases of preeclampsia, however, there may be *incomplete trophoblastic invasion*. With this, decidual vessels, but not myometrial vessels, become lined with endovascular

trophoblasts. The deeper myometrial arterioles do not lose their endothelial lining and musculoelastic tissue, and their mean external diameter is only half that of corresponding vessels in normal placentas (Fisher, 2014). In general, the magnitude of defective trophoblastic invasion is thought to correlate with severity of the hypertensive disorder (Madazli, 2000).

Using electron microscopy, De Wolf and coworkers (1980) examined arteries taken from the implantation site. They reported that early preeclamptic changes included endothelial damage, insudation of plasma constituents into vessel walls, proliferation of myointimal cells, and medial necrosis. Lipid accumulated first in myointimal cells and then within macrophages. These lipid-laden cell changes, shown in Figure 40-3, were referred to as *atherosis* by Hertig (1945). Nelson and colleagues (2014) completed placental examination in more than 1200 women with preeclampsia. These investigators reported that vascular lesions including spiral arteriole narrowing, atherosclerosis, and infarcts were more common in placentas from women diagnosed with preeclampsia before 34 weeks.

Thus, the abnormally narrow spiral arteriolar lumen likely impairs placental blood flow. McMahon and colleagues (2014) have provided evidence that decreased soluble anti-angiogenic growth factors may be involved in faulty endovascular remodeling. Diminished perfusion and a hypoxic environment eventually lead to release of *placental debris* or *microparticles* that incite a systemic inflammatory response (Lee, 2012; Redman, 2012). Fisher and Roberts (2014) have provided an elegant review of the molecular mechanisms involved in these interactions.

Defective placentation is posited to further cause the susceptible (pregnant) woman to develop gestational hypertension, the preeclampsia syndrome, preterm delivery, a growth-restricted fetus, and/or placental abruption (Brosens, 2011; Kovo, 2010; McElrath, 2008; Nelson, 2014). In addition, Staff and coworkers (2013) have hypothesized that acute atherosclerosis identifies a group of women at increased risk for later atherosclerosis and cardiovascular disease.

FIGURE 40-2 Schematic representation of normal placental implantation shows proliferation of extravillous trophoblasts from an anchoring villus. These trophoblasts invade the decidua and extend into the walls of the spiral arteriole to replace the endothelium and muscular wall to create a dilated low-resistance vessel. With preeclampsia, there is defective implantation characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts. This results in a small-caliber vessel with high resistance to flow.

FIGURE 40-3 Atherosclerosis in a blood vessel from a placental bed. **A.** Photomicrograph shows disruption of the endothelium that results in a narrowed lumen because of subendothelial accumulation of plasma proteins and foamy macrophages. Some of the foamy macrophages are shown by curved arrows, and straight arrows highlight areas of endothelial disruption. **B.** Schematic diagram of the photomicrograph. (Modified from Rogers, 1999, with permission.)

Immunological Factors

Maternal immune tolerance to paternally derived placental and fetal antigens is discussed in Chapter 5 (p. 97). Loss of this tolerance, or perhaps its *dysregulation*, is another theory cited to account for preeclampsia syndrome (Erlebacher, 2013). Certainly, the histological changes at the maternal-placental interface are suggestive of acute graft rejection. Some of the factors possibly associated with dysregulation include “immunization” from a previous pregnancy, some inherited human leukocyte antigen (HLA) and natural killer (NK)-cell receptor haplotypes, and possibly shared susceptibility genes with diabetes and hypertension (Fukui, 2012; Ward, 2014).

Inferential data also suggest preeclampsia to be an immune-mediated disorder. For example, the risk of preeclampsia is appreciably enhanced in circumstances in which formation of blocking antibodies to placental antigenic sites *might* be impaired. In this scenario, the first pregnancy would carry a higher risk. Tolerance dysregulation might also explain an increased risk when the paternal antigenic load is increased, that is, with two sets of paternal chromosomes—a “double dose.” Namely, women with molar pregnancies have a high incidence of early-onset preeclampsia. Women with a trisomy 13 fetus also have a 30- to 40-percent incidence of preeclampsia. These women have elevated serum levels of antiangiogenic factors, and the gene for one of these factors, sFlt-1, is on chromosome 13 (Bdolah, 2006). Conversely, women previously exposed to paternal antigens, such as a prior pregnancy with the *same* partner, are “immunized” against preeclampsia. This phenomenon is not as apparent in women with a prior abortion. Strickland and associates (1986) studied more than 29,000 pregnancies at Parkland Hospital. These investigators reported that hypertensive disorder rates were decreased in women who previously had miscarried compared with nulligravidas. However, the difference, although statistically significant, was not great—22 versus 25 percent. Other studies have shown that multiparas impregnated by a new consort have an increased risk of preeclampsia (Mostello, 2002).

Redman and colleagues (2014) reviewed the possible role of *immune maladaptation* in preeclampsia pathophysiology. In women destined to be preeclamptic, extravillous trophoblasts early in pregnancy express reduced amounts of immunosuppressive nonclassic HLA G. Black women more commonly have the 1597ΔC allele that further predisposes to preeclampsia (Loisel, 2013). Zhou and coworkers (2012b) have shown this to be associated with high levels of placental oxidative products. These changes may contribute to defective placental vascularization in stage 1 of the preeclampsia syndrome (p. 732). Recall that as discussed in Chapter 4 (p. 56), during normal pregnancy, T-helper (Th) lymphocytes are produced so that type 2 activity is increased in relation to type 1—termed *type 2 bias* (Redman, 2012, 2014). Th2 cells promote humoral immunity, whereas Th1 cells stimulate inflammatory cytokine secretion. Beginning in the early second trimester in women who develop preeclampsia, Th1 action is increased and the Th1/Th2 ratio changes. Contributors to an enhanced immunologically mediated inflammatory reaction are stimulated by placental *microparticles* and by adipocytes (Redman, 2012, 2014).

Endothelial Cell Activation

In many ways, inflammatory changes are believed to be a continuation of the stage 1 changes caused by defective placentation as discussed above. In response to placental factors released by ischemic changes or by any other inciting cause, a cascade of events begins (Davidge, 2014). Thus, antiangiogenic and metabolic factors and other inflammatory mediators are thought to provoke endothelial cell injury.

Endothelial cell dysfunction may result from an extreme activated state of leukocytes in the maternal circulation (Faas, 2000; Gervasi, 2001). Briefly, cytokines such as tumor necrosis factor- α (TNF- α) and the interleukins (IL) may contribute to the oxidative stress associated with preeclampsia. This is characterized by reactive oxygen species and free radicals that lead to formation of self-propagating lipid peroxides (Manten, 2005). These in turn generate highly toxic radicals that injure

endothelial cells, modify their nitric oxide production, and interfere with prostaglandin balance. Other consequences of oxidative stress include production of the lipid-laden macrophage foam cells seen in atherosclerosis and shown in Figure 40-3; activation of microvascular coagulation manifest by thrombocytopenia; and increased capillary permeability manifest by edema and proteinuria.

These observations on the effects of oxidative stress in preeclampsia have given rise to increased interest in the potential benefit of antioxidants to prevent preeclampsia. Unfortunately, dietary supplementation with vitamins E (α -tocopherol) and C (ascorbic acid) to prevent preeclampsia has thus far proven unsuccessful (Task Force, 2013). This is discussed subsequently.

Nutritional Factors

John and colleagues (2002) showed that in the general population, a diet high in fruits and vegetables with antioxidant activity is associated with decreased blood pressure. Zhang and associates (2002) reported that the incidence of preeclampsia was doubled in women whose daily intake of ascorbic acid was less than 85 mg. These studies were followed by randomized trials to study dietary supplementation. Villar and coworkers (2006) showed that calcium supplementation in populations with a *low dietary calcium intake* had a small effect to lower perinatal mortality rates but no effect on preeclampsia incidence (p. 748). According to the 2013 Task Force, in several trials, supplementation with the antioxidant vitamins C or E showed no benefits.

Genetic Factors

From a hereditary viewpoint, preeclampsia is a multifactorial, polygenic disorder. In their comprehensive review, Ward and Taylor (2014) cite an incident risk for preeclampsia of 20 to 40 percent for daughters of preeclamptic mothers; 11 to 37 percent for sisters of preeclamptic women; and 22 to 47 percent for twins. In a study by Nilsson and colleagues (2004) that included almost 1.2 million Swedish births, there was a genetic component for gestational hypertension and for preeclampsia. They also reported 60-percent concordance in monozygotic female twin pairs.

The hereditary predisposition for preeclampsia likely is the result of interactions of literally hundreds of inherited genes—both maternal and paternal—that control myriad enzymatic and metabolic functions throughout every organ system. Plasma-derived factors may induce some of these genes in preeclampsia (Mackenzie, 2012). Thus, the clinical manifestation in any given woman with the preeclampsia syndrome will occupy a spectrum as previously discussed. In this regard, phenotypic expression will differ among similar genotypes depending on interactions with environmental factors (Yang, 2013).

Candidate Genes

Hundreds of genes have been studied for their possible association with preeclampsia (Buurma, 2013; Ward, 2014). Several of those that may have positive significant association with preeclampsia are listed in Table 40-3. Polymorphisms of the

TABLE 40-3. Genes with Possible Associations with Preeclampsia Syndrome

Gene (Polymorphism)	Function Affected
MTHFR (C677T)	Methylene tetrahydrofolate reductase
F5 (Leiden)	Factor V _{Leiden}
AGT (M235T)	Angiotensinogen
HLA (Various)	Human leukocyte antigens
NOS3 (Glu 298 Asp)	Endothelial nitric oxide
F2 (G20210A)	Prothrombin (factor II)
ACE (I/D ^{at} Intron 16)	Angiotensin-converting enzyme
CTLA4	Cytotoxic T-lymphocyte-associated protein
LPL	Lipoprotein lipase
SERPINE1	Serine peptidase inhibitor

Data from Buurma, 2013; Staines-Urias, 2012; Ward, 2014.

genes for Fas receptor, hypoxia-inducible factor-1 α protein (HIF-1 α), IL-1 β , lymphotoxin- α , transforming growth factor beta 3 (TGF- β 3), apolipoprotein E (ApoE), and TNF- α have also been studied with varying results (Borowski, 2009; Heffler, 2001; Jamalzei, 2013; Lachmeijer, 2001; Livingston, 2001; Wilson, 2009). Because of the heterogeneity of the preeclampsia syndrome and especially of the other genetic and environmental factors that interact with its complex phenotypic expression, it is doubtful that any *one* candidate gene will be found responsible. Indeed, Majander and associates (2013) have linked preeclampsia predisposition to *fetal* genes on chromosome 18.

Other Genetic Variables

An extensive list of other variables affect genotypic and phenotypic expression of the preeclampsia syndrome. Some include maternal and paternal genotypes, associated disorders, genomic ethnicity, gene-gene interactions, epigenetic phenomena, and gene-environmental interactions. Combinations of these are infinite. Ethnoracial factors are important as discussed regarding the high incidence of preeclampsia in African-American women. It may be that Latina women have a lower prevalence because of interactions of American Indian and white race genes (Shahabi, 2013).

Pathogenesis

Vasospasm

The concept of vasospasm with preeclampsia was advanced by Volhard (1918) based on his direct observations of small blood vessels in the nail beds, ocular fundi, and bulbar conjunctivae. It was also surmised from histological changes seen in various affected organs (Hinselmann, 1924; Landesman, 1954). Endothelial activation causes vascular constriction with increased resistance and subsequent hypertension. At the same time, endothelial cell damage causes interstitial leakage through which blood constituents, including platelets and fibrinogen,

are deposited subendothelially. Wang and associates (2002) have also demonstrated disruption of endothelial junctional proteins. Suzuki and coworkers (2003) described ultrastructural changes in the subendothelial region of resistance arteries in preeclamptic women. The much larger venous circuit is similarly involved, and with diminished blood flow because of maldistribution, ischemia of the surrounding tissues can lead to necrosis, hemorrhage, and other end-organ disturbances characteristic of the syndrome. One important clinical correlate is the markedly attenuated blood volume seen in women with severe preeclampsia (Zeeman, 2009).

Endothelial Cell Injury

As discussed on page 733, during the past two decades, endothelial cell injury has become the centerpiece in the contemporary understanding of preeclampsia pathogenesis (Davidge, 2014). In this scheme, protein factor(s)—likely placental—are secreted into the maternal circulation and provoke activation and dysfunction of the vascular endothelium. Many of the facets of the clinical syndrome of preeclampsia are thought to result from these widespread endothelial cell changes. Grundmann and associates (2008) have reported that *circulating endothelial cell*—CEC—levels are elevated fourfold in the peripheral blood of preeclamptic women. Similarly, Petrozella and colleagues (2012) demonstrated increased levels of circulating endothelial microparticles—EMPs—in preeclamptic women.

Intact endothelium has anticoagulant properties, and endothelial cells blunt the response of vascular smooth muscle to agonists by releasing nitric oxide. Damaged or activated endothelial cells may produce less nitric oxide and secrete substances that promote coagulation and increase sensitivity to vasopressors (Gant, 1974). Further evidence of endothelial activation includes the characteristic changes in glomerular capillary endothelial morphology, increased capillary permeability, and elevated blood concentrations of substances associated with endothelial activation. These latter substances are transferable, and serum from women with preeclampsia stimulates some of these substances in greater amounts. It seems likely that multiple factors in plasma of preeclamptic women combine to have these vasoactive effects (Myers, 2007; Walsh, 2009).

Increased Pressor Responses

As discussed in Chapter 4 (p. 61), pregnant women normally develop refractoriness to infused vasopressors (Abdul-Karim, 1961). Women with early preeclampsia, however, have increased vascular reactivity to infused norepinephrine and angiotensin II (Raab, 1956; Talledo, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension (Gant, 1974).

Prostaglandins

Several prostanoids are thought to be central to preeclampsia syndrome pathophysiology. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to decreased vascular responsiveness mediated by endothelial prostaglandin synthesis. For example, compared with normal pregnancy, endothelial prostacyclin (PGI₂) production

is decreased in preeclampsia. This action appears to be mediated by phospholipase A₂ (Davidge, 2014). At the same time, thromboxane A₂ secretion by platelets is increased, and the prostacyclin:thromboxane A₂ ratio decreases. The net result favors increased sensitivity to infused angiotensin II and, ultimately, vasoconstriction (Spitz, 1988). These changes are apparent as early as 22 weeks in women who later develop preeclampsia (Chavarria, 2003).

Nitric Oxide

This potent vasodilator is synthesized from L-arginine by endothelial cells. Withdrawal of nitric oxide results in a clinical picture similar to preeclampsia in a pregnant animal model (Conrad, 1989). Inhibition of nitric oxide synthesis increases mean arterial pressure, decreases heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. In humans, nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of fetoplacental perfusion (Myatt, 1992; Weiner, 1992). It also is produced by fetal endothelium, and here it is increased in response to preeclampsia, diabetes, and sepsis (Parra, 2001; von Mandach, 2003).

The effects of nitric oxide production in preeclampsia are unclear (Davidge, 2014). It appears that the syndrome is associated with decreased endothelial nitric oxide synthase expression, thus increasing nitric oxide inactivation. These responses may be race related, with African-American women producing more nitric oxide (Wallace, 2009).

Endothelins

These 21-amino acid peptides are potent vasoconstrictors, and endothelin-1 (ET-1) is the primary isoform produced by human endothelium (George, 2011). Plasma ET-1 levels are increased in normotensive pregnant women, but women with preeclampsia have even higher levels (Ajne, 2003; Clark, 1992). According to Taylor and Roberts (1999), the placenta is not the source of increased ET-1 concentrations, and they likely arise from systemic endothelial activation. Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz, 2003).

Angiogenic and Antiangiogenic Proteins

Placental vasculogenesis is evident by 21 days after conception. There is an ever-expanding list of pro- and antiangiogenic substances involved in placental vascular development. The families of vascular endothelial growth factor (VEGF) and angiopoietin (Ang) are most extensively studied. *Angiogenic imbalance* is used to describe excessive amounts of antiangiogenic factors that are hypothesized to be stimulated by worsening hypoxia at the uteroplacental interface. Trophoblast of women destined to develop preeclampsia overproduces at least two antiangiogenic peptides that enter the maternal circulation (Karumanchi, 2014):

1. *Soluble Fms-like tyrosine kinase 1 (sFlt-1)* is a variant of the Flt-1 receptor for placental growth factor (PlGF) and for VEGF. Increased maternal sFlt-1 levels inactivate and decrease circulating free PlGF and VEGF concentrations,

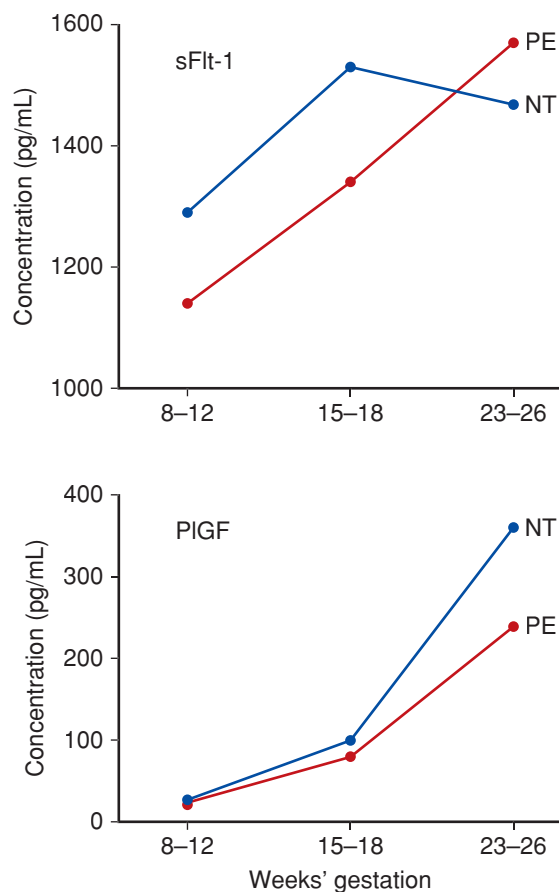

FIGURE 40-4 Angiogenic and antiangiogenic factors in normotensive (NT) and preeclamptic (PE) women across pregnancy. Both pairs of factors are significantly divergent by 23 to 26 weeks. sFlt = soluble Fms-like tyrosine kinase 1; PlGF = placental growth factor. (Data from Myatt, 2013.)

leading to endothelial dysfunction (Maynard, 2003). As shown in [Figure 40-4](#), sFlt-1 levels begin to increase in maternal serum months before preeclampsia is evident. Haggerty and colleagues (2012) observed that these high levels in the second trimester were associated with a doubling of the risk for preeclampsia. This divergence from normal levels appears to occur even sooner with early-onset preeclampsia (Vatten, 2012).

2. **Soluble endoglin (sEng)** is a placenta-derived 65-kDa molecule that blocks endoglin, which is a surface coreceptor for the TGF β family. Also called CD105, this soluble form of endoglin inhibits various TGF β isoforms from binding to endothelial receptors and results in decreased endothelial nitric oxide-dependent vasodilatation (Levine, 2006; Venkatesha, 2006). Serum levels of sEng also begin to increase months before clinical preeclampsia develops (Haggerty, 2012).

The cause of placental overproduction of antiangiogenic proteins remains an enigma. Concentrations of the soluble forms are not increased in the fetal circulation or amniotic fluid, and their levels in maternal blood dissipate after delivery (Staff, 2007). Research currently is focused on immunological mechanisms, oxidative stress, mitochondrial pathology,

and hypoxia genes (Karumanchi, 2014). Clinical research is directed at use of antiangiogenic proteins in the prediction and diagnosis of preeclampsia. In a systematic review, Widmer and associates (2007) concluded that third-trimester elevation of sFlt-1 levels and decreased PlGF concentrations correlate with preeclampsia development after 25 weeks. These results require verification in prospective studies. Subsequently, Haggerty and coworkers (2012) reported that doubling of expressions of sFlt-1 and sEng increased the preeclampsia risk 39 and 74 percent, respectively.

PATHOPHYSIOLOGY

Although the cause of preeclampsia remains unknown, evidence for its manifestation begins early in pregnancy with covert pathophysiological changes that gain momentum across gestation and eventually become clinically apparent. Unless delivery supervenes, these changes ultimately result in multiorgan involvement with a clinical spectrum ranging from an attenuated manifestation to one of cataclysmic deterioration that is life threatening for both mother and fetus. As discussed, these are thought to be a consequence of endothelial dysfunction, vasospasm, and ischemia. Although the many maternal consequences of the preeclampsia syndrome are usually described in terms of individual organ systems, they frequently are multiple, and they overlap clinically.

Cardiovascular System

Severe disturbances of normal cardiovascular function are common with preeclampsia syndrome. These are related to: (1) increased cardiac afterload caused by hypertension; (2) cardiac preload, which is affected negatively by pathologically diminished hypervolemia of pregnancy and is increased by intravenous crystalloid or oncotic solutions; and (3) endothelial activation with interendothelial extravasation of intravascular fluid into the extracellular space and importantly, into the lungs.

Hemodynamic Changes and Cardiac Function

The cardiovascular aberrations of pregnancy-related hypertensive disorders vary depending on several modifiers. These factors include hypertension severity, underlying chronic disease, preeclampsia severity, and in which part of the clinical spectrum these are studied. In some women, these cardiovascular changes may precede hypertension onset (De Paco, 2008; Easterling, 1990; Khalil, 2012; Melchiorre, 2013). Nevertheless, with the clinical onset of preeclampsia, cardiac output declines, due at least in part to increased peripheral resistance. When assessing cardiac function in preeclampsia, consideration is given to echocardiographic measures of *myocardial function* and to clinically relevant *ventricular function*.

Myocardial Function. Serial echocardiographic studies have documented in preeclampsia evidence for ventricular remodeling that is accompanied by diastolic dysfunction in 40 percent of women (Melchiorre, 2012). In some of these women, functional differences persisted up to 16 months after delivery (Evans, 2011). Ventricular remodeling was judged to be an

FIGURE 40-5 Ventricular function in normally pregnant women (striped area) and in women with eclampsia (boxed area) is plotted on a Braunwald ventricular function curve. Normal values are from Clark, 1989, and those for eclampsia are from Hankins, 1984. LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.

adaptive response to maintain normal contractility with the increased afterload of preeclampsia. In the otherwise healthy pregnant woman, these changes are usually clinically inconsequential. But when combined with underlying ventricular dysfunction—for example, concentric ventricular hypertrophy from chronic hypertension—further diastolic dysfunction may cause cardiogenic pulmonary edema as discussed in Chapters 47 (p. 943) and 49 (p. 990).

Ventricular Function. Despite the relatively high frequency of diastolic dysfunction with preeclampsia, in most women clinical cardiac function is appropriate. This has been shown by several studies in which ventricular function was assessed using invasive hemodynamic methods (Hibbard, 2014). Importantly, both normally pregnant women and those with preeclampsia syndrome can have normal or slightly hyperdynamic ventricular function (Fig. 40-5). Thus, both have a cardiac output that is appropriate for left-sided filling pressures. Data from preeclamptic women obtained by invasive hemodynamic studies are confounded because of the heterogeneity of populations and interventions that also may significantly alter these measurements. Some of these are crystalloid infusions, antihypertensive agents, and magnesium sulfate.

Ventricular function studies of preeclamptic women from several investigations are shown in Figure 40-6. Although cardiac function was hyperdynamic in all women, filling pressures were dependent on the volume of intravenous fluids. Specifically, aggressive hydration resulted in overtly hyperdynamic ventricular function in most women. However, this was accompanied by elevated pulmonary capillary wedge pressures. In some of these women, pulmonary edema may develop despite normal ventricular function because of an alveolar endothelial-epithelial leak. This is compounded by decreased oncotic pressure from a low serum albumin concentration (American College of Obstetricians and Gynecologists, 2012b).

Thus, increased cardiac output and hyperdynamic ventricular function is largely a result of low wedge pressures and not a result of augmented myocardial contractility. By comparison, women given appreciably larger volumes of fluid commonly had filling pressures that exceeded normal, but their ventricular function remained hyperdynamic because of concomitantly increased cardiac output.

From these studies, it is reasonable to conclude that aggressive fluid administration to otherwise normal women with severe preeclampsia substantially elevates normal left-sided filling pressures and increases a physiologically normal cardiac output to hyperdynamic levels.

Blood Volume

For nearly 100 years, *hemoconcentration* has been a hallmark of eclampsia. This was not precisely quantified until Zeeman and colleagues (2009) expanded the previous observations

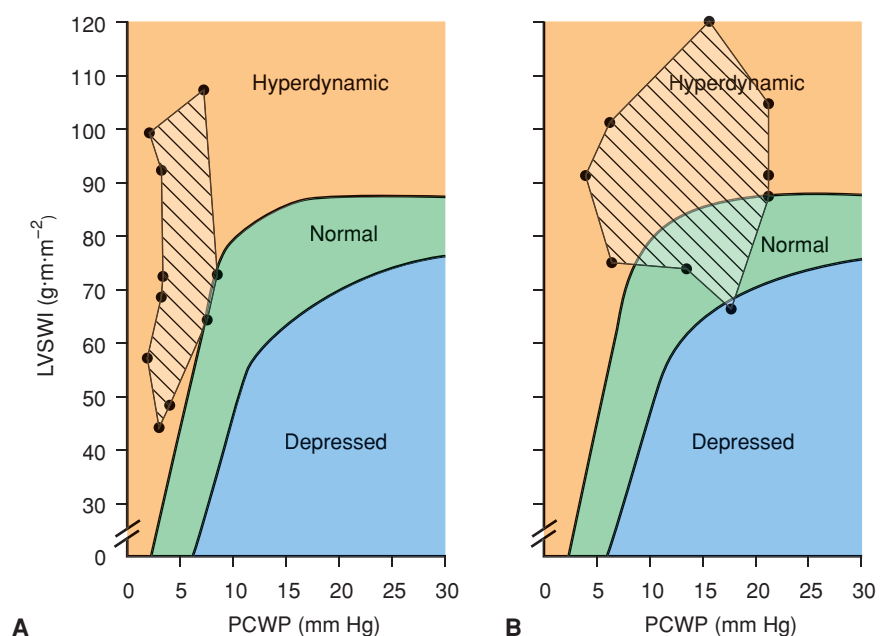

FIGURE 40-6 Ventricular function in women with severe preeclampsia-eclampsia plotted on the Braunwald ventricular function curve. The pulmonary capillary wedge pressures (PCWP) are lower in those managed with restricted fluid administration (striped area in **A**) compared with women managed with aggressive fluid therapy (striped area in **B**). In those managed with aggressive fluid infusions, eight developed pulmonary edema despite normal to hyperdynamic ventricular function in all but one. LVSWI = left ventricular stroke work index. (Data for **A** from Benedetti, 1980; Hankins, 1984; data for **B** from Rafferty, 1980; Phelan, 1982.)

of Pritchard and associates (1984) and showed in *eclamptic* women that the normally expected hypervolemia is severely curtailed (Fig. 40-7). Women of average size should have a blood volume of nearly 4500 mL during the last several weeks of a normal pregnancy. In nonpregnant women, this volume approximates only 3000 mL. With eclampsia, however, much or all of the anticipated normal excess 1500 mL is lost. Such hemoconcentration results from generalized vasoconstriction that follows endothelial activation and leakage of plasma into the interstitial space because of increased permeability. In women with *preeclampsia*, and depending on its severity, hemoconcentration is usually not as marked. Women with gestational hypertension, but without preeclampsia, usually have a normal blood volume (Silver, 1998).

For women with severe hemoconcentration, it was once taught that an acute fall in hematocrit suggested resolution of preeclampsia. In this scenario, hemodilution follows endothelial healing with return of interstitial fluid into the intravascular space. *Although this is somewhat correct, it is important to recognize that a substantive cause of this fall in hematocrit is usually the consequence of blood loss at delivery* (Chap. 41, p. 783). It may also partially result from increased erythrocyte destruction as subsequently described. Vasospasm and endothelial leakage of plasma may persist for a variable time after delivery as the endothelium is restored to normalcy. As this takes place, vasoconstriction reverses, and as the blood volume increases, the hematocrit usually falls. Thus, women with eclampsia:

- Are unduly sensitive to vigorous fluid therapy administered in an attempt to expand the contracted blood volume to normal pregnancy levels
- Are sensitive to amounts of blood loss at delivery that are considered normal for a normotensive woman.

Hematological Changes

Several hematological abnormalities are associated with the preeclampsia syndrome. Among those commonly identified is thrombocytopenia, which at times may become severe enough to be life threatening. Occasionally, the levels of some plasma clotting factors may be decreased, and erythrocytes display abnormal morphology and undergo rapid hemolysis.

Thrombocytopenia

Decreased platelet concentrations with eclampsia were described as early as 1922 by Stancke. The platelet count is routinely measured in women with any form of gestational hypertension. The frequency and intensity of thrombocytopenia vary and are dependent on the severity and duration of the preeclampsia syndrome and the frequency with which platelet counts are performed (Heilmann, 2007; Hupucz, 2007). Overt thrombocytopenia—

FIGURE 40-7 The two bar graphs on the left compare mean blood volumes in nonpregnant and term normally pregnant women. On the right, graphs display values for a group of 29 women with eclampsia and their nonpregnant values. The red bar reflects values for a subset of 14 who had a subsequent normotensive pregnancy. Extensions above bars represent one standard deviation. Comparison between values with identical lowercase letters, that is, a-a, b-b, c-c, d-d, are significant $p < .001$. (Data from Zeeman, 2009, with permission.)

defined by a platelet count $< 100,000/\mu\text{L}$ —indicates severe disease (see Table 40-2). In general, the lower the platelet count, the higher the rates of maternal and fetal morbidity and mortality (Leduc, 1992). In most cases, delivery is advisable because thrombocytopenia usually continues to worsen. After delivery, the platelet count may continue to decline for the first day or so. It then usually increases progressively to reach a normal level within 3 to 5 days. As discussed on page 768, in some instances with HELLP syndrome, the platelet count continues to fall after delivery. If these do not reach a nadir until 48 to 72 hours, then preeclampsia syndrome may be incorrectly attributed to one of the thrombotic microangiopathies (George, 2013). These syndromes are discussed in Chapter 56 (p. 1116).

Other Platelet Abnormalities

In addition to thrombocytopenia, there are myriad other platelet alterations described with the preeclampsia syndrome. These were reviewed by Kenny and coworkers (2014) and include platelet activation with increased α -degranulation producing β -thromboglobulin, factor 4, and increased clearance. Paradoxically, in most studies, in vitro platelet aggregation is decreased compared with the normal increase characteristic of pregnancy. This likely is due to platelet “exhaustion” following in vivo activation. Although the cause is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated. Platelet-bound and circulating platelet-bindable immunoglobulins are increased, which suggest platelet surface alterations.

Neonatal Thrombocytopenia

Severe thrombocytopenia does not develop in the fetus or infant born to preeclamptic women despite severe maternal thrombocytopenia (Kenny, 2014; Pritchard, 1987). *Importantly,*

maternal thrombocytopenia in hypertensive women is not a fetal indication for cesarean delivery.

Hemolysis

Severe preeclampsia is frequently accompanied by evidence of hemolysis as manifest by elevated serum lactate dehydrogenase levels and decreased haptoglobin levels. Other evidence comes from schizocytosis, spherocytosis, and reticulocytosis in peripheral blood (Cunningham, 1985; Pritchard, 1954, 1976). These derangements result in part from *microangiopathic hemolysis* caused by endothelial disruption with platelet adherence and fibrin deposition. Sanchez-Ramos and colleagues (1994) described increased erythrocyte membrane fluidity with HELLP syndrome. Cunningham and coworkers (1995) postulated that these changes were due to serum lipid alterations, and Mackay and associates (2012) found substantively decreased long-chain fatty acid content in erythrocytes of preeclamptic women. Erythrocytic membrane changes, increased adhesiveness, and aggregation may also promote a hypercoagulable state (Gamzu, 2001).

HELLP Syndrome. Subsequent to reports of hemolysis and thrombocytopenia with severe preeclampsia, descriptions followed that abnormally elevated serum liver transaminase levels were commonly found and were indicative of hepatocellular necrosis (Chesley, 1978). Weinstein (1982) referred to this combination of events as the *HELLP syndrome*—and this moniker now is used worldwide. Also, and as shown in Table 40-2, facets of the HELLP syndrome are included in criteria that differentiate severe from nonsevere preeclampsia. The HELLP syndrome is discussed in further detail on page 742.

Coagulation Changes

Subtle changes consistent with intravascular coagulation, and less often erythrocyte destruction, commonly are found with preeclampsia and especially eclampsia (Kenny, 2014). Some of these changes include increased factor VIII consumption, increased levels of fibrinopeptides A and B and of D-dimers, and decreased levels of regulatory proteins—antithrombin III and protein C and S. Except for thrombocytopenia discussed above, coagulation aberrations generally are mild and are seldom clinically significant (Kenny, 2014; Pritchard, 1984). Unless there is associated placental abruption, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy. Fibrin degradation products such as D-dimers are elevated only occasionally. *Fibronectin*, a glycoprotein associated with vascular endothelial cell basement membrane, is elevated in women with preeclampsia (Brubaker, 1992). As preeclampsia worsens, so do abnormal findings with *thromboelastography* (Pisani-Conway, 2013). Despite these changes, routine laboratory assessments of coagulation, including prothrombin time, activated partial thromboplastin time, and plasma fibrinogen level, were found to be unnecessary in the management of pregnancy-associated hypertensive disorders (Barron, 1999).

Volume Homeostasis

The normal pregnancy-induced extra- and intracellular volume increases that are accompanied by vasodilatation undergo

further complex shifts with the preeclampsia syndrome. In addition to blood volume changes shown in Figure 40-7, there are many hormonal, fluid, and electrolyte aberrations.

Endocrine Changes

Plasma levels of *renin*, *angiotensin II*, *angiotensin 1–7*, *aldosterone*, and *atrial natriuretic peptide* are substantively increased during normal pregnancy. *Deoxycorticosterone (DOC)* is a potent mineralocorticoid that is also increased remarkably in normal pregnancy (Chap. 4, p. 71). This compound results from conversion of plasma progesterone to DOC rather than increased maternal adrenal secretion. Because of this, DOC secretion is not reduced by sodium retention or hypertension. This may explain why women with preeclampsia retain sodium (Winkel, 1980). In pregnancy, the mineralocorticoid receptor becomes less sensitive to aldosterone (Armanini, 2012).

Vasopressin levels are similar in nonpregnant, normally pregnant, and preeclamptic women even though the metabolic clearance is increased in the latter two (Dürr, 1999).

Atrial natriuretic peptide is released during atrial wall stretching from blood volume expansion, and it responds to cardiac contractility (Chap. 4, p. 61). Serum levels rise in pregnancy, and its secretion is further increased in women with preeclampsia (Borghi, 2000; Luft, 2009). Levels of its precursor—proatrial natriuretic peptide—are also increased in preeclampsia (Sugulle, 2012).

Fluid and Electrolyte Changes

In women with severe preeclampsia, the volume of *extracellular fluid*, manifest as edema, is usually much greater than that in normal pregnant women. The mechanism responsible for pathological fluid retention is thought to be endothelial injury (Davidge, 2014). In addition to generalized edema and proteinuria, these women have reduced plasma oncotic pressure. This reduction creates a filtration imbalance and further displaces intravascular fluid into the surrounding interstitium.

Electrolyte concentrations do not differ appreciably in women with preeclampsia compared with those of normal pregnant women. This may not be the case if there has been vigorous diuretic therapy, sodium restriction, or administration of free water with sufficient oxytocin to produce antidiuresis.

Following an eclamptic convulsion, the *serum pH* and *bicarbonate* concentration are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced—metabolic acidosis—and the rate at which carbon dioxide is exhaled—respiratory acidosis.

Kidney

During normal pregnancy, renal blood flow and glomerular filtration rate are increased appreciably (Chap. 4, p. 63). With development of preeclampsia, there may be a number of reversible anatomical and pathophysiological changes. Of clinical importance, renal perfusion and glomerular filtration are reduced. Levels that are much less than normal nonpregnant values are infrequent and are the consequence of severe disease.

A small degree of decreased glomerular filtration may result from reduced plasma volume. Most of the decrement, however, is from increased renal afferent arteriolar resistance that may be elevated up to fivefold (Conrad, 2014; Cornelis, 2011). There are also morphological changes characterized by *glomerular endotheliosis* blocking the filtration barrier. This is discussed further subsequently. Diminished filtration causes serum creatinine levels to rise to values seen in nonpregnant individuals, that is, 1 mg/mL, and sometimes even higher (Lindheimer, 2008a). Abnormal values usually begin to normalize 10 days or later after delivery (Spaan, 2012a).

In most preeclamptic women, urine sodium concentration is elevated. Urine osmolality, urine:plasma creatinine ratio, and fractional excretion of sodium also indicate that a prerenal mechanism is involved. Kirshon and coworkers (1988) infused dopamine intravenously into oliguric women with preeclampsia, and this renal vasodilator stimulated increased urine output, fractional sodium excretion, and free water clearance. As was shown in Figure 40-6, sodium-containing crystalloid infusion increases left ventricular filling pressure, and although oliguria temporarily improves, rapid infusions may cause clinically apparent pulmonary edema. *Intensive intravenous fluid therapy is not indicated as “treatment” for preeclamptic women with oliguria. Exceptions are diminished urine output from hemorrhage or fluid loss from vomiting or fever.*

Plasma uric acid concentration is typically elevated in preeclampsia. The elevation exceeds the reduction in glomerular filtration rate and likely is also due to enhanced tubular reabsorption (Chesley, 1945). At the same time, preeclampsia is associated with diminished urinary excretion of calcium, perhaps because of increased tubular reabsorption (Taufield, 1987). Another possibility is from increased placental urate production compensatory to increased oxidative stress.

Proteinuria

As shown in Table 40-1, some degree of proteinuria will establish the diagnosis of preeclampsia syndrome. Proteinuria may develop late, and some women may already be delivered or have had an eclamptic convulsion before it appears. For example, 10 to 15 percent of women with HELLP syndrome did not have proteinuria at presentation (Sibai, 2004). In another report, 17 percent of eclamptic women did not have proteinuria by the time of seizures (Zwart, 2008).

Problematically, the optimal method of establishing abnormal levels of either urine protein or albumin remains to be defined. Chen and associates (2008) have shown that clean-catch and catheterized urine specimens correlate well. But dipstick qualitative determinations depend on urinary concentration and are notorious for false-positive and -negative results. For a 24-hour quantitative specimen, the “consensus” threshold value used is $> 300 \text{ mg}/24 \text{ h}$ (Task Force, 2013). Tun and colleagues (2012) have shown equivalent efficacy using protein excretion of 165 mg in a 12-hour sample. Importantly, these values have not been irrefutably established.

Determination of urinary protein:creatinine ratio may supplant the cumbersome 24-hour quantification (Ethridge, 2013; Kyle, 2008; Morris, 2012). In a systematic review, Papanna and associates (2008) concluded that random urine

protein:creatinine ratios that are below 130 to 150 mg/g, that is, 0.13 to 0.15, indicate a low likelihood of proteinuria exceeding 300 mg/day. Midrange ratios, that is, 300 mg/g or 0.3 have poor sensitivity and specificity. Stout and colleagues (2013) found that values < 0.08 or > 1.19 had negative- or positive-predictive values of 86 and 96 percent, respectively. At this time, most recommend that with midrange ratio values, 24-hour protein excretion should be quantified.

There are several methods used to measure proteinuria, and none detect all of the various proteins normally excreted (Nayeri, 2013). A more accurate method involves measurement of albumin excretion. Albumin filtration exceeds that of larger globulins, and with glomerular disease such as preeclampsia, most of the protein in urine is albumin. There are test kits that permit rapid measurement of urinary albumin:creatinine ratios in an outpatient setting (Kyle, 2008).

Although worsening or nephrotic-range proteinuria has been considered by most to be a sign of severe disease, this does not appear to be the case (Airoldi, 2007). Certainly, this concept was not accepted by the 2013 Task Force. Finally, increasing proteinuria is more common in multifetal pregnancy complicated by preeclampsia (Zilberberg, 2013).

Anatomical Changes

Sheehan and Lynch (1973) commonly found changes identifiable at autopsy by light and electron microscopy in the kidneys of eclamptic women. Glomeruli are enlarged by approximately 20 percent, they are “bloodless,” and capillary loops variably are dilated and contracted. Endothelial cells are swollen—termed *glomerular capillary endotheliosis* by Spargo and associates (1959). Endothelial cells are often so swollen that they block or partially block the capillary lumens (Fig. 40-8). Homogeneous subendothelial deposits of proteins and fibrin-like material are seen.

Endothelial swelling may result from angiogenic factor “withdrawal” caused by free angiogenic proteins complexing with the circulating antiangiogenic protein receptor discussed on page 735 (Conrad, 2014; Eremina, 2007; Karumanchi, 2009). The angiogenic proteins are crucial for podocyte health, and their inactivation leads to podocyte dysfunction and endothelial swelling. One marker of this is excretion of podocyte proteins such as nephrin, podocalyxin, and $\beta\text{ig-h}3$ (transforming growth factor, β -induced) (Wang, 2012b). Also, eclampsia is characterized by increased excretion of urinary podocytes, a phenomenon shared by other proteinuric disorders (Garrett, 2013; Wagner, 2012). Of interest, podocytes are epithelia, and thus renal pathology involves both endothelial and epithelial cells (see Fig. 40-8).

Acute Kidney Injury

Rarely is *acute tubular necrosis* caused by preeclampsia alone. Although mild degrees are encountered in neglected cases, clinically apparent renal failure is invariably induced by coexistent hemorrhage with hypovolemia and hypotension (Chap. 41, p. 814). This is usually caused by severe obstetrical hemorrhage for which adequate blood replacement is not given. Drakeley and coworkers (2002) described 72 women with preeclampsia and renal failure. Half had HELLP syndrome, and a third had placental abruption. As discussed on page 742, Haddad and colleagues (2000) reported that 5 percent of 183 women

FIGURE 40-8 Schematic showing glomerular capillary endotheliosis. The capillary of the normal glomerulus shown on the left has wide endothelial fenestrations, and the pedicels emanating from the podocytes are widely spaced (arrow). The illustration on the right is of a glomerulus with changes induced by the preeclampsia syndrome. The endothelial cells are swollen and their fenestrae narrowed, as are the pedicels that now abut each other.

with HELLP syndrome had kidney injury. Half of these, however, also had a placental abruption, and most had postpartum hemorrhage. Rarely, irreversible *renal cortical necrosis* develops (Chap. 53, p. 1064).

Liver

Hepatic changes in women with fatal eclampsia were described in 1856 by Virchow. The characteristic lesions were regions of periportal hemorrhage in the liver periphery. In their elegant autopsy studies, Sheehan and Lynch (1973) described that some degree of hepatic infarction accompanied hemorrhage in almost half of women who died with eclampsia. These corresponded with reports that had appeared during the 1960s describing elevated serum hepatic transaminase levels. Along with the earlier observations by Pritchard and associates (1954), who described hemolysis and thrombocytopenia with eclampsia, this constellation of hemolysis, hepatocellular necrosis, and thrombocytopenia was later termed *HELLP syndrome* by Weinstein (1985) to call attention to its seriousness (p. 742).

Lesions as extensive as those shown in Figure 40-9 are unusual, even in the autopsy series by Sheehan and Lynch (1973). From a pragmatic point, liver involvement with preeclampsia may be clinically significant in several circumstances.

First, symptomatic involvement is considered a sign of severe disease. It typically manifests by moderate to severe right-upper quadrant or midepigastria pain and tenderness. In many cases, such women also have elevated levels of serum aminotransferase, namely, aspartate aminotransferase (AST) or alanine aminotransferase (ALT). In some cases, however, the amount of hepatic tissue involved with infarction may be surprisingly extensive yet still clinically insignificant. In our experiences, infarction may be worsened by hypotension from obstetrical hemorrhage, and it occasionally causes hepatic failure—so-

called shock liver (Alexander, 2009).

Second, asymptomatic elevations of serum hepatic transaminase levels—AST and ALT—are also considered markers for severe preeclampsia. Values seldom exceed 500 U/L, but have been reported to be greater than 2000 U/L in some women (Chap. 55, p. 1085). In general, serum levels inversely follow platelet levels, and they both usually normalize within 3 days following delivery as previously discussed on page 738.

In a third example of liver involvement, hemorrhagic infarction may extend to form a hepatic hematoma. These in turn may extend to form a subcapsular hematoma that may rupture. They can be identified using computed tomography (CT) scanning or

magnetic resonance (MR) imaging as shown in Figure 40-10. Unruptured hematomas are probably more common than clinically suspected and are more likely to be found with HELLP syndrome (Carlson, 2004; Vigil-De Gracia, 2012). Although once considered a surgical condition, contemporaneous management usually consists of observation and conservative treatment of hematomas unless hemorrhage is ongoing. In some cases, however, prompt surgical intervention may be lifesaving. Vigil-De Gracia and coworkers (2012) reviewed 180 cases of hepatic hematoma or rupture. More than 90 percent had HELLP syndrome, and in 90 percent, the capsule had ruptured. The maternal mortality rate was 22 percent, and the perinatal mortality rate was 31 percent. In rare cases, liver transplant is necessary (Hunter, 1995; Wicke, 2004).

Last, acute fatty liver of pregnancy is sometimes confused with preeclampsia (Nelson, 2013; Sibai, 2007a). It too has an onset in late pregnancy, and often there is accompanying

FIGURE 40-9 Gross liver specimen from a woman with preeclampsia who died from aspiration pneumonitis. Periportal hemorrhagic necrosis was seen microscopically. (From Cunningham, 1993.)

FIGURE 40-10 Abdominal CT imaging performed postpartum in a woman with severe HELLP syndrome and right-upper quadrant pain. A large subcapsular hematoma (*asterisk*) is seen confluent with intrahepatic infarction and hematoma (*arrowhead*). Numerous flame-shaped hemorrhages are seen at the hematoma interface (*arrows*).

hypertension, elevated serum transaminase and creatinine levels, and thrombocytopenia (Chap. 55, p. 1086).

HELLP Syndrome

There is no universally accepted strict definition of this syndrome, and thus its incidence varies by investigator. When it is identified, the likelihood of hepatic hematoma and rupture is substantially increased. In a multicenter study, Haddad and colleagues (2000) described 183 women with HELLP syndrome of whom 40 percent had adverse outcomes including two maternal deaths. The incidence of subcapsular liver hematoma was 1.6 percent. Other complications included eclampsia—6 percent, placental abruption—10 percent, acute kidney injury—5 percent, and pulmonary edema—10 percent. Other serious complications included stroke, coagulopathy, acute respiratory distress syndrome, and sepsis.

Women with preeclampsia complicated by the HELLP syndrome typically have worse outcomes than those without these findings (Kozic, 2011; Martin, 2012, 2013). In their review of 693 women with HELLP syndrome, Keiser and coworkers (2009) reported that 10 percent had concurrent eclampsia. Sep and associates (2009) also described a significantly increased risk for complications in women with HELLP syndrome compared with those with “isolated preeclampsia.” These included eclampsia—15 versus 4 percent; preterm birth—93 versus 78 percent; and perinatal mortality rate—9 versus 4 percent, respectively. Because of these marked clinical differences, these investigators postulate that HELLP syndrome has a distinct pathogenesis. Others have shown a difference in the ratio of antiangiogenic and inflammatory acute-phase proteins in these two conditions and have reached similar conclusions (Reimer, 2013). Given all of the variables contributing to the incidence and pathophysiology of preeclampsia as discussed on page 736, this is a reasonable conclusion. Sibai and Stella (2009) have discussed some of these aspects under the rubric of “atypical preeclampsia-eclampsia.”

Pancreas

According to Sheehan and Lynch (1973), there are no convincing data that the pancreas has special involvement with preeclampsia syndrome. If so, the occasional case reports of concurrent hemorrhagic pancreatitis are likely unrelated (Swank, 2012). That said, severe hemoconcentration may predispose to pancreatic inflammation.

Brain

Headaches and visual symptoms are common with severe preeclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but CT- and MR-imaging and Doppler studies have added many important insights into cerebrovascular involvement.

Neuroanatomical Lesions

Most gross anatomical descriptions of the brain in eclamptic women are taken from eras when mortality rates were high. One consistent finding was that brain pathology accounted for only about a third of fatal cases such as the one shown in [Figure 40-11](#). In fact, most deaths were from pulmonary edema, and brain lesions were coincidental. Thus, although gross intracerebral hemorrhage was seen in up to 60 percent of eclamptic women, it was fatal in only half of these (Melrose, 1984; Richards, 1988; Sheehan, 1973). As shown in [Figure 40-12](#), other principal lesions found at autopsy of eclamptic women were cortical and subcortical petechial hemorrhages. The classic microscopic vascular lesions consist of fibrinoid necrosis of the arterial wall and perivascular microinfarcts and hemorrhages. Other frequently described major lesions include subcortical edema, multiple nonhemorrhagic areas of “softening” throughout the brain, and hemorrhagic areas in the white matter. There also may be hemorrhage in the basal ganglia or pons, often with rupture into the ventricles.

Cerebrovascular Pathophysiology

Clinical, pathological, and neuroimaging findings have led to two general theories to explain cerebral abnormalities with

FIGURE 40-11 This autopsy brain slice shows a fatal hypertensive hemorrhage in a primigravida with eclampsia.

FIGURE 40-12 Composite illustration showing location of cerebral hemorrhages and petechiae in women with eclampsia. Insert shows the level of the brain from which the main image was constructed. (Data from Sheehan, 1973.)

eclampsia. Importantly, endothelial cell dysfunction that characterizes the preeclampsia syndrome likely plays a key role in both. The first theory suggests that in response to acute and severe hypertension, cerebrovascular overregulation leads to vasospasm (Trommer, 1988). This presumption is based on the angiographic appearance of diffuse or multifocal segmental narrowings suggestive of vasospasm (Ito, 1995). In this scheme, diminished cerebral blood flow is hypothesized to result in ischemia, cytotoxic edema, and eventually tissue infarction. Although this theory was widely embraced for many years, there is little objective evidence to support it.

The second theory is that sudden elevations in systemic blood pressure exceed the normal cerebrovascular autoregulatory capacity (Hauser, 1988; Schwartz, 2000). Regions of forced vasodilation and vasoconstriction develop, especially in arterial boundary zones. At the capillary level, disruption of end-capillary pressure causes increased hydrostatic pressure, hyperperfusion, and extravasation of plasma and red cells through endothelial tight-junction openings. This leads to *vasogenic edema*. This theory is incomplete because very few eclamptic women have mean arterial pressures that exceed limits of autoregulation—approximately 160 mm Hg.

It seems reasonable to conclude that the most likely mechanism is a combination of the two. Thus, a preeclampsia-associated interendothelial cell leak develops at blood pressure (hydraulic) levels much lower than those usually causing vasogenic edema and is coupled with a loss of upper-limit autoregulation (Zeeman, 2009). With imaging studies, these changes manifest as facets of the *reversible posterior leukoencephalopathy syndrome* (Hinchey, 1996). This subsequently became referred to as the *posterior reversible encephalopathy syndrome*—PRES. This term is misleading because although PRES lesions principally involve the posterior brain—the occipital and parietal cortices—in at least a third of cases, they also involve other brain areas (Edlow, 2013; Zeeman,

2004a). The most frequently affected region is the parietooccipital cortex—the boundary zone of the anterior, middle, and posterior cerebral arteries. Also, in most cases, these lesions are reversible (Cipolla, 2014).

Cerebral Blood Flow

Autoregulation is the mechanism by which cerebral blood flow remains relatively constant despite alterations in cerebral perfusion pressure. In nonpregnant individuals, this mechanism protects the brain from hyperperfusion when mean arterial pressures increase to as high as 160 mm Hg. These are pressures far greater than those seen in all but a very few women with eclampsia. Thus, to explain eclamptic seizures, it was theorized that autoregulation must be altered by pregnancy. Although species differences must be considered, studies by Cipolla and colleagues (2007, 2009, 2014) have convincingly shown that autoregulation is unchanged across pregnancy in rodents. That said, some, but not others, have provided evidence of impaired

autoregulation in women with preeclampsia (Janzarik, 2014; van Veen, 2013).

Zeeman and associates (2003) showed that cerebral blood flow during the first two trimesters of normal pregnancy is similar to nonpregnant values, but thereafter, it significantly decreases by 20 percent during the last trimester. These investigators also documented significantly increased cerebral blood flow in women with severe preeclampsia compared with that of normotensive pregnant women (Zeeman, 2004b). Taken together, these findings suggest that eclampsia occurs when cerebral hyperperfusion forces capillary fluid interstitially because of endothelial damage, which leads to perivascular edema characteristic of the preeclampsia syndrome. In this regard, eclampsia is an example of the posterior reversible encephalopathy syndrome as previously discussed.

Neurological Manifestations

There are several neurological manifestations of the preeclampsia syndrome. Each signifies severe involvement and requires immediate attention. First, *headache and scotomata* are thought to arise from cerebrovascular hyperperfusion that has a predilection for the occipital lobes. According to Sibai (2005) and Zwart and coworkers (2008), 50 to 75 percent of women have headaches and 20 to 30 percent have visual changes preceding eclamptic convulsions. The headaches may be mild to severe and intermittent to constant. In our experiences, they are unique in that they do not usually respond to traditional analgesia, but they do improve after magnesium sulfate infusion is initiated.

Convulsions are a second potential manifestation and are diagnostic for eclampsia. These are caused by excessive release of excitatory neurotransmitters—especially glutamate; massive depolarization of network neurons; and bursts of action potentials (Meldrum, 2002). Clinical and experimental evidence

suggest that extended seizures can cause significant brain injury and later brain dysfunction.

As a third manifestation, *blindness* is rare with preeclampsia alone, but it complicates eclamptic convulsions in up to 15 percent of women (Cunningham, 1995). Blindness has been reported to develop up to a week or more following delivery (Chambers, 2004). There are at least two types of blindness as discussed subsequently.

Last, *generalized cerebral edema* may develop and is usually manifest by mental status changes that vary from confusion to coma. This situation is particularly dangerous because fatal transtentorial herniation may result.

Neuroimaging Studies

With CT imaging, localized hypodense lesions at the gray- and white-matter junction, primarily in the parietooccipital lobes, are typically found in eclampsia. Such lesions may also be seen in the frontal and inferior temporal lobes, the basal ganglia, and thalamus (Brown, 1988). The spectrum of brain involvement is wide, and increasing involvement can be identified with CT imaging. Edema of the occipital lobes or diffuse cerebral edema may cause symptoms such as blindness, lethargy, and confusion (Cunningham, 2000). In the latter cases, widespread edema shows as a marked compression or even obliteration of the cerebral ventricles. Such women may develop signs of impending life-threatening transtentorial herniation.

Several MR imaging acquisitions are used to study eclamptic women. Common findings are hyperintense T2 lesions—posterior reversible encephalopathy syndrome (PRES)—in the subcortical and cortical regions of the parietal and occipital lobes (Fig. 40-13). There is also relatively common involvement of the basal ganglia, brainstem, and cerebellum (Brewer, 2013; Zeeman, 2004a). Although these PRES lesions are almost universal in women with eclampsia, their incidence in women with preeclampsia is less frequent. They are more likely to be found

FIGURE 40-13 Cranial magnetic resonance imaging in a nullipara with eclampsia. Multilobe T2-FLAIR high-signal lesions are apparent. FLAIR = fluid-attenuated inversion recovery. (Image contributed by Dr. Gerda Zeeman.)

FIGURE 40-14 Cranial magnetic resonance imaging performed 3 days postpartum in a woman with eclampsia and HELLP syndrome. Neurovisual defects persisted at 1 year, causing job disability. (From Murphy, 2005, with permission.)

in women who have severe disease and who have neurological symptoms (Schwartz, 2000). And although usually reversible, a fourth of these hyperintense lesions represent cerebral infarctions that have persistent findings (Loureiro, 2003; Zeeman, 2004a).

Visual Changes and Blindness

Scotomata, blurred vision, or diplopia are common with severe preeclampsia and eclampsia. These usually improve with magnesium sulfate therapy and/or lowered blood pressure. Blindness is less common, is usually reversible, and may arise from three potential areas. These are the visual cortex of the occipital lobe, the lateral geniculate nuclei, and the retina. In the retina, pathological lesions may be ischemia, infarction, or detachment (Roos, 2012).

Occipital blindness is also called *amaurosis*—from the Greek *dimming*. Affected women usually have evidence of extensive occipital lobe vasogenic edema on imaging studies. Of 15 women cared for at Parkland Hospital, occipital blindness lasted from 4 hours to 8 days, but it resolved completely in all cases (Cunningham, 1995). Rarely, extensive cerebral infarctions may result in total or partial visual defects (Fig. 40-14).

Blindness from retinal lesions is caused either by serous retinal detachment or rarely by retinal infarction, which is termed *Purtscher retinopathy* (Fig. 40-15). *Serous retinal detachment* is usually unilateral and seldom causes total visual loss. In fact, asymptomatic serous retinal detachment is relatively common (Saito, 1998). In most cases of eclampsia-associated blindness, visual acuity subsequently improves, but if caused by retinal artery occlusion, vision may be permanently impaired (Lara-Torre, 2002; Roos, 2012). In some women, these findings are additive. Moseman and Shelton (2002) described a woman with permanent blindness due to a combination of retinal infarctions and bilateral lesions in the lateral geniculate nuclei.

FIGURE 40-15 Purtscher retinopathy caused by choroidal ischemia and infarction in preeclampsia syndrome. **A.** Ophthalmoscopy shows scattered yellowish, opaque lesions of the retina (arrows). **B.** The late phase of fluorescein angiography shows areas of intense hyperfluorescence representing pooling of extravasated dye. Cerebral Edema

Clinical manifestations suggesting widespread cerebral edema are worrisome. During 13 years at Parkland Hospital, 10 of 175 women with eclampsia were diagnosed with symptomatic cerebral edema (Cunningham, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In most cases, symptoms waxed and waned. Mental status changes generally correlated with the degree of involvement seen with CT and MR imaging studies. *These women are very susceptible to sudden and severe blood pressure elevations, which can acutely worsen the already widespread vasogenic edema.* Thus, careful blood pressure control is essential. In the 10 women with generalized edema, three became comatose and had imaging findings of impending transtentorial herniation. One of these three died from herniation. Consideration is given for treatment with mannitol or dexamethasone.

Long-Term Neurocognitive Sequelae

Women with eclampsia have been shown to have some cognitive decline when studied 5 to 10 years following an eclamptic pregnancy. This is discussed further on page 770.

■ Uteroplacental Perfusion

Defects in endovascular trophoblastic invasion and placenta- tion germane to development of the preeclampsia syndrome and fetal-growth restriction were discussed on page 732. Of immense clinical importance, compromised uteroplacental perfusion is almost certainly a major culprit in the increased perinatal morbidity and mortality rates. Thus, measurement of uterine, intervillous, and placental blood flow would likely be informative. Attempts to assess these in humans have been hampered by several obstacles that include inaccessibility of the placenta, the complexity of its venous effluent, and the need for radioisotopes or invasive techniques.

Measurement of uterine artery blood flow velocity has been used to estimate resistance to uteroplacental blood flow (Chap. 17, p. 345). Vascular resistance is estimated by comparing arte-

rial systolic and diastolic velocity waveforms. By the completion of placentation, impedance to uterine artery blood flow is markedly decreased, but with abnormal placentation, abnormally high resistance persists (Everett, 2012; Ghidini, 2008; Napolitano, 2012). Earlier studies were done to assess this by measuring peak systolic:diastolic velocity ratios from uterine and umbilical arteries in preeclamptic pregnancies. The results were interpreted as showing that in some cases, but certainly not all, there was increased resistance (Fleischer, 1986; Trudinger, 1990).

Another Doppler waveform—uterine artery “notching”—has been reported to be associated with increased risks for preeclampsia or fetal-growth restriction (Groom, 2009). In the MFMU Network study reported by Myatt and colleagues (2012a), however, notching had a low predictive value except for early-onset severe disease.

Matijevic and Johnson (1999) measured resistance in *uterine spiral arteries*. Impedance was higher in peripheral than in central vessels—a so-called ring-like distribution. Mean resistance was higher in all women with preeclampsia compared with that in normotensive controls. Ong and associates (2003) used MR imaging and other techniques to assess placental perfusion ex vivo in the myometrial arteries removed from women with preeclampsia or fetal-growth restriction. These investigators confirmed that in both conditions myometrial arteries exhibited endothelium-dependent vasodilatory response. Moreover, other pregnancy conditions are also associated with increased resistance (Urban, 2007). One major adverse effect, fetal-growth restriction, is discussed in Chapter 44 (p. 874).

Pimenta and colleagues (2013) assessed placental vascularity using a three-dimensional power Doppler histogram. These researchers described the *placental vascularity index*, which was decreased in women with any pregnancy-associated hypertensive disorders—11.1 percent compared with 15.2 percent in normal controls.

Despite these findings, evidence for compromised uteroplacental circulation is found in only a few women who go on to develop preeclampsia. Indeed, when preeclampsia develops during the third trimester, only a third of women with severe

disease have abnormal uterine artery velocimetry (Li, 2005). In a study of 50 women with HELLP syndrome, only a third had abnormal uterine artery waveforms (Bush, 2001). In general, the extent of abnormal waveforms correlates with severity of fetal involvement (Ghidini, 2008; Groom, 2009).

PREDICTION AND PREVENTION

Prediction

Measurement during early pregnancy—or across pregnancy—of various biological, biochemical, and biophysical markers implicated in preeclampsia syndrome pathophysiology has been proposed to predict its development. Attempts have been made to identify early markers of faulty placentation, impaired placental perfusion, endothelial cell activation and dysfunction, and activation of coagulation. For the most, these have resulted in testing strategies with poor sensitivity and with poor positive-predictive value for preeclampsia (Conde-Agudelo, 2014; Lindheimer, 2008b; Odibo, 2013). Currently, no screening tests are predictably reliable, valid, and economical (Kleinrouweler, 2012). There are, however, combinations of tests, some yet to be adequately evaluated, that may be promising (Dugoff, 2013; Kuc, 2011; Navaratnam, 2013; Olsen, 2012).

The list of predictive factors evaluated during the past three decades is legion. Although most have been evaluated in the first half of pregnancy, some have been tested as predictors of severity in the third trimester (Chaiworapongsa, 2013; Mosimann, 2013; Rana, 2012). Others have been used to forecast recurrent preeclampsia (Demers, 2014). Some of these tests are listed in Table 40-4, which is by no means all inclusive. Conde-Agudelo and coworkers (2014) have recently provided a thorough review of many of these testing strategies.

Vascular Resistance Testing and Placental Perfusion

Most of these are cumbersome, time consuming, and overall inaccurate.

Provocative Pressor Tests. Three tests have been extensively evaluated to assess the blood pressure rise in response to a stimulus. The *roll-over test* measures the hypertensive response in women at 28 to 32 weeks who are resting in the left lateral decubitus position and then roll over to the supine position. Increased blood pressure signifies a positive test. The *isometric exercise test* employs the same principle by squeezing a handball. The *angiotensin II infusion test* is performed by giving incrementally increasing doses intravenously, and the hypertensive response is quantified. In their updated metaanalysis, Conde-Agudelo and associates (2014) found sensitivities of all three tests to range from 55 to 70 percent, and specificities approximated 85 percent.

Uterine Artery Doppler Velocimetry. Faulty trophoblastic invasion of the spiral arteries, which is depicted in Figure 40-2, results in diminished placental perfusion and upstream increased uterine artery resistance. Increased uterine artery velocimetry determined by Doppler ultrasound in the first two trimesters should provide indirect evidence of this process and thus serve as a predictive test for preeclampsia (Gebb, 2009a,b; Groom, 2009). As described on page 745 and in Chapter 10 (p. 220), increased flow resistance results in an abnormal waveform represented by an exaggerated *diastolic notch*. These have value for fetal-growth restriction but not preeclampsia (American College of Obstetricians and Gynecologists, 2013a). Several flow velocity waveforms—alone or in combination—have been investigated for preeclampsia prediction. In some of these, predictive values for early-onset preeclampsia were promising (Herraiz, 2012).

TABLE 40-4. Predictive Tests for Development of the Preeclampsia Syndrome

Testing Related To:	Examples
Placental perfusion/ vascular resistance	Roll-over test, isometric handgrip or cold pressor test, pressor response to aerobic exercise, angiotensin-II infusion, midtrimester mean arterial pressure, platelet angiotensin-II binding, renin, 24-hour ambulatory blood pressure monitoring, uterine artery or fetal transcranial Doppler velocimetry
Fetal-placental unit endocrine dysfunction	Human chorionic gonadotropin (hCG), alpha-fetoprotein (AFP), estriol, pregnancy-associated protein A (PAPP A), inhibin A, activin A, placental protein 13, corticotropin-releasing hormone, A disintegrin, ADAM-12, kisspeptin
Renal dysfunction	Serum uric acid, microalbuminuria, urinary calcium or kallikrein, microtransferrinuria, N-acetyl-β-glucosaminidase, cystatin C, podocyuria
Endothelial dysfunction/ oxidant stress	Platelet count and activation, fibronectin, endothelial adhesion molecules, prostaglandins, prostacyclin, MMP-9, thromboxane, C-reactive protein, cytokines, endothelin, neurokinin B, homocysteine, lipids, insulin resistance, antiphospholipid antibodies, plasminogen activator-inhibitor (PAI), leptin, p-selectin, angiogenic factors such as placental growth factor (PlGF), vascular endothelial growth factor (VEGF), fms-like tyrosine kinase receptor-1 (sFlt-1), endoglin
Others	Antithrombin-III(AT-3), atrial natriuretic peptide (ANP), β ₂ -microglobulin, haptoglobin, transferrin, ferritin, 25-hydroxyvitamin D, genetic markers, cell-free fetal DNA, serum and urine proteomics and metabolomic markers, hepatic aminotransferases

ADAM12 = ADAM metallopeptidase domain 12; MMP = matrix metalloproteinase.
Adapted from Conde-Agudelo, 2014.

At this time, however, none is suitable for clinical use (Conde-Agudelo, 2014; Kleinrouweler, 2012; Myatt, 2012a).

Pulse Wave Analysis. Like the uterine artery, finger arterial pulse “stiffness” is an indicator of cardiovascular risk. Investigators have preliminarily evaluated its usefulness in preeclampsia prediction (Vollebregt, 2009).

Fetal-Placental Unit Endocrine Function

Several serum analytes that have been proposed to help predict preeclampsia are shown in Table 40-4. Newer ones are continuously added (Jeyabalan, 2009; Kanasaki, 2008; Kenny, 2009). Many of these gained widespread use in the 1980s to identify fetal malformations and were also found to be associated with other pregnancy abnormalities such as neural-tube defects and aneuploidy (Chap. 14, p. 289). Although touted for hypertension prediction, in general, none of these tests has been shown to be clinically beneficial for that purpose.

Tests of Renal Function

Serum Uric Acid. One of the earliest laboratory manifestations of preeclampsia is hyperuricemia (Powers, 2006). It likely results from reduced uric acid clearance from diminished glomerular filtration, increased tubular reabsorption, and decreased secretion (Lindheimer, 2008a). It is used by some to define preeclampsia, but Cnossen and coworkers (2006) reported that its sensitivity ranged from 0 to 55 percent, and specificity was 77 to 95 percent.

Microalbuminuria. As a predictive test for preeclampsia, microalbuminuria has sensitivities ranging from 7 to 90 percent and specificities between 29 and 97 percent (Conde-Agudelo, 2014). Poon and colleagues (2008) likewise found unacceptable sensitivity and specificity for urine albumin:creatinine ratios.

Endothelial Dysfunction and Oxidant Stress

As discussed on page 733, endothelial activation and inflammation are major participants in the pathophysiology of the preeclampsia syndrome. As a result, compounds such as those listed in Table 40-4 are found in circulating blood of affected women, and some have been assessed for their predictive value.

Fibronectins. These high-molecular-weight glycoproteins are released from endothelial cells and extracellular matrix following endothelial injury (Chavarria, 2002). More than 30 years ago, plasma concentrations were reported to be elevated in women with preeclampsia (Stubbs, 1984). Following their systematic review, however, Leeftang and associates (2007) concluded that neither cellular nor total fibronectin levels were clinically useful to predict preeclampsia.

Coagulation Activation. Thrombocytopenia and platelet dysfunction are integral features of preeclampsia as discussed on page 738. Platelet activation causes increased destruction and decreased concentrations, and mean platelet volume rises because of platelet immaturity (Kenny, 2014). Although markers of coagulation activation are increased, the substantive overlap with levels in normotensive pregnant women stultifies their predictive value.

Oxidative Stress. Increased levels of lipid peroxides coupled with decreased antioxidant activity have raised the possibility that markers of oxidative stress might predict preeclampsia. For example, malondialdehyde is a marker of lipid peroxidation. Other markers are various prooxidants or their potentiators. These include iron, transferrin, and ferritin; blood lipids, including triglycerides, free fatty acids, and lipoproteins; and antioxidants such as ascorbic acid and vitamin E (Bainbridge, 2005; Conde-Agudelo, 2014; Mackay, 2012; Powers, 2000). These have not been found to be predictive, and treatment to prevent preeclampsia with some of them has been studied as discussed on page 748.

Hyperhomocysteinemia causes oxidative stress and endothelial cell dysfunction and is characteristic of preeclampsia. Although women with elevated serum homocysteine levels at midpregnancy had a three- to fourfold risk of preeclampsia, these tests have not been shown to be clinically useful predictors (D’Anna, 2004; Mignini, 2005; Zeeman, 2003).

Angiogenic Factors. As discussed on page 735, evidence has accrued that an imbalance between proangiogenic and antiangiogenic factors is related to preeclampsia pathogenesis. Serum levels of some proangiogenic factors—vascular endothelial growth factor (VEGF) and placental growth factor (PlGF)—begin to decrease before clinical preeclampsia develops. And, recall as shown in Figure 40-4 that at the same time levels of some antiangiogenic factors such as sFlt-1 and sEng become increased (Maynard, 2008). In one study, these abnormalities were identified coincidentally with rising uterine artery Doppler resistance (Coolman, 2012).

Conde-Agudelo and colleagues (2014) reviewed the predictive accuracy of some of these factors for severe preeclampsia. Sensitivities for all cases of preeclampsia ranged from 30 to 50 percent, and specificity was about 90 percent. Their predictive accuracy was higher for early-onset preeclampsia. These preliminary results suggest a clinical role for preeclampsia prediction. However, until this role is better substantiated, their general clinical use is not currently recommended (Boucoiran, 2013; Kleinrouweler, 2012; Widmer, 2007). Automated assays are being studied, and the World Health Organization (WHO) began a multicenter trial in 2008 to evaluate these factors (Sunderji, 2009).

Cell-Free Fetal DNA

As discussed in Chapter 13 (p. 279), cell-free fetal DNA can be detected in maternal plasma. It has been reported that fetal-maternal cell trafficking is increased in pregnancies complicated by preeclampsia (Holzgreve, 1998). It is hypothesized that cell-free DNA is released by accelerated apoptosis of cytotrophoblasts (DiFederico, 1999). From their review, Conde-Agudelo and associates (2014) concluded that cell-free fetal DNA quantification is not yet useful for prediction purposes.

Proteomic, Metabolomic, and Transcriptomic Markers

Methods to study serum and urinary proteins and cellular metabolites have opened a new vista for preeclampsia prediction. Preliminary studies indicate that these may become useful (Bahado-Singh, 2013; Carty, 2011; Liu, 2013; Myers, 2013).

TABLE 40-5. Some Methods to Prevent Preeclampsia That Have Been Evaluated in Randomized Trials

Dietary manipulation —low-salt diet, calcium or fish oil supplementation
Exercise —physical activity, stretching
Cardiovascular drugs —diuretics, antihypertensive drugs
Antioxidants —ascorbic acid (vitamin C), α -tocopherol (vitamin E), vitamin D
Antithrombotic drugs —low-dose aspirin, aspirin/dipyridamole, aspirin + heparin, aspirin + ketanserin

Modified from Staff, 2014.

Prevention

Various strategies used to prevent or modify preeclampsia severity have been evaluated. Some are listed in Table 40-5. In general, none of these has been found to be convincingly and reproducibly effective.

Dietary and Lifestyle Modifications

A favorite of many theorists and faddists for centuries, dietary “treatment” for preeclampsia has produced some interesting abuses as chronicled by Chesley (1978).

Low-Salt Diet. One of the earliest research efforts to prevent preeclampsia was salt restriction (De Snoo, 1937). This interdiction was followed by years of inappropriate diuretic therapy. Although these practices were discarded, it ironically was not until relatively recently that the first randomized trial was done and showed that a sodium-restricted diet was ineffective in preventing preeclampsia in 361 women (Knuist, 1998). Guidelines from the United Kingdom National Institute for Health and Clinical Excellence (2010) recommend against salt restrictions.

Calcium Supplementation. Studies performed in the 1980s outside the United States showed that women with low dietary calcium intake were at significantly increased risk for gestational hypertension (Belizan, 1980; López-Jaramillo, 1989; Marya, 1987). Calcium supplementation has been studied in several trials, including one by the National Institute of Child Health and Human Development (NICHD) that included more than 4500 nulliparous women (Levine, 1997). In one recent meta-analysis, Patreli and coworkers (2012) reported that increased calcium intake lowered the risk for preeclampsia in high-risk women. In aggregate, most of these trials have shown that unless women are calcium deficient, supplementation has no salutary effects (Staff, 2014).

Fish Oil Supplementation. Cardioprotective fatty acids found in some fatty fishes are plentiful in diets of Scandinavians and American Eskimos. The most common dietary sources are EPA—eicosapentaenoic acid, ALA—alpha-linoleic acid, and DHA—docosahexaenoic acid. With proclamations that supplementation with these fatty acids would prevent inflammatory-mediated atherogenesis, it was not a quantum leap to posit that they might also prevent preeclampsia. Unfortunately,

randomized trials conducted thus far have shown no such benefits (Makrides, 2006; Olafsdottir, 2006; Olsen, 2000; Zhou, 2012a).

Exercise. There are a few studies done to assess the protective effects of physical activity on preeclampsia. In their systematic review, Kasawara and associates (2012) reported a trend toward risk reduction with exercise. More research is needed in this area (Staff, 2014).

Antihypertensive Drugs

Because of the putative effects of sodium restriction, diuretic therapy became popular with the introduction of chlorothiazide in 1957 (Finnerty, 1958; Flowers, 1962). In their metaanalysis, Churchill and colleagues (2007) summarized nine randomized trials that included more than 7000 pregnancies. They found that women given diuretics had a decreased incidence of edema and hypertension but not of preeclampsia.

Because women with chronic hypertension are at high risk for preeclampsia, several randomized trials—only a few placebo-controlled—have been done to evaluate various antihypertensive drugs to reduce the incidence of superimposed preeclampsia. A critical analysis of these trials by Staff and coworkers (2014) failed to demonstrate salutary effects.

Antioxidants

There are inferential data that an imbalance between oxidant and antioxidant activity may play an important role in the pathogenesis of preeclampsia (p. 747). Thus, naturally occurring antioxidants—vitamins C, D, and E—might decrease such oxidation. Indeed, women who developed preeclampsia were found to have reduced plasma levels of these antioxidants (De-Regil, 2012; Raijmakers, 2004). There have now been several randomized studies to evaluate vitamin supplementation for women at high risk for preeclampsia (Poston, 2006; Rumbold, 2006; Villar, 2007). The one by the MFMU Network included almost 10,000 low-risk nulliparas (Roberts, 2009). None of these studies showed reduced preeclampsia rates in women given vitamins C and E compared with those given placebo. The recent metaanalysis by De-Regil and colleagues (2012) likewise showed no benefits of vitamin D supplementation.

The rationale for the use of *statins* to prevent preeclampsia is that they stimulate hemoxygenase-1 expression that inhibits sFlt-1 release. There are preliminary animal data that statins may prevent hypertensive disorders of pregnancy. The MFMU Network plans a randomized trial to test pravastatin for this purpose (Costantine, 2013).

Antithrombotic Agents

There are sound theoretical reasons that antithrombotic agents might reduce the incidence of preeclampsia. As discussed on page 734, the syndrome is characterized by vasospasm, endothelial cell dysfunction, and inflammation, as well as activation of platelets and the coagulation-hemostasis system. Moreover, prostaglandin imbalance(s) may be operative, and other sequelae include placental infarction and spiral artery thrombosis (Nelson, 2014).

TABLE 40-6. Maternal-Fetal Medicine Units Network Trial of Low-Dose Aspirin in Women at High Risk for Preeclampsia

Risk Factors	No.	Preeclampsia (%) ^a	
		Aspirin	Placebo
Normotensive, no proteinuria	1613	14.5	17.7
Proteinuria plus hypertension	119	31.7	22.0
Proteinuria only	48	25.0	33.3
Hypertension only	723	24.8	25.0
Insulin-dependent diabetes	462	18.3	21.6
Chronic hypertension	763	26.0	24.6
Multifetal gestation	678	11.5	15.9
Previous preeclampsia	600	16.7	19.0

^aNo statistically significant difference for any comparison between groups.
Data from Caritis, 1998.

Low-Dose Aspirin. In oral doses of 50 to 150 mg daily, aspirin effectively inhibits platelet thromboxane A₂ biosynthesis but has minimal effects on vascular prostacyclin production (Wallenburg, 1986). However, clinical trials have shown limited benefits. For example, results in Table 40-6 are from the MFMU Network, and none of the outcomes shown were significantly improved. Some reports are more favorable. For example, the Paris Collaborative Group performed a meta-analysis that included 31 randomized trials involving 32,217 women (Askie, 2007). For women assigned to receive antiplatelet agents, the relative risk for development of preeclampsia, superimposed preeclampsia, preterm delivery, or any adverse pregnancy outcome was significantly decreased by 10 percent. Another review and metaanalysis reported marginal benefits for low-dose aspirin and severe preeclampsia (Roberge, 2012). A recent small Finnish multicenter trial included 152 women at high risk for preeclampsia (Villa, 2013). Although there were no benefits to low-dose aspirin, the accompanying metaanalysis reported a lowering of risk. The 2013 Task Force recommended the use of low-dose aspirin in some high-risk women to prevent preeclampsia.

Low-Dose Aspirin plus Heparin. In women with lupus anticoagulant, treatment with low-dose aspirin and heparin mitigates thrombotic sequelae (Chap. 59, p. 1175). Because of the high prevalence of placental thrombotic lesions found with severe preeclampsia, observational trials have been done to evaluate such treatments for affected women. Sergis and associates (2006) reviewed effects of prophylaxis with low-molecular-weight heparin plus low-dose aspirin on pregnancy outcomes in women with a history of severe early-onset preeclampsia and low-birthweight neonates. They reported better pregnancy outcomes in women given low-molecular-weight heparin plus low-dose aspirin compared with those given low-dose aspirin alone. Similar findings were reported in a trial that included 139 women with thrombophilia and a history of early-onset preeclampsia (de Vries, 2012). Despite

these small trials, evidence is insufficient to recommend these regimens to prevent preeclampsia (National Institute for Health and Clinical Excellence, 2010; Staff, 2014).

MANAGEMENT

Pregnancy complicated by gestational hypertension is managed based on severity, gestational age, and presence of preeclampsia. With preeclampsia, management varies with the severity of endothelial cell injury and multiorgan dysfunction.

Preeclampsia cannot always be diagnosed definitively (p. 728). Thus, the Task Force of the American College of Obstetricians and Gynecologists (2013b) recommends more frequent prenatal visits if preeclampsia is “suspected.” *Increases in systolic and diastolic blood pressure can be either normal physiological changes or signs of developing pathology.* Increased surveillance permits more prompt recognition of ominous changes in blood pressure, critical laboratory findings, and clinical signs and symptoms (Macdonald-Wallis, 2012).

The basic management objectives for any pregnancy complicated by preeclampsia are: (1) termination of pregnancy with the least possible trauma to mother and fetus, (2) birth of an infant who subsequently thrives, and (3) complete restoration of health to the mother. In many women with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor. *One of the most important clinical questions for successful management is precise knowledge of fetal age.*

Early Diagnosis of Preeclampsia

Traditionally, the frequency of prenatal visits is increased during the third trimester, and this aids early detection of preeclampsia. *Women without overt hypertension, but in whom early developing preeclampsia is suspected during routine prenatal visits, are seen more frequently.* The protocol used successfully for many years at Parkland Hospital for women with new-onset diastolic blood pressures > 80 mm Hg but < 90 mm Hg or with sudden abnormal weight gain of more than 2 pounds per week includes, at minimum, return visits at 7-day intervals. Outpatient surveillance is continued unless overt hypertension, proteinuria, headache, visual disturbances, or epigastric discomfort supervene. Women with overt new-onset hypertension—either diastolic pressures ≥ 90 mm Hg or systolic pressures ≥ 140 mm Hg—are admitted to determine if the increase is due to preeclampsia, and if so, to evaluate its severity. Women with persistent severe disease are generally delivered, as discussed subsequently. Conversely, women with apparently mild disease can often be managed as outpatients, although there should be a low threshold for continued hospitalization for the nullipara, especially if there is proteinuria.

Evaluation

Hospitalization is considered at least initially for women with new-onset hypertension, especially if there is persistent or

worsening hypertension or development of proteinuria. A systematic evaluation is instituted to include the following:

- Detailed examination, which is followed by daily scrutiny for clinical findings such as headache, visual disturbances, epigastric pain, and rapid weight gain
- Weight determined daily
- Analysis for proteinuria or urine protein:creatinine ratio on admittance and at least every 2 days thereafter
- Blood pressure readings in the sitting position with an appropriate-size cuff every 4 hours, except between 2400 and 0600 unless previous readings had become elevated
- Measurements of plasma or serum creatinine and hepatic aminotransferase levels and a hemogram that includes platelet quantification. The frequency of testing is determined by hypertension severity. Some recommend measurement of serum uric acid and lactic acid dehydrogenase levels and coagulation studies. However, the value of these tests has been called into question (Cnossen, 2006; Conde-Agudelo, 2014; Thangaratnam, 2006).
- Evaluation of fetal size and well-being and amniotic fluid volume, with either physical examination or sonography.

Goals of management include early identification of worsening preeclampsia and development of a management plan for timely delivery. If any of these observations lead to a diagnosis of severe preeclampsia as previously defined by the criteria in Table 40-2, further management is subsequently described.

Reduced physical activity throughout much of the day is likely beneficial, but as the 2013 Task Force concluded, absolute bed rest is not desirable. Ample protein and calories should be included in the diet, and sodium and fluid intake should not be limited or forced. Further management depends on: (1) preeclampsia severity, (2) gestational age, and (3) condition of the cervix.

Fortunately, many cases are sufficiently mild and near enough to term that they can be managed conservatively until labor commences spontaneously or until the cervix becomes favorable for labor induction. Complete abatement of all signs and symptoms, however, is uncommon until after delivery. *Almost certainly, the underlying disease persists until delivery is accomplished.*

■ Consideration for Delivery

Termination of pregnancy is the only cure for preeclampsia. Headache, visual disturbances, or epigastric pain are indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia demands anticonvulsant and frequently antihypertensive therapy, followed by delivery. Treatment is identical to that described subsequently for eclampsia. The prime objectives are to forestall convulsions, to prevent intracranial hemorrhage and serious damage to other vital organs, and to deliver a healthy newborn.

When the fetus is preterm, the tendency is to temporize in the hope that a few more weeks in utero will reduce the risk of neonatal death or serious morbidity from prematurity. As discussed, such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function

are performed, especially when the fetus is immature. Most recommend frequent performance of various tests to assess fetal well-being as described by the American College of Obstetricians and Gynecologists (2012a). These include the *nonstress test* or the *biophysical profile* (Chap. 17, pp. 338 and 341). Measurement of the lecithin-sphingomyelin (L/S) ratio in amniotic fluid may provide evidence of lung maturity (Chap. 34, p. 655).

With moderate or severe preeclampsia that does not improve after hospitalization, delivery is usually advisable for the welfare of both mother and fetus. This is true even when the cervix is unfavorable (Tajik, 2012). Labor induction is carried out, usually with preinduction cervical ripening from a prostaglandin or osmotic dilator (Chap. 26, p. 525). Whenever it appears that induction almost certainly will not succeed or attempts have failed, then cesarean delivery is indicated.

For a woman near term, with a soft, partially effaced cervix, even milder degrees of preeclampsia probably carry more risk to the mother and her fetus-infant than does induction of labor (Tajik, 2012). The decision to deliver late-preterm fetuses is not clear. Barton and coworkers (2009) reported excessive neonatal morbidity in women delivered before 38 weeks despite having stable, mild, nonproteinuric hypertension. The Netherlands study of 4316 newborns delivered between 34^{0/7} and 36^{6/7} weeks also described substantive neonatal morbidity in these cases (Langenveld, 2011). Most of these deliveries were before 36 weeks, and the higher cesarean delivery rates were associated with more respiratory complications. Conversely, one randomized trial of 756 women with mild preeclampsia supported delivery after 37 weeks (Koopmans, 2009).

Elective Cesarean Delivery

Once severe preeclampsia is diagnosed, labor induction and vaginal delivery have traditionally been considered ideal. Temporization with an immature fetus is considered subsequently. Several concerns, including an unfavorable cervix, a perceived sense of urgency because of preeclampsia severity, and a need to coordinate neonatal intensive care, have led some to advocate cesarean delivery. Alexander and colleagues (1999) reviewed 278 singleton live-born neonates weighing 750 to 1500 g delivered of women with severe preeclampsia at Parkland Hospital. In half of the women, labor was induced, and the remainder underwent cesarean delivery without labor. Induction was successful in accomplishing vaginal delivery in a third, and it was not harmful to the very-low-birthweight infants. Alanis and associates (2008) reported similar observations. The results of a systematic review also confirmed these conclusions (Le Ray, 2009).

■ Hospitalization versus Outpatient Management

For women with mild to moderate stable hypertension—whether or not preeclampsia has been confirmed—surveillance is continued in the hospital, at home for some reliable patients, or in a day-care unit. At least intuitively, reduced physical activity throughout much of the day seems beneficial. Several observational studies and randomized trials have addressed the benefits of inpatient care and outpatient management.

Somewhat related, Abenhaim and coworkers (2008) reported a retrospective cohort study of 677 nonhypertensive women hospitalized for bed rest because of threatened preterm delivery. When outcomes of these women were compared with those of the general obstetrical population, bed rest was associated with a significantly reduced relative risk—RR 0.27—of developing preeclampsia. In a review of two small randomized trials totaling 106 women at high risk for preeclampsia, prophylactic bed rest for 4 to 6 hours daily at home was successful in significantly lowering the incidence of preeclampsia but not gestational hypertension (Meher, 2006).

These and other observations support the claim that restricted activity alters the underlying pathophysiology of the preeclampsia syndrome. That said, complete bed rest is not recommended by the 2013 Task Force. First, this is pragmatically unachievable because of the severe restrictions it places on otherwise well women. Also, as discussed in Chapter 52 (p. 1029), it likely also predisposes to thromboembolism (Knight, 2007).

High-Risk Pregnancy Unit

The concept of prolonged hospitalization for women with hypertension arose during the 1970s. At Parkland Hospital, an inpatient antepartum unit was established in 1973 by Dr. Peggy Whalley in large part to provide care for such women. Initial results from this unit were reported by Hauth (1976) and Gilstrap (1978) and their colleagues. Most hospitalized women have a beneficial response characterized by amelioration or improvement of hypertension. *These women are not “cured,” and nearly 90 percent have recurrent hypertension before or during labor.* By 2013, more than 10,000 nulliparas with mild to moderate early-onset hypertension during pregnancy had been managed successfully in this unit. Provider costs—not charges—for this relatively simple physical facility, modest nursing care, no drugs other than iron and folate supplements, and few essential laboratory tests are minimal compared with the cost of neonatal intensive care for a preterm infant. None of these women have suffered thromboembolic disease.

Home Health Care

Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has legitimized third-party payers to deny hospitalization reimbursement. Consequently, many women with mild to moderate hypertension are managed at home. Outpatient management may continue as long as preeclampsia syndrome does not worsen and fetal jeopardy is not suspected. Sedentary activity throughout the greater part of the day is recommended. These women are instructed in detail to report symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may prove beneficial. Caution is exercised regarding use of certain automated home blood pressure monitors (Lo, 2002; Ostchega, 2012).

In an observational study by Barton and associates (2002), 1182 nulliparas with mild gestational hypertension—20 percent had proteinuria—were managed with home health care. Their mean gestational ages were 32 to 33 weeks at enrollment and 36 to 37 weeks at delivery. Severe preeclampsia developed

in approximately 20 percent, about 3 percent developed HELLP syndrome, and two women had eclampsia. Perinatal outcomes were generally good. In approximately 20 percent, there was fetal-growth restriction, and the perinatal mortality rate was 4.2 per 1000.

Several prospective studies have been designed to compare continued hospitalization with either home health care or a day-care unit. In a pilot study from Parkland Hospital, Horsager and colleagues (1995) randomly assigned 72 nulliparas with new-onset hypertension from 27 to 37 weeks either to continued hospitalization or to outpatient care. In all of these women, proteinuria had receded to less than 500 mg per day when they were randomized. Outpatient management included daily blood pressure monitoring by the patient or her family. Weight and dipstick spot urine protein determinations were evaluated three times weekly. A home health nurse visited twice weekly, and the women were seen weekly in the clinic. Perinatal outcomes were similar in each group. The only significant difference was that women in the home care group developed severe preeclampsia significantly more frequently than hospitalized women—42 versus 25 percent.

A larger randomized trial reported by Crowther and coworkers (1992) included 218 women with mild gestational nonproteinuric hypertension. After evaluation, half remained hospitalized, whereas the other half was managed as outpatients. As shown in Table 40-7, the mean duration of hospitalization was 22.2 days for women with inpatient management compared with only 6.5 days in the home-care group. Preterm delivery before 34 and before 37 weeks was increased twofold in the outpatient group, but maternal and infant outcomes otherwise were similar.

Day-Care Unit

Another approach, popular in European countries, is day care (Milne, 2009). This approach has been evaluated by several investigators. In the study by Tuffnell and associates (1992), 54 women with hypertension after 26 weeks' gestation were assigned to either day care or routine outpatient management (see Table 40-7). Progression to overt preeclampsia and labor inductions were significantly increased in the routine management group. Turnbull and coworkers (2004) enrolled 395 women who were randomly assigned to either day care or inpatient management (see Table 40-7). Almost 95 percent had mild to moderate hypertension. Of enrolled women, 288 were without proteinuria, and 86 had $\geq 1+$ proteinuria. There were no perinatal deaths, and none of the women developed eclampsia or HELLP syndrome. Surprisingly, costs for either scheme were not significantly different. Perhaps not surprisingly, general satisfaction favored day care.

Summary of Hospitalization versus Outpatient Management

From the above, either inpatient or close outpatient management is appropriate for a woman with mild de novo hypertension, including those with nonsevere preeclampsia. Most of these studies were carried out in academic centers with dedicated management teams. That said, the key to success is close follow-up and a conscientious patient with good home support.

TABLE 40-7. Randomized Clinical Trials Comparing Hospitalization versus Routine Care for Women with Mild Gestational Hypertension or Preeclampsia

Antihypertensive Therapy for Mild to Moderate Hypertension

The use of antihypertensive drugs in attempts to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various types and severities of hypertensive disorders has been of considerable interest. Treatment for women with chronic hypertension complicating pregnancy is discussed in detail in Chapter 50 (p. 1005).

Drug treatment for early mild preeclampsia has been disappointing as shown in representative randomized trials listed in Table 40-8. Sibai and colleagues (1987a) evaluated the effectiveness of labetalol and hospitalization compared with hospitalization alone in 200 nulliparas with gestational hypertension from 26 to 35 weeks' gestation. Although women given labetalol had significantly lower mean blood pressures, there were no differences between the groups in terms of mean pregnancy prolongation, gestational age at delivery, or birthweight. The cesarean delivery rates were similar, as were the number of infants admitted to special-care nurseries. *The frequency of growth-restricted infants was doubled in women given labetalol—19 versus 9 percent.* The three other studies listed in Table 40-8 were performed to compare labetalol or the calcium-channel blockers, nifedipine and isradipine, with placebo. Except for fewer episodes of severe hypertension, none of these studies showed any benefits of antihypertensive treatment. Moreover, there may have been treatment-induced adverse fetal growth (Von Dadelszen, 2002).

Abalos and associates (2007) reviewed 46 randomized trials of active antihypertensive therapy compared with either no treatment or placebo given to women with mild to moderate gestational hypertension. Except for a halving of the risk for developing severe hypertension, active antihypertensive therapy had no beneficial effects. They further reported that fetal-growth restriction *was not increased* in treated women. In this vein, it is also controversial whether β -blocking agents cause fetal-growth restriction if given for chronic hypertension

(August, 2014; Umans, 2014). Thus, any salutary or adverse effects of antihypertensive therapy seem minimal at most.

Delayed Delivery

Up through the early 1990s, it was the practice that all women with severe preeclampsia were delivered without delay. During the past 25 years, however, another approach for women with preterm severe preeclampsia has been advocated. This approach calls for “conservative” or “expectant” management with the aim of improving neonatal outcome without compromising maternal safety. Aspects of such management always include careful daily—and usually more frequent—inpatient monitoring of the mother and her fetus.

Expectant Management of Preterm Severe Preeclampsia

Theoretically, antihypertensive therapy has potential application when severe preeclampsia develops before intact neonatal survival is likely. Such management is controversial, and it may be dangerous. In one of the first studies, Sibai and the Memphis group (1985) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia between 18 and 27 weeks. The results were disastrous. *The perinatal mortality rate was 87 percent. Although no mothers died, 13 suffered placental abruption, 10 had eclampsia, three developed renal failure, two had hypertensive encephalopathy, and one each had an intracerebral hemorrhage and a ruptured hepatic hematoma.*

Because of these catastrophic outcomes, the Memphis group redefined their study criteria and performed a randomized trial of expectant versus aggressive management for 95 women who had severe preeclampsia but with more advanced gestations of 28 to 32 weeks (Sibai, 1994). *Women with HELLP syndrome were excluded from this trial.* Aggressive management included glucocorticoid administration for fetal lung maturation followed by

delivery in 48 hours. Expectantly managed women were observed at bed rest and given either labetalol or nifedipine orally if there was severe hypertension. In this study, pregnancy was prolonged for a mean of 15.4 days in the expectant management group. An overall improvement in neonatal outcomes was also reported.

Following these experiences, expectant management became more commonly practiced, but with the caveat that women with HELLP syndrome or growth-restricted fetuses were usually excluded. But in a subsequent follow-up observational study, the Memphis group compared outcomes in 133 preeclamptic women with and 136 without HELLP syndrome who presented between 24 and 36 weeks (Abramovici, 1999). Women were subdivided into three study groups. The first group included those with *complete HELLP syndrome*. The second group included women with *partial HELLP syndrome*—defined as either one or two but not all three of the defining laboratory findings. The third group included women who had severe preeclampsia without HELLP syndrome laboratory findings. Perinatal outcomes were similar in each group, and importantly, outcomes were not improved with procrastination. Despite this, the investigators concluded that women with partial HELLP syndrome and those with severe preeclampsia alone could be managed expectantly.

Sibai and Barton (2007b) reviewed expectant management of severe preeclampsia from 24 to 34 weeks. More than 1200 women were included, and although the average time gained ranged from 5 to 10 days, the maternal morbidity rates were formidable. As shown in Table 40-9, serious complications in some of these and in later studies included placental abruption, HELLP syndrome, pulmonary edema, renal failure, and eclampsia. Moreover, perinatal mortality rates averaged 90 per 1000. Fetal-growth restric-

tion was common, and in the study from The Netherlands by Ganzevoort and associates (2005a,b), it was an astounding 94 percent. Perinatal mortality rates are disproportionately high in these growth-restricted infants, but maternal outcomes were not appreciably different from pregnancies in women without growth-restricted fetuses (Haddad, 2007; Shear, 2005).

The MEXPRE Latin Study was a multicenter trial that randomly assigned 267 women with severe preeclampsia at 28 to 32 weeks to prompt delivery or to expectant management (Vigil-De Gracia, 2013). The perinatal mortality rate approximated 9 percent in each group, and these investigators found no improvements in composite neonatal morbidity with expectant management. On the other hand, fetal-growth restriction—22 versus 9 percent—and placental abruption—7.6 versus 1.5 percent—were significantly higher in the group managed expectantly.

Barber and associates (2009) conducted a 10-year review of 3408 women with severe preeclampsia from 24 to 32 weeks. They found that increasing lengths of antepartum hospital stays were associated with slight but significantly increased rates of maternal and neonatal morbidity.

Expectant Management of Midtrimester Severe Preeclampsia

Several small studies have focused on expectant management of severe preeclampsia syndrome *before 28 weeks*. In their review, Bombrys and coworkers (2008) found eight such studies that included nearly 200 women with severe preeclampsia with an onset < 26 completed weeks. Maternal complications were common. Because there were no neonatal survivors in women presenting before 23 weeks, the Task Force of the American College of Obstetricians and Gynecologists (2013b) recommends

TABLE 40-9. Maternal and Perinatal Outcomes Reported Since 2005 with Expectant Management of Severe Preeclampsia from 24 to 34 Weeks

pregnancy termination. For women with slightly more advanced pregnancies, however, the decision is less clear. For example, at 23 weeks' gestation, the perinatal survival rate was 18 percent, but long-term perinatal morbidity is yet unknown. For women with pregnancies at 24 to 26 weeks, perinatal survival approached 60 percent, and it averaged almost 90 percent for those at 26 weeks.

There have been at least five studies published since 2005 of women with severe midtrimester preeclampsia who were managed expectantly (Abdel-Hady, 2010; Belghiti, 2011; Bombrys, 2008; Budden, 2006; Gaugler-Senden, 2006). Maternal complications developed in 60 percent, and there was one death. Perinatal mortality was 65 percent. At this time, there are no comparative studies attesting to the perinatal benefits of such expectant treatment versus early delivery in the face of serious maternal complications that approach 50 percent.

Glucocorticoids for Lung Maturation

In attempts to enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a decrease in the incidence of respiratory distress and improved fetal survival has been cited. That said, there is only one randomized trial of corticosteroids given to hypertensive women for fetal lung maturation. This trial, by Amorim and colleagues (1999), included 218 women with severe preeclampsia between 26 and 34 weeks who were randomly assigned to betamethasone or placebo administration. Neonatal complications, including respiratory distress, intraventricular hemorrhage, and death, were decreased significantly when betamethasone was given compared with placebo. *On the heavily weighted negative side,*

there were two maternal deaths and 18 stillbirths. We add these findings to buttress our unenthusiastic acceptance of attempts to prolong gestation in many of these women (Alexander, 2014; Bloom, 2003).

Corticosteroids to Ameliorate HELLP Syndrome

Almost 30 years ago, Thiagarajah and associates (1984) suggested that glucocorticoids might aid treatment of the laboratory abnormalities associated with HELLP syndrome. Subsequently, Tompkins (1999) and O'Brien (2002) and their colleagues reported less than salutary effects. Martin and coworkers (2003) reviewed observational outcomes of almost 500 such women treated at their institution and reported salutary results with treatment. Unfortunately, their subsequent randomized trial compared two corticosteroids and did not include a nontreated group (Isler, 2001).

Since these observational studies, at least two prospective randomized trials have addressed this question. Fonseca and associates (2005) randomly assigned 132 women with HELLP syndrome to either dexamethasone or placebo administration. Outcomes assessed included duration of hospitalization, recovery time of abnormal laboratory test results, resolution of clinical parameters, and complications that included acute renal failure, pulmonary edema, eclampsia, and death. None of these was significantly different between the two groups. In another randomized study, Katz and coworkers (2008) assigned 105 postpartum women with HELLP syndrome to treatment with dexamethasone or placebo. They analyzed outcomes similar to the Fonseca study and found no advantage to dexamethasone. Shown in [Figure 40-16](#) are recovery times for platelet counts and serum aspartate aminotransferase (AST) levels. These times were almost identical in the two groups. For these reasons, the 2013 Task Force does not recommend

corticosteroid treatment for thrombocytopenia with HELLP syndrome. A caveat is that in women with dangerously low platelet counts, corticosteroids *might* serve to increase platelets.

Expectant Management—Risks versus Benefits—Recommendations

Taken in toto, these studies do not show overwhelming benefits compared with risks for expectant management of severe preeclampsia in those with gestations from 24 to 32 weeks. The Society for Maternal-Fetal Medicine (2011) has determined that such management is a reasonable alternative in selected women with severe preeclampsia before 34 weeks. The Task Force of the American College of Obstetricians and Gynecologists (2013b) supports this recommendation. As shown in Figure 40-17, such management calls for in-hospital maternal and fetal surveillance with delivery prompted by evidence for worsening severe preeclampsia or maternal or fetal compromise. Although attempts are made for vaginal delivery in most cases, the likelihood of cesarean delivery increases with decreasing gestational age.

Our view is more conservative. Undoubtedly, the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. There are no data to suggest that expectant management is beneficial for the mother. Indeed, it seems obvious that a delay to prolong gestation in women with severe preeclampsia may have serious maternal consequences such as those shown in Table 40-9. Notably, placental abruption develops in up to 20 percent, and pulmonary edema in as many as 4 percent. Moreover, there are substantive risks for eclampsia, cerebrovascular hemorrhage, and especially maternal death. These observations are even more pertinent when considered with the absence of convincing evidence that perinatal outcomes are markedly improved by the average prolongation of pregnancy of about 1 week. If undertaken, the caveats that mandate delivery shown in Table 40-10 should be strictly heeded.

Eclampsia

Preeclampsia complicated by generalized tonic-clonic convulsions appreciably increases the risk to both mother and fetus. Mattar and Sibai (2000) described outcomes in 399 consecutive women with eclampsia from 1977 through 1998. Major maternal complications included placental abruption—10 percent, neurological deficits—7 percent, aspiration pneumonia—7 percent, pulmonary edema—5 percent, cardiopulmonary arrest—4 percent, and acute renal failure—4 percent. Moreover, 1 percent of these women died.

FIGURE 40-16 Recovery times for platelet counts and serum aspartate aminotransferase (AST) levels in women with HELLP syndrome assigned to receive treatment with dexamethasone or placebo. (Data from Katz, 2008.)

TABLE 40-10. Indications for Delivery in Women < 34 Weeks' Gestation Managed Expectantly**Corticosteroid Therapy for Lung Maturation^a and Delivery after Maternal Stabilization:**

Uncontrolled severe hypertension
Eclampsia
Pulmonary edema
Placental abruption
Disseminated intravascular coagulation
Nonreassuring fetal status
Fetal demise

Corticosteroid Therapy for Lung Maturation—Delay Delivery 48 hr if Possible:

Preterm ruptured membranes or labor
Thrombocytopenia < 100,000/ μ L
Hepatic transaminase levels twice upper limit of normal
Fetal-growth restriction
Oligohydramnios
Reversed end-diastolic Doppler flow in umbilical artery
Worsening renal dysfunction

^aInitial dose only, do not delay delivery.

From the Society for Maternal-Fetal Medicine, 2011, and the Task Force of the American College of Obstetricians and Gynecologists, 2013b.

European maternity units also report excessive maternal and perinatal morbidity and mortality rates with eclampsia. In a report from Scandinavia, Andersgaard and associates (2006) described 232 women with eclampsia. Although there was but a single maternal death, a third of the women experienced major complications that included HELLP syndrome, renal failure, pulmonary edema, pulmonary embolism, and stroke. The United Kingdom Obstetric Surveillance System (UKOSS) audit reported by Knight (2007) described no maternal deaths in 214 eclamptic women, but five women experienced cerebral hemorrhage. In The Netherlands, there were three maternal deaths among 222 eclamptic women (Zwart, 2008). From Dublin, Akkawi and coworkers (2009) reported four maternal deaths among 247 eclamptic women (Akkawi, 2009). Data from Australia are similar (Thornton, 2013). Thus, in developed countries, the maternal mortality rate approximates 1 percent in women with eclampsia. In perspective, this is a thousand-fold increase above the overall maternal death rates for these countries.

Almost without exception—but at times unnoticed—preeclampsia precedes the onset of eclamptic convulsions. Depending on whether convulsions appear before, during, or after labor, eclampsia is designated as antepartum, intrapartum, or postpartum. Eclampsia is most common in the last trimester and becomes increasingly frequent as term approaches. In more recent years, the incidence of postpartum eclampsia has risen. This is presumably related to improved access to prenatal care, earlier detection of preeclampsia, and prophylac-

tic use of magnesium sulfate (Chames, 2002). Importantly, other diagnoses should be considered in women with convulsions more than 48 hours postpartum or in women with focal neurological deficits, prolonged coma, or atypical eclampsia (Sibai, 2009, 2012).

Immediate Management of Seizure

Eclamptic seizures may be violent, and the woman must be protected, especially her airway. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (Fig. 40-18). This phase, in which the muscles alternately contract and relax, may last approximately a minute. Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless. After a seizure, the woman is postictal, but in some, a coma of variable duration ensues. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In severe cases, coma persists from one convulsion to another, and death may result. In rare instances, a single convulsion may be followed by coma from which the woman may never emerge. As a rule, however, death does not occur until after frequent convulsions. Finally and also rarely, convulsions continue unabated—*status epilepticus*—and require deep sedation and even general anesthesia to obviate anoxic encephalopathy.

Respirations after an eclamptic convulsion are usually increased in rate and may reach 50 or more per minute in response to hypercarbia, lactic acidemia, and transient hypoxia. Cyanosis may be observed in severe cases. High fever is a grave sign as it likely emanates from cerebrovascular hemorrhage.

Proteinuria is usually, but not always, present as discussed on page 730. Urine output may be diminished appreciably, and occasionally anuria develops. There may be hemoglobinuria, but hemoglobinemia is observed rarely. Often, as shown in

**FIGURE 40-18** Hematoma of tongue from laceration during an eclamptic convulsion. Thrombocytopenia may have contributed to the bleeding.

FIGURE 40-19 Severe edema in a young nullipara with antepartum preeclampsia. (Photograph contributed by Dr. Nidhi Shah.)

Figure 40-19, peripheral and facial edema is pronounced, but it may also be absent.

As with severe preeclampsia, an increase in urinary output after delivery is usually an early sign of improvement. If there is renal dysfunction, serum creatinine levels should be monitored. Proteinuria and edema ordinarily disappear within a week postpartum. In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery (Berks, 2009). As subsequently discussed, the longer hypertension persists postpartum and the more severe it is, the more likely it is that the woman also has chronic vascular disease (Podymow, 2010).

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and may progress rapidly. If the convulsions occur during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, it is not unusual for fetal bradycardia to follow a seizure (**Fig. 40-20**). Bradycardia usually recovers within 3 to 5 minutes. If it persists more than about 10 minutes, however, then another cause such as placental abruption or imminent delivery must be considered.

Pulmonary edema may follow shortly after eclamptic convulsions or up to several hours later. This usually is caused by aspiration pneumonitis from gastric-content inhalation during vomiting that frequently accompanies convulsions. In some women, pulmonary edema may be caused by ventricular failure from increased afterload that may result from severe hypertension and further aggravated by vigorous intravenous fluid administration (Dennis, 2012b). Such pulmonary edema from ventricular

failure is more common in morbidly obese women and in those with previously unappreciated chronic hypertension.

Occasionally, sudden death occurs synchronously with an eclamptic convulsion, or it follows shortly thereafter. Most often in these cases, death results from a massive cerebral hemorrhage (see **Fig. 40-11**). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension as discussed on page 761. Rarely, they may be due to a ruptured cerebral berry aneurysm or arteriovenous malformation (Witlin, 1997a).

In approximately 10 percent of women, some degree of blindness follows a seizure. The causes of blindness or impaired vision are discussed on page 744. Blindness with severe preeclampsia without convulsions is usually due to retinal detachment (Vigil-De Gracia, 2011). Conversely, blindness with eclampsia is almost always due to occipital lobe edema (Cunningham, 1995). In both instances, however, the prognosis for return to normal function is good and is usually complete within 1 to 2 weeks postpartum.

Up to 5 percent of women with eclampsia have substantively altered consciousness, including persistent coma, following a seizure. This is due to extensive cerebral edema, and transtentorial herniation may cause death as discussed on page 744 (Cunningham, 2000).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This may last for several days to 2 weeks, but the prognosis for return to normal function is good, provided there was no preexisting mental illness. It is presumed to be similar to postpartum psychosis discussed in detail in Chapter 61 (p. 1210). Antipsychotic medications have proved effective in the few cases of post eclampsia psychosis treated at Parkland Hospital.

Differential Diagnosis

Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked. Epilepsy, encephalitis, meningitis, brain tumor, neurocysticercosis, amniotic fluid embolism, postdural puncture cephalgia, and ruptured cerebral

FIGURE 40-20 Fetal heart rate tracing shows fetal bradycardia following an intrapartum eclamptic convulsion. Bradycardia resolved and beat-to-beat variability returned approximately 5 minutes following the seizure.

TABLE 40-11. Magnesium Sulfate Dosage Schedule for Severe Preeclampsia and Eclampsia

Continuous Intravenous (IV) Infusion

Give 4- to 6-g loading dose of magnesium sulfate diluted in 100 mL of IV fluid administered over 15–20 min
Begin 2 g/hr in 100 mL of IV maintenance infusion. Some recommend 1 g/hr
Monitor for magnesium toxicity:
Assess deep tendon reflexes periodically
Some measure serum magnesium level at 4–6 hr and adjust infusion to maintain levels between 4 and 7 mEq/L (4.8 to 8.4 mg/dL)
Measure serum magnesium levels if serum creatinine \geq 1.0 mg/dL
Magnesium sulfate is discontinued 24 hr after delivery

Intermittent Intramuscular Injections

Give 4 g of magnesium sulfate ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ USP) as a 20% solution intravenously at a rate not to exceed 1 g/min
Follow promptly with 10 g of 50% magnesium sulfate solution, one half (5 g) injected deeply in the upper outer quadrant of each buttock through a 3-inch-long 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly
Every 4 hr thereafter, give 5 g of a 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after ensuring that:
The patellar reflex is present,
Respirations are not depressed, and
Urine output the previous 4 hr exceeded 100 mL

aneurysm during late pregnancy and the puerperium may simulate eclampsia. Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia.

Management of Eclampsia

It has been long recognized that magnesium sulfate is highly effective in preventing convulsions in women with preeclampsia and in stopping them in those with eclampsia. In his review, Chesley (1978) cited observational data by Pritchard and colleagues (1955, 1975) from Parkland Hospital and from his own institution, Kings County Hospital in Brooklyn. At that time, most eclampsia regimens used in the United States adhered to a similar philosophy still in use today, the tenets of which include the following:

1. Control of convulsions using an intravenously administered loading dose of magnesium sulfate that is followed by a maintenance dose, usually intravenous, of magnesium sulfate
2. Intermittent administration of an antihypertensive medication to lower blood pressure whenever it is considered dangerously high
3. Avoidance of diuretics unless there is obvious pulmonary edema, limitation of intravenous fluid administration unless fluid loss is excessive, and avoidance of hyperosmotic agents
4. Delivery of the fetus to achieve a remission of preeclampsia.

Magnesium Sulfate to Control Convulsions

In more severe cases of preeclampsia and in eclampsia, magnesium sulfate administered parenterally is an effective anticonvulsant that avoids producing central nervous system depression in either the mother or the infant. It may be given intravenously by continuous infusion or intramuscularly

by intermittent injection (Table 40-11). The dosages for severe preeclampsia are the same as for eclampsia. Because labor and delivery is a more likely time for convulsions to develop, women with preeclampsia-eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum.

Magnesium sulfate is almost universally administered intravenously. In most units, the intramuscular route has been abandoned. Of concern, magnesium sulfate solutions, although inexpensive to prepare, are not readily available in all parts of the developing world. And even when the solutions are available, the technology to infuse them may not be. Therefore, it should not be overlooked that the drug can be administered intramuscularly and that this route is as effective as intravenous administration (Salinger, 2013). In two reports from India, intramuscular regimens were nearly equivalent in preventing recurrent convulsions and maternal deaths in women with eclampsia (Chowdhury, 2009; Jana, 2013). These observations comport with earlier ones from Parkland Hospital as described by Pritchard and colleagues (1975, 1984).

Magnesium sulfate is not given to treat hypertension. Based on several studies cited subsequently and extensive clinical observations, magnesium most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial 4-g loading dose. By an hour or two, she regains consciousness sufficiently to be oriented to place and time.

The magnesium sulfate dosages presented in Table 40-11 usually result in plasma magnesium levels illustrated in Figure 40-21. When magnesium sulfate is given to arrest eclamptic seizures, 10 to 15 percent of women will have a subsequent convulsion. If so, an additional 2-g dose of magnesium

FIGURE 40-21 Comparison of serum magnesium levels in mEq/L following a 4-g intravenous loading dose of magnesium sulfate and then maintained by either an intramuscular or continuing infusion. Multiply by 1.2 to convert mEq/L to mg/dL. (Data from Sibai, 1984.)

sulfate in a 20-percent solution is slowly administered intravenously. In a small woman, this additional 2-g dose may be used once, but it can be given twice if needed in a larger woman. In only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use supplementary anticonvulsant medication to control convulsions (Pritchard, 1984). For these, an intravenous barbiturate is given slowly. Midazolam or lorazepam may be given in a small single dose, but prolonged use is avoided because it is associated with a higher mortality rate (Royal College of Obstetricians and Gynaecologists, 2006).

Maintenance magnesium sulfate therapy is continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions. Ehrenberg and Mercer (2006) studied abbreviated postpartum magnesium administration in 200 women with *mild* preeclampsia. Of 101 women randomized to 12-hour treatment, seven had worsening preeclampsia, and treatment was extended to 24 hours. None of these 101 women and none of the other cohort of 95 given the 24-hour magnesium infusion developed eclampsia. This abbreviated regimen needs further study before being routinely administered for severe preeclampsia or eclampsia.

Pharmacology and Toxicology. Magnesium sulfate USP is $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ and not simple MgSO_4 . It contains 8.12 mEq per 1 g. Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium intoxication is unusual when the glomerular filtration rate is normal or only slightly decreased. Adequate urine output usually correlates with preserved glomerular filtration rates. That said, magnesium

excretion is not urine flow dependent, and urinary volume per unit time does not, per se, predict renal function. *Thus, serum creatinine levels must be measured to detect a decreased glomerular filtration rate.*

Eclamptic convulsions are almost always prevented or arrested by plasma magnesium levels maintained at 4 to 7 mEq/L, 4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L. Although laboratories typically report *total* magnesium levels, free or *ionized* magnesium is the active moiety for suppressing neuronal excitability. Taber and associates (2002) found poor correlation between total and ionized levels. Further studies are necessary to determine if either measurement provides a superior method for surveillance.

After a 4-g intravenous loading dose in nonobese women, magnesium levels observed with the intramuscular regimen and those observed with the maintenance infusion of 2 g/hr are similar (see Fig. 40-21). The obesity epidemic has affected these observations. Tudela and colleagues (2013) reported our observations from Parkland Hospital with magnesium administration to obese women. More than 60 percent of women whose body mass index (BMI) exceeded 30 kg/m^2 and who were receiving the 2-g/hr dose had subtherapeutic levels at 4 hours. Thus, 40 percent of obese women would require 3 g/hr to maintain effective plasma levels. That said, currently most do not recommend routine magnesium level measurements (American College of Obstetricians and Gynecologists, 2013b; Royal College of Obstetricians and Gynaecologists, 2006).

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq/L—about 12 mg/dL—presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity. When plasma levels rise above 10 mEq/L, breathing becomes weakened. At 12 mEq/L or higher levels, respiratory paralysis and respiratory arrest follow. Somjen and coworkers (1966) induced marked hypermagnesemia in themselves by intravenous infusion and achieved plasma levels up to 15 mEq/L. Predictably, at such high plasma levels, respiratory depression developed that necessitated mechanical ventilation, but depression of the sensorium was not dramatic as long as hypoxia was prevented.

Treatment with calcium gluconate or calcium chloride, 1 g intravenously, along with withholding further magnesium sulfate, usually reverses mild to moderate respiratory depression. One of these agents should be readily available whenever magnesium is being infused. Unfortunately, the effects of intravenously administered calcium may be short-lived if there is a steady-state toxic level. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium are uncommon. It appears that cardiac dysfunction associated with magnesium is due to respiratory arrest and hypoxia. With appropriate ventilation, cardiac action is satisfactory even when plasma magnesium levels are exceedingly high (McCubbin, 1981; Morisaki, 2000).

Because magnesium is cleared almost exclusively by renal excretion, the dosages described will become excessive if glomerular filtration is substantially decreased. The initial 4-g loading dose

of magnesium sulfate can be safely administered regardless of renal function. It is important to administer the standard loading dose and not to reduce it under the mistaken conception that diminished renal function requires it. This is because after distribution, a loading dose achieves the desired therapeutic level, and the infusion maintains the steady-state level. *Thus, only the maintenance infusion rate should be altered with diminished glomerular filtration rate.* Renal function is estimated by measuring plasma creatinine. Whenever plasma creatinine levels are > 1.0 mg/mL, serum magnesium levels are measured to guide the infusion rate. With severe renal dysfunction, only the loading dose of magnesium sulfate is required to produce a steady-state therapeutic level.

Acute cardiovascular effects of parenteral magnesium in women with severe preeclampsia have been studied using data obtained by pulmonary and radial artery catheterization. After a 4-g intravenous dose administered over 15 minutes, mean arterial pressure fell slightly, accompanied by a 13-percent increase in cardiac index (Cotton, 1986b). Thus, magnesium decreased systemic vascular resistance and mean arterial pressure. At the same time, it increased cardiac output without evidence of myocardial depression. These findings were coincidental with transient nausea and flushing, and the cardiovascular effects persisted for only 15 minutes despite continued magnesium infusion.

Thurnau and associates (1987) showed that there was a small but highly significant increase in total magnesium concentration in the cerebrospinal fluid with magnesium therapy. The magnitude of the increase was directly proportional to the corresponding serum concentration.

Magnesium is anticonvulsant and neuroprotective in several animal models. Some proposed mechanisms of action include: (1) reduced presynaptic release of the neurotransmitter glutamate, (2) blockade of glutamatergic *N*-methyl-D-aspartate (NMDA) receptors, (3) potentiation of adenosine action, (4) improved calcium buffering by mitochondria, and (5) blockade of calcium entry via voltage-gated channels (Arango, 2006; Wang, 2012a).

Uterine Effects. Relatively high serum magnesium concentrations depress myometrial contractility both in vivo and in vitro. With the regimen described and the plasma levels that result, no evidence of myometrial depression has been observed beyond a transient decrease in activity during and immediately after the initial intravenous loading dose. Leveno and associates (1998) compared outcomes in 480 nulliparous women given phenytoin for preeclampsia with outcomes in 425 preeclamptic women given magnesium sulfate. Magnesium did not significantly alter the need for oxytocin stimulation of labor, admission-to-delivery intervals, or route of delivery. Similar results have been reported by others (Atkinson, 1995; Szal, 1999; Witlin, 1997b).

The mechanisms by which magnesium might inhibit uterine contractility are not established. It is generally assumed, however, that these depend on its effects on intracellular calcium as discussed in detail in Chapter 21 (p. 417). Inhibition of uterine contractility is magnesium dose dependent, and serum levels of at least 8 to 10 mEq/L are necessary to inhibit uterine

contractions (Watt-Morse, 1995). This likely explains why there are few if any uterine effects seen clinically when magnesium sulfate is given for preeclampsia. And as discussed in Chapter 42 (p. 852), magnesium is also not considered to be an effective tocolytic agent.

Fetal and Neonatal Effects. Magnesium administered parenterally promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amniotic fluid (Hallak, 1993). Levels in amniotic fluid increase with duration of maternal infusion (Gortzak-Uzen, 2005). Current evidence supports the view that magnesium sulfate has small but significant effects on the fetal heart rate pattern—specifically beat-to-beat variability. Hallak and coworkers (1999) compared an infusion of magnesium sulfate with a saline infusion. These investigators reported that magnesium was associated with a small and clinically insignificant decrease in variability. Similarly, in a retrospective study, Duffy and associates (2012) reported a lower heart rate baseline that was within the normal range; decreased variability; and fewer prolonged decelerations. They noted no adverse outcomes.

Overall, maternal magnesium therapy appears safe for perinates. For example, a recent MFMU Network study of more than 1500 exposed preterm neonates found no association between the need for neonatal resuscitation and cord blood magnesium levels (Johnson, 2012). Still, there are a few neonatal adverse events associated with its use. In a Parkland Hospital study of 6654 mostly term exposed newborns, 6 percent had hypotonia (Abbassi-Ghanavati, 2012). In addition, exposed neonates had lower 1- and 5-minute Apgar scores, a higher intubation rate, and more admissions to the special care nursery. The study showed that neonatal depression occurs only if there is *severe* hypermagnesemia at delivery.

Observational studies have suggested a protective effect of magnesium against the development of cerebral palsy in very-low-birthweight infants (Nelson, 1995; Schendel, 1996). At least five randomized trials have also assessed neuroprotective effects in preterm newborns. These findings are discussed in detail in Chapter 42 (p. 854). Nguyen and colleagues (2013) expanded this possibility to include term newborn neuroprotection. They performed a Cochrane Database review to compare term neonatal outcomes with and without exposure to peripartum magnesium therapy and reported that there were insufficient data to draw conclusions.

Finally, as discussed in Chapter 42 (p. 852), long-term use of magnesium, given for several days for tocolysis, has been associated with neonatal osteopenia (American College of Obstetricians and Gynecologists, 2013c).

Maternal Safety and Efficacy of Magnesium Sulfate.

The multinational Eclampsia Trial Collaborative Group study (1995) involved 1687 women with eclampsia randomly allocated to different anticonvulsant regimens. In one cohort, 453 women were randomly assigned to be given magnesium sulfate and compared with 452 given diazepam. In a second cohort, 388 eclamptic women were randomly assigned to be given magnesium sulfate and compared with

TABLE 40-12. Randomized Comparative Trials of Magnesium Sulfate with Another Anticonvulsant to Prevent Recurrent Eclamptic Convulsions

Study	Comparison Drug	Recurrent Seizures			Maternal Deaths		
		MgSO ₄ (%)	Other Drug (%)	RR (95% CI)	MgSO ₄ (%)	Other Drug (%)	RR (95% CI)
Crowther (1990)	Diazepam	5/24	7/27	0.80 (0.29–2.2)	1/24	0/27

	Diazepam	22/388	66/387	0.33 (0.21–0.53)	17/453	24/452	0.74 (0.40–1.36)
Totals		88/910 (9.7)	210/911 (23)	0.41 (0.32–0.51)	28/910 (3.1)	45/911 (4.9)	0.62 (0.39–0.99)

Data adapted from Alexander, 2014.

387 women given phenytoin. The results of these and other comparative studies that each enrolled at least 50 women are summarized in [Table 40-12](#). In aggregate, magnesium sulfate therapy was associated with a significantly lower incidence of recurrent seizures compared with women given an alternative anticonvulsant—9.7 versus 23 percent. Importantly, the maternal death rate of 3.1 percent with magnesium sulfate was significantly lower than that of 4.9 percent for the other regimens.

Magnesium safety and toxicity was recently reviewed by Smith and coworkers (2013). In more than 9500 treated women, the overall rate of absent patellar tendon reflexes was 1.6 percent; respiratory depression 1.3 percent; and calcium gluconate administration 0.2 percent. They reported only one maternal death due to magnesium toxicity. Our anecdotal experiences are similar—in the estimated 50 years of its use in more than 40,000 women, there has been only one maternal death from an overdose (Pritchard, 1984).

Management of Severe Hypertension

Dangerous hypertension can cause cerebrovascular hemorrhage and hypertensive encephalopathy, and it can trigger eclamptic convulsions in women with preeclampsia. Other complications include hypertensive afterload congestive heart failure and placental abruption (Clark, 2012).

Because of these sequelae, the National High Blood Pressure Education Program Working Group (2000) and the 2013 Task Force recommend treatment to lower systolic pressures to or below 160 mm Hg and diastolic pressures to or below 110 mm Hg. Martin and associates (2005) reported provocative observations that highlight the importance of treating systolic hypertension. They described 28 selected women with severe preeclampsia who suffered an associated stroke. Most of these were hemorrhagic strokes—93 percent—and all women had systolic pressures > 160 mm Hg before suffering their stroke. By contrast, only 20 percent of

these same women had diastolic pressures > 110 mm Hg. It seems likely that at least half of serious hemorrhagic strokes associated with preeclampsia are in women with chronic hypertension (Cunningham, 2005). Long-standing hypertension results in development of *Charcot-Bouchard aneurysms* in the deep penetrating arteries of the lenticulostriate branch of the middle cerebral arteries. These vessels supply the basal ganglia, putamen, thalamus, and adjacent deep white matter, as well as the pons and deep cerebellum. These unique aneurysmal weakenings predispose these small arteries to rupture during sudden hypertensive episodes (Chap. 50, p. 1007).

Antihypertensive Agents

Several drugs are available to rapidly lower dangerously elevated blood pressure in women with the gestational hypertensive disorders. The three most commonly employed are hydralazine, labetalol, and nifedipine. For years, parenteral hydralazine was the only one of these three available. But when parenteral labetalol was later introduced, it was considered to be equally effective for obstetrical use. Orally administered nifedipine has since then gained some popularity as first-line treatment for severe gestational hypertension.

Hydralazine

This is probably still the most commonly used antihypertensive agent in the United States for treatment of women with severe gestational hypertension. Hydralazine is administered intravenously with a 5-mg initial dose, and this is followed by 5- to 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved (American College of Obstetricians and Gynecologists, 2012b). Some limit the total dose to 30 mg per treatment cycle (Sibai, 2003). The target response antepartum or intrapartum is a decrease in diastolic blood pressure to 90 to 110 mm Hg. Lower diastolic pressures risk compromised placental perfusion. Hydralazine has proven remarkably effective

to prevent cerebral hemorrhage. Its onset of action can be as rapid as 10 minutes. Although repeated administration every 15 to 20 minutes may theoretically lead to undesirable hypotension, this has not been our experience when given in these 5- to 10-mg increments.

At Parkland Hospital, between 5 and 10 percent of all women with intrapartum hypertensive disorders are given a parenteral antihypertensive agent. Most often, we use hydralazine as described. We do not limit the total dose, and seldom has a second antihypertensive agent been needed. We estimate that nearly 6000 women have been so treated at Parkland during the past 50 years. Although less popular in Europe, hydralazine is used in some centers, according to the Royal College of Obstetricians and Gynaecologists (2006). A dissenting opinion for first-line intrapartum use of hydralazine was voiced by the Vancouver group after a systematic review (Magee, 2009). At the same time, however, Umans and coworkers (2014) concluded that objective outcome data did not support the use of one drug over another.

As with any antihypertensive agent, the tendency to give a larger initial dose of hydralazine if the blood pressure is higher must be avoided. The response to even 5- to 10-mg doses cannot be predicted by hypertension severity. Thus, our protocol is to always administer 5 mg as the initial dose. An adverse response to exceeding this initial dose is shown in [Figure 40-22](#). This woman had chronic hypertension complicated by severe superimposed preeclampsia, and hydralazine was injected more frequently than recommended. Her blood pressure decreased in less than 1 hour from 240–270/130–150 mm Hg to 110/80 mm Hg, and fetal heart rate decelerations characteristic of uteroplacental insufficiency became evident. Decelerations persisted until her blood pressure was increased with rapid crystalloid infusion. In some cases, this fetal response to diminished uterine perfusion may be confused with placental abruption and may result in unnecessary and potentially dangerous emergent cesarean delivery.

Labetalol

This effective intravenous antihypertensive agent is an α_1 - and nonselective β -blocker. Some prefer its use over hydralazine because of fewer side effects (Sibai, 2003). At Parkland Hospital, we give 10 mg intravenously initially. If the blood pressure has not decreased to the desirable level in 10 minutes, then 20 mg is given. The next 10-minute incremental dose is 40 mg and is followed by another 40 mg if needed. If a salutary response is not achieved, then an 80-mg dose is given. Sibai (2003) recommends 20 to 40 mg every 10 to 15 minutes as needed and a maximum dose of 220 mg per treatment cycle. The American College of Obstetricians and

Gynecologists (2012b) recommends starting with a 20-mg intravenous bolus. If not effective within 10 minutes, this is followed by 40 mg, then 80 mg every 10 minutes. Administration should not exceed a 220-mg total dose per treatment cycle.

Hydralazine versus Labetalol

Comparative studies of these two antihypertensive agents show equivalent results (Umans, 2014). In an older trial, Mabie and colleagues (1987) compared intravenous hydralazine with labetalol for blood pressure control in 60 peripartum women. Labetalol lowered blood pressure more rapidly, and associated tachycardia was minimal. However, hydralazine lowered mean arterial pressures to safe levels more effectively. In a later trial, Vigil-De Gracia and associates (2007) randomly assigned 200 severely hypertensive women intrapartum to be given either: (1) intravenous hydralazine—5 mg, which could be given every 20 minutes and repeated to a maximum of five doses, or (2) intravenous labetalol—20 mg initially, followed by 40 mg in 20 minutes and then 80 mg every 20 minutes if needed up to a maximum 300-mg dose. Maternal and neonatal outcomes were similar. Hydralazine caused significantly more maternal tachycardia and palpitations, whereas labetalol more frequently caused maternal hypotension and bradycardia. Both drugs have been associated with a reduced frequency of fetal heart rate accelerations (Cahill, 2013).

Nifedipine

This calcium-channel blocking agent has become popular because of its efficacy for control of acute pregnancy-related hypertension. The NHBPEP Working Group (2000) and the Royal College of Obstetricians and Gynaecologists (2006) recommend a 10-mg initial oral dose to be repeated in 30 minutes if necessary. *Nifedipine given sublingually is no longer recommended.* Randomized trials that compared nifedipine with labetalol found neither drug definitively superior to the other. However, nifedipine lowered blood pressure more quickly (Scardo, 1999; Shekhar, 2013; Vermillion, 1999).

FIGURE 40-22 Hydralazine was given at 5-minute intervals instead of 15-minute intervals. The mean arterial pressure decreased from 180 to 90 mm Hg within 1 hour and was associated with fetal bradycardia. Rapid crystalloid infusion raised the mean pressure to 115 mm Hg, and the fetus recovered.

Other Antihypertensive Agents

A few other generally available antihypertensive agents have been tested in clinical trials but are not widely used (Umans, 2014). Belfort and associates (1990) administered the calcium antagonist *verapamil* by intravenous infusion at 5 to 10 mg per hour. Mean arterial pressure was lowered by 20 percent. Belfort and coworkers (1996, 2003) reported that *nimodipine* given either by continuous infusion or orally was effective to lower blood pressure in women with severe preeclampsia. Bolte and colleagues (1998, 2001) reported good results in preeclamptic women given intravenous *ketanserin*, a selective serotonergic (5HT_{2A}) receptor blocker. *Nitroprusside* or *nitroglycerine* is recommended by some if there is not optimal response to first-line agents. With these latter two agents, fetal cyanide toxicity may develop after 4 hours. We have not had the need for either due to our consistent success with first-line treatment using hydralazine, labetalol, or a combination of the two given in succession, but never simultaneously.

There are experimental antihypertensive drugs that may become useful for preeclampsia treatment. One is *calcitonin gene related peptide (CGRP)*, a 37-amino acid potent vasodilator. Another is *antidigoxin antibody Fab (DIF)* directed against *endogenous digitalis-like factors*, also called *cardiotonic steroids* (Bagrov, 2008; Lam, 2013).

Diuretics

Potent loop diuretics can further compromise placental perfusion. Immediate effects include depletion of intravascular volume, which most often is already reduced compared with that of normal pregnancy (p. 737). Therefore, before delivery, diuretics are not used to lower blood pressure (Zeeman, 2009; Zondervan, 1988). We limit *antepartum* use of furosemide or similar drugs solely to treatment of pulmonary edema.

Fluid Therapy

Lactated Ringer solution is administered routinely at the rate of 60 mL to no more than 125 mL per hour unless there is unusual fluid loss from vomiting, diarrhea, or diaphoresis, or, more likely, excessive blood loss with delivery. Oliguria is common with severe preeclampsia. Thus, coupled with the knowledge that maternal blood volume is likely constricted compared with that of normal pregnancy, it is tempting to administer intravenous fluids more vigorously. But controlled, conservative fluid administration is preferred for the typical woman with severe preeclampsia who already has excessive extracellular fluid that is inappropriately distributed between intravascular and extravascular spaces. As discussed on page 737, infusion of large fluid volumes enhances the maldistribution of extravascular fluid and thereby appreciably increases the risk of pulmonary and cerebral edema (Dennis, 2012a; Sciscione, 2003; Zinaman, 1985). For labor analgesia with neuraxial analgesia, crystalloid solutions are infused slowly in graded amounts (Chap. 25, p. 516).

Pulmonary Edema

Women with severe preeclampsia-eclampsia who develop pulmonary edema most often do so postpartum (Cunningham, 1986, 2012; Zinaman, 1985). With pulmonary edema in

the eclamptic woman, aspiration of gastric contents, which may be the result of convulsions, anesthesia, or over sedation, should be excluded. As discussed in Chapter 47 (p. 942), there are three common causes of pulmonary edema in women with severe preeclampsia syndrome—pulmonary capillary permeability edema, cardiogenic edema, or a combination of the two.

Some women with severe preeclampsia—especially if given vigorous fluid replacement—will have mild pulmonary congestion from permeability edema (see Fig. 40-6). This is caused by normal pregnancy changes magnified by the preeclampsia syndrome as discussed in Chapter 4 (p. 58). Importantly, plasma oncotic pressure decreases appreciably in normal term pregnancy because of decreased serum albumin concentration, and oncotic pressure falls even more with preeclampsia (Zinaman, 1985). And both increased extravascular fluid oncotic pressure and increased capillary permeability have been described in women with preeclampsia (Brown, 1989; Øian, 1986).

Invasive Hemodynamic Monitoring

Knowledge concerning cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia-eclampsia has accrued from studies done using invasive monitoring and a flow-directed pulmonary artery catheter (see Figs. 40-5 and 40-6). Clark and Dildy (2010) have reviewed such monitoring in obstetrics. Two conditions frequently cited as indications are preeclampsia associated with either oliguria or pulmonary edema. Somewhat ironically, it is usually vigorous treatment of the former that results in most cases of the latter. The American College of Obstetricians and Gynecologists (2013a) recommends against routine invasive monitoring. The College notes that such monitoring should be reserved for severely preeclamptic women with accompanying severe cardiac disease, renal disease, or both or in cases of refractory hypertension, oliguria, and pulmonary edema. An alternative noninvasive hemodynamic monitoring strategy has been evaluated in preliminary studies (Moroz, 2013).

Plasma Volume Expansion

Because the preeclampsia syndrome is associated with hemoconcentration, attempts to expand blood volume seem intuitively reasonable (Ganzevoort, 2004). This has led some to infuse various fluids, starch polymers, albumin concentrates, or combinations thereof to expand blood volume. There are, however, older observational studies that describe serious complications—especially pulmonary edema—with volume expansion (Benedetti, 1985; López-Llera, 1982; Sibai, 1987b). In general, these studies were not controlled or even comparative (Habek, 2006).

The Amsterdam randomized study reported by Ganzevoort and coworkers (2005a,b) was a well-designed investigation done to evaluate volume expansion. A total of 216 women with severe preeclampsia were enrolled between 24 and 34 weeks' gestation. The study included women whose preeclampsia was complicated by HELLP syndrome, eclampsia, or fetal growth restriction. All women were given magnesium sulfate to prevent eclampsia, betamethasone to promote fetal pulmonary

TABLE 40-13. Maternal and Perinatal Outcomes in a Randomized Trial of Plasma Volume Expansion versus Saline Infusion in 216 Women with Severe Preeclampsia between 24 and 34 Weeks

Outcomes	Control Group ^a (n = 105)	Treatment Group ^a (n = 111)
Maternal Outcomes (%)		
Eclampsia (after enrollment)	1.9	1.8
HELLP (after enrollment)	19.0	17.0
Pulmonary edema	2.9	4.5
Placental abruption	3.8	1.0
Perinatal Outcomes		
Fetal deaths (%)	7	12
Prolongation of pregnancy (mean)	11.6 d	6.7 d
EGA at death (mean)	26.7 wk	26.3 wk
Birthweight (mean)	625 g	640 g
Live births (%)	93	88
Prolongation of pregnancy (mean)	10.5 d	7.4 d
EGA at delivery (mean)	31.6 wk	31.4 wk
RDS (%)	30	35
Neonatal death (%)	7.6	8.1
Perinatal mortality rate (n per 1000)	142/1000	207/1000

EGA = estimated gestational age; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; RDS = respiratory distress syndrome.

Data from Ganzevoort, 2005a, b.

maturity, ketanserine to control dangerous hypertension, and normal saline infusions restricted only to deliver medications. In the group randomly assigned to volume expansion, each woman was given 250 mL of 6-percent hydroxyethyl starch infused over 4 hours twice daily. Their maternal and perinatal outcomes were compared with a control group and are shown in [Table 40-13](#). None of these outcomes was significantly different between the two groups. Importantly, serious maternal morbidity and a substantive perinatal mortality rate accompanied their “expectant” management (see [Table 40-9](#)).

■ Neuroprophylaxis—Prevention of Seizures

There have been several randomized trials designed to test the efficacy of seizure prophylaxis for women with gestational hypertension, with or without proteinuria. In most of these, magnesium sulfate was compared with another anticonvulsant or with a placebo. *In all studies, magnesium sulfate was reported to be superior to the comparator agent to prevent eclampsia.* Four of the larger studies are summarized in [Table 40-14](#). In the study from Parkland Hospital, Lucas and colleagues (1995) reported that magnesium sulfate therapy was superior to phenytoin to prevent eclamptic seizures in women with gestational hypertension and preeclampsia. Belfort and coworkers (2003) compared magnesium sulfate and nimodipine—a calcium-channel blocker with specific cerebral vasodilator activity—for eclampsia prevention. In this unblinded randomized trial involving 1650 women with severe preeclampsia, the rate

of eclampsia was more than threefold higher for women allocated to the nimodipine group—2.6 versus 0.8 percent.

The largest comparative study was the entitled *MAGnesium Sulfate for Prevention of Eclampsia* and reported by the Magpie Trial Collaboration Group (2002). More than 10,000 women with severe preeclampsia from 33 countries were randomly allocated to treatment with magnesium sulfate or placebo. Women given magnesium had a 58-percent significantly lower risk of eclampsia than those given placebo. Smyth and associates (2009) provided follow-up data of infants born to these mothers given magnesium sulfate. At approximately 18 months, child behavior did not differ in those exposed compared with those not exposed to magnesium sulfate.

Who Should Be Given Magnesium Sulfate?

Magnesium will prevent proportionately more seizures in women with correspondingly worse disease. As previously discussed, however, severity is difficult to quantify, and thus it is difficult to decide which individual woman might benefit most from neuroprophylaxis. *The 2013 Task Force recommends that women with either eclampsia or severe preeclampsia should be given magnesium sulfate prophylaxis.* Again, criteria that establish “severity” are not totally uniform (see [Table 40-2](#)). At the same time, however, the 2013 Task Force suggests that all women with “mild” preeclampsia do not need magnesium sulfate neuroprophylaxis. The conundrum is whether or not to give neuroprophylaxis to any of these women with “nonsevere” gestational hypertension or preeclampsia (Alexander, 2006).

TABLE 40-14. Randomized Comparative Trials of Prophylaxis with Magnesium Sulfate and Placebo or Another Anticonvulsant in Women with Gestational Hypertension

Study/Inclusions	No. with Seizures/Total No. Treated (%)		
	Magnesium Sulfate	Control	Comparison ^a

Belfort et al (2003) Severe preeclampsia	7/831 (0.8)	Nimodipine 21/819 (2.6)	RR = 0.33 (0.14–0.77)

^aAll comparisons significant $p < 0.05$.^bIncluded women with and without proteinuria and those with all severities of preeclampsia.^cMagpie Trial Collaboration Group, 2002.

In many other countries, and principally following dissemination of the Magpie Trial Collaboration Group (2002) study results, magnesium sulfate is now recommended for women with severe preeclampsia. In some, however, debate continues concerning whether therapy should be reserved for women who have an eclamptic seizure. We are of the opinion that eclamptic seizures are dangerous for reasons discussed on page 742. Maternal mortality rates of up to 5 percent have been reported even in recent studies (Andersgaard, 2006; Benhamou, 2009; Moodley, 2010; Schutte, 2008; Zwart, 2008). Moreover, there are substantially increased perinatal mortality rates in both industrialized countries and underdeveloped ones (Abd El Aal, 2012; Knight, 2007; Ndaboine, 2012; Schutte, 2008; von Dadelszen, 2012). Finally, the possibility of adverse long-term neuropsychological and vision-related sequelae of eclampsia described by Aukes (2009, 2012), Postma (2009), Wiegman (2012), and their coworkers, which are discussed on page 770, have raised additional concerns that eclamptic seizures are not “benign.”

Selective versus Universal Magnesium Sulfate Prophylaxis

There is uncertainty around which women with nonsevere gestational hypertension should be given magnesium sulfate neuroprophylaxis. An opportunity to address these questions was afforded by a change in our prophylaxis protocol for women delivering at Parkland Hospital. Before this time, Lucas and associates (1995) had found that the risk of eclampsia without magnesium prophylaxis was approximately 1 in 100 for women with *mild preeclampsia*. Up until 2000, all women with gestational hypertension were given magnesium prophylaxis intramuscularly as first described by Pritchard in 1955. After 2000, we instituted a standardized protocol for intravenously administered magnesium sulfate (Alexander, 2006). At the same time, we also changed our practice of universal

seizure prophylaxis for all women with gestational hypertension to one of selective prophylaxis given only to women who met our criteria for severe gestational hypertension. These criteria, shown in Table 40-15, included women with $\geq 2+$ proteinuria measured by dipstick in a catheterized urine specimen.

Following this protocol change, 60 percent of 6518 women with gestational hypertension during a 4½-year period were

TABLE 40-15. Selective versus Universal Magnesium Sulfate Prophylaxis: Parkland Hospital Criteria to Define Severity of Gestational Hypertension

In a woman with new-onset proteinuric hypertension, at least one of the following criteria is required:

Systolic BP ≥ 160 or diastolic BP ≥ 110 mm Hg
Proteinuria $\geq 2+$ by dipstick in a catheterized urine specimen
Serum creatinine > 1.2 mg/dL
Platelet count $< 100,000/\mu\text{L}$
Aspartate aminotransferase (AST) elevated two times above upper limit of normal range
Persistent headache or scotomata
Persistent midepigastria or right-upper quadrant pain

BP = blood pressure.

Criteria based on those from National High Blood Pressure Education Program Working Group, 2000; American College of Obstetricians and Gynecologists, 2012b; cited by Alexander, 2006.

Gest. HTN = gestational hypertension.
Data from Alexander, 2006.

given magnesium sulfate neuroprophylaxis (Table 40-16). The remaining 40 percent with nonsevere hypertension were not treated, and of these, 27 women developed eclamptic seizures—1 in 92. The seizure rate was only 1 in 358 for 3935 women with criteria for severe disease who were given magnesium sulfate, and thus these cases were treatment failures. To assess morbidity, outcomes in 87 eclamptic women were compared with outcomes in all 6431 noneclamptic hypertensive women. Although most maternal outcomes were similar, almost a fourth of women with eclampsia who underwent emergent cesarean delivery required general anesthesia. This is a great concern because eclamptic women have laryngotracheal edema and are at a higher risk for failed intubation, gastric acid aspiration, and death (American College of Obstetricians and Gynecologists, 2013d). Neonatal outcomes were also a concern because the composite morbidity defined in Table 40-16 was significantly increased tenfold in eclamptic compared with noneclamptic women—12 versus 1 percent, respectively.

Thus, if one uses the Parkland criteria for nonsevere gestational hypertension, about 1 of 100 such women who are not given magnesium sulfate prophylaxis can be expected to have an eclamptic seizure. A fourth of these women likely will require emergent cesarean delivery with attendant maternal and perinatal morbidity and mortality from general anesthesia. From this, the major question regarding management of nonsevere gestational hypertension remains—whether it is acceptable to avoid unnecessary treatment of 99 women to risk eclampsia in one? The answer appears to be yes as suggested by the 2013 Task Force.

■ Delivery

To avoid maternal risks from cesarean delivery, steps to effect vaginal delivery are used initially in women with eclampsia.

Following a seizure, labor often ensues spontaneously or can be induced successfully even in women remote from term (Alanis, 2008). An immediate cure does not promptly follow delivery by any route, but serious morbidity is less common during the puerperium in women delivered vaginally.

Blood Loss at Delivery

Hemoconcentration or lack of normal pregnancy-induced hypervolemia is an almost predictable feature of severe preeclampsia-eclampsia as quantified by Zeeman and associates (2009) and shown in Figure 40-7. *These women, who consequently lack normal pregnancy hypervolemia, are much less tolerant of even normal blood loss than are normotensive pregnant women.* It is of great importance to recognize that an appreciable fall in blood pressure soon after delivery most often means excessive blood loss and not sudden resolution of vasospasm and endothelial damage. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss. If identified, hemorrhage should be treated appropriately by careful crystalloid and blood transfusion.

Analgesia and Anesthesia

During the past 20 years, the use of conduction analgesia for women with preeclampsia syndrome has proven ideal. Initial problems with this method included hypotension and diminished uterine perfusion caused by sympathetic blockade in these women with attenuated hypervolemia. But pulmonary edema was mitigated by techniques that used slow induction of epidural analgesia with dilute solutions of anesthetic agents to counter the need for rapid infusion of large volumes of crystalloid or colloid to correct maternal hypotension (Hogg, 1999; Wallace, 1995). Moreover, epidural blockade avoids general anesthesia, in which the stimulation of tracheal intubation may cause sudden severe hypertension. Such blood pressure increases, in turn, can cause pulmonary edema, cerebral edema, or intracranial hemorrhage. Finally, tracheal intubation may be particularly difficult and thus hazardous in women with airway edema due to preeclampsia (American College of Obstetricians and Gynecologists, 2013d).

At least three randomized studies have been performed to evaluate these methods of analgesia and anesthesia. Wallace and colleagues (1995) studied 80 women at Parkland Hospital with severe preeclampsia who were to undergo cesarean delivery. They had not been given labor epidural analgesia and were randomized to receive general anesthesia, epidural analgesia, or combined spinal-epidural analgesia. Their average preoperative blood pressures approximated 170/110 mm Hg, and all had proteinuria. Anesthetic and obstetrical management included antihypertensive drug therapy and limited intravenous fluids as previously described. Perinatal outcomes in each group were similar. Maternal hypotension resulting from regional analgesia was managed with judicious intravenous fluid administration. In women undergoing general anesthesia, maternal blood pressure was managed to avoid severe hypertension (Fig. 40-23). There were no serious maternal or fetal complications attributable to any of the three anesthetic methods. It was concluded that all three are

FIGURE 40-23 Blood pressure effects of general anesthesia versus epidural or spinal-epidural analgesia for cesarean delivery in 80 women with severe preeclampsia. MAP = mean arterial pressure. Time posts (T): OR = operating room; IN = induction of anesthesia; T = tracheal intubation; IN5 = induction + 5 min; IN10 = induction + 10 min; IN20 = induction + 20 min; SKI = skin incision; D = delivery; SKC = skin closure; O = extubation. (From Wallace, 1995, with permission.)

acceptable for use in women with pregnancies complicated by severe preeclampsia if steps are taken to ensure a careful approach to the selected method.

Another randomized study included 70 women with severe preeclampsia receiving spinal analgesia versus general anesthesia (Dyer, 2003). All had a nonreassuring fetal heart rate tracing as the indication for cesarean delivery, and outcomes were equivalent. Dyer and coworkers (2008) later showed that decreased mean arterial blood pressure induced by epidural blockade could be effectively counteracted by phenylephrine infusion to maintain cardiac output.

In a study from the University of Alabama at Birmingham, Head and colleagues (2002) randomly assigned 116 women with severe preeclampsia to receive either epidural or patient-controlled intravenous meperidine analgesia during labor. A standardized protocol limited intravenous fluids to 100 mL/hr. More women—9 percent—from the group assigned to epidural analgesia required ephedrine for hypotension. As expected, pain relief was superior in the epidural group, but maternal

and neonatal complications were similar between groups. One woman in each group developed pulmonary edema.

It is important to emphasize that epidural analgesia is not to be considered *treatment* of preeclampsia. Lucas and associates (2001) studied 738 laboring women at Parkland Hospital who were 36 weeks or more and who had gestational hypertension of varying severity. Patients were randomly assigned to receive either epidural analgesia or patient-controlled intravenous meperidine analgesia. Maternal and neonatal outcomes were similar in the two study groups. However, as shown in [Table 40-17](#), epidural analgesia resulted in a greater decrement of mean maternal arterial pressure compared with meperidine, but it was not superior in preventing recurrent severe hypertension later in labor.

For these reasons, judicious fluid administration is essential in severely preeclamptic women who receive regional analgesia. Newsome and coworkers (1986) showed that vigorous crystalloid infusion with epidural blockade in women with severe preeclampsia caused elevation of pulmonary capillary wedge pressures (see [Fig. 40-6](#)). Aggressive volume replacement in these women increases their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark, 1985; Cotton, 1986a). When pulmonary edema develops, there is also concern for development of cerebral edema. Finally, Heller and associates (1983) demonstrated that most cases of pharyngolaryngeal edema were related to aggressive volume therapy.

Persistent Severe Postpartum Hypertension

The potential problem of antihypertensive agents causing serious compromise of uteroplacental perfusion and thus of fetal well-being is obviated by delivery. Postpartum, if difficulty arises in controlling severe hypertension or if intravenous hydralazine or labetalol are being used repeatedly, then oral regimens can be given. Examples include labetalol or another β -blocker, nifedipine or another calcium-channel blocker, and possible addition of a thiazide diuretic. Persistent or refractory hypertension is likely due to mobilization of pathological interstitial fluid and redistribution into the intravenous compartment, underlying chronic hypertension, or usually both (Sibai, 2012; Tan, 2002). In women with chronic hypertension and left-ventricular hypertrophy, severe postpartum hypertension can cause

TABLE 40-17. Comparison of Cardiovascular Effects of Epidural versus Patient-Controlled Meperidine Analgesia During Labor in Women with Gestational Hypertension

Hemodynamic Change	Labor Analgesia		p value
	Epidural (n = 372)	Meperidine (n = 366)	
Mean arterial pressure change (mean)	-25 mm Hg	-15 mm Hg	< 0.001
Ephedrine for hypotension (%)	11%	0	< 0.001
Severe hypertension after analgesia (%) (BP \geq 160/110 mm Hg)	< 1%	1%	NS

NS = not significant.
Data from Lucas, 2001.

pulmonary edema from cardiac failure (Cunningham, 1986, 2012; Sibai, 1987a).

Furosemide

Because persistence of severe hypertension corresponds to the onset and length of diuresis and extracellular fluid mobilization, it seems logical that furosemide-augmented diuresis might serve to hasten blood pressure control. To study this, Ascarelli and coworkers (2005) designed a randomized trial that included 264 postpartum preeclamptic women. After onset of spontaneous diuresis, patients were assigned to 20-mg oral furosemide given daily or no therapy. Women with mild disease had similar blood pressure control regardless of whether they received treatment or placebo. However, women with severe preeclampsia who were treated, compared with those receiving placebo, had a lower mean systolic blood pressure at 2 days—142 versus 153 mm Hg. They also required less frequently administered antihypertensive therapy during the remainder of hospitalization—14 versus 26 percent, respectively.

We have used a simple method to estimate excessive extracellular/interstitial fluid. The *postpartum weight* is compared with the most recent *prenatal weight*, either from the last clinic visit or on admission for delivery. On average, soon after delivery, maternal weight should be reduced by at least 10 to 15 pounds depending on infant and placental weight, amniotic fluid volume, and blood loss. Because of various interventions, especially intravenous crystalloid infusions given during operative vaginal or cesarean delivery, women with severe preeclampsia often have an immediate postpartum weight *in excess of their last prenatal weight*. If this weight increase is associated with severe persistent postpartum hypertension, then diuresis with intravenous furosemide is usually helpful in controlling blood pressure.

Plasma Exchange

Martin and colleagues (1995) have described an atypical syndrome in which severe preeclampsia-eclampsia persists despite delivery. These investigators described 18 such women whom they encountered during a 10-year period. They advocate single or multiple plasma exchange for these women. In some cases, 3 L of plasma was exchanged three times—a 36- to 45-donor unit exposure for each patient—before a response was forthcoming. Others have described plasma exchange performed in postpartum women with HELLP syndrome (Förster, 2002; Obeidat, 2002). In all of these cases, however, the distinction between HELLP syndrome and thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear. As further discussed in Chapter 56 (p. 1116), in our experiences with more than 50,000 women with gestational hypertension among nearly 450,000 pregnancies cared for at Parkland Hospital through 2012, we have encountered very few women with persistent postpartum hypertension, thrombocytopenia, and renal dysfunction who were diagnosed as having a thrombotic microangiopathy (Dashe, 1998). These latter syndromes complicating pregnancy were reviewed by Martin (2008) and George (2013) and their colleagues, who conclude that a rapid diagnostic test for ADAMTS-13 enzyme activity might be helpful to differentiate most of these syndromes.

FIGURE 40-24 Reversible cerebral vasoconstriction syndrome. Magnetic resonance angiography shows generalized vasoconstriction of the anterior and posterior cerebral circulation (arrows). (From Garcia-Reitboeck, 2013, with permission.)

Reversible Cerebral Vasoconstriction Syndrome

This is another cause of persistent hypertension, “thunderclap” headaches, seizures, and central nervous system findings. It is a form of *postpartum angiopathy*. As shown in [Figure 40-24](#), it is characterized by diffuse segmental constriction of cerebral arteries and may be associated with ischemic and hemorrhagic strokes. The reversible cerebral vasoconstriction syndrome has several inciting causes that include pregnancy, and particularly preeclampsia (Ducros, 2012). It is more common in women, and in some cases, vasoconstriction may be so severe as to cause cerebral ischemia and infarction. The appropriate management is not known at this time (Edlow, 2013).

COUNSELING FOR FUTURE PREGNANCIES

As discussed on page 732, defective remodeling of the spiral arteries in some placentations has been posited as the cause of at least one preeclampsia phenotype. Lack of deep placental attachment has been associated with preeclampsia, placental abruption, fetal-growth restriction, and preterm birth (Wikström, 2011). With this type of “overlap syndrome,” hypertensive disorders may serve as markers for subsequent preterm labor and fetal-growth restriction. For example, even in subsequent nonhypertensive pregnancies, women who had preterm preeclampsia are at increased risk for preterm birth (Connealy, 2013.)

In addition, women who have had either gestational hypertension or preeclampsia are at higher risk to develop hypertension in future pregnancies. Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. Sibai and colleagues (1986, 1991) found that nulliparas diagnosed with preeclampsia before 30 weeks have a recurrence risk as high as 40 percent during a subsequent

pregnancy. In a prospective study of 500 women previously delivered for preeclampsia at 37 weeks, the recurrence rate in a subsequent gestation was 23 percent (Bramham, 2011). These investigators also found an increased risk during subsequent pregnancies for preterm delivery and fetal-growth restriction even if these women remained normotensive.

In a study from the Denmark Birth Registry, Lykke and coworkers (2009b) analyzed singleton births in more than 535,000 women who had a first and second delivery. Women whose first pregnancy was complicated by preeclampsia between 32 and 36 weeks had a significant twofold increased incidence of preeclampsia in their second pregnancy—25 versus 14 percent—compared with women who were normotensive during the first pregnancy. Analyzed from another view, they also found that preterm delivery and fetal-growth restriction in the first pregnancy significantly increased the risk for preeclampsia in the second pregnancy.

As probably expected, women with HELLP syndrome have a substantive risk for recurrence in subsequent pregnancies. In two studies the risk ranged from 5 to 26 percent, but the true recurrence risk likely lies between these two extremes (Habli, 2009; Sibai, 1995). Even if HELLP syndrome does not recur with subsequent pregnancies, there is a high incidence of preterm delivery, fetal-growth restriction, placental abruption, and cesarean delivery (Habli, 2009; Hnat, 2002).

LONG-TERM CONSEQUENCES

Over the past 20 years, evidence has accrued that preeclampsia, like fetal-growth disorders and preterm birth, is a marker for subsequent cardiovascular morbidity and mortality. Thus, women with hypertension identified during pregnancy should be evaluated during the first several months postpartum and counseled regarding long-term risks. The Working Group concluded that hypertension attributable to pregnancy should resolve within 12 weeks of delivery (National High Blood Pressure Education Program, 2000). Persistence beyond this time is considered to be chronic hypertension (Chap. 50, p. 1000). The Magpie Trial Follow-Up Collaborative Group (2007) reported that 20 percent of 3375 preeclamptic women seen at a median of 26 months postpartum had hypertension. Importantly, even if hypertension does not persist in the short term, convincing evidence suggests that the risk for long-term cardiovascular morbidity is significantly increased in preeclamptic women.

Cardiovascular and Neurovascular Morbidity

With the advent of national databases, several studies confirm that any hypertension during pregnancy is a marker for an increased risk for morbidity and mortality in later life (American College of Obstetricians and Gynecologists, 2013c). In a case-control study from Iceland, Arnadottir and associates (2005) analyzed outcomes for 325 women who had hypertension complicating pregnancy and who were delivered from 1931 through 1947. At a median follow-up of 50 years, 60 percent of women with pregnancy-related hypertension compared with only 53 percent of controls had died. Compared with 629 normotensive pregnant controls, the prevalences of *ischemic heart disease*—24 versus

15 percent, and *stroke*—9.5 versus 6.5 percent, were significantly increased in the women who had gestational hypertension. In a Swedish population study of more than 400,000 nulliparas delivered between 1973 and 1982, Wikström and coworkers (2005) also found an increased incidence of ischemic heart disease in women with prior pregnancy-associated hypertension.

Lykke and associates (2009a) cited findings from a Danish registry of more than 780,000 nulliparous women. After a mean follow-up of almost 15 years, the incidence of *chronic hypertension* was significantly increased 5.2-fold in those who had gestational hypertension, 3.5-fold after mild preeclampsia, and 6.4-fold after severe preeclampsia. After two hypertensive pregnancies, there was a 5.9-fold increase in the incidence. Importantly, these investigators also reported a significant 3.5-fold increased risk for *type 2 diabetes*.

Bellamy and coworkers (2007) performed a systematic review and metaanalysis of long-term risks for cardiovascular disease in women with preeclampsia. As shown in [Figure 40-25](#), the risks in later life were increased for hypertension, ischemic heart disease, stroke, venous thromboembolism, and all-cause mortality. As emphasized by several investigators, other cofactors or comorbidities are related to acquisition of these long-term adverse outcomes (Gastrich, 2012; Harskamp, 2007; Hermes, 2012; Spaan, 2012b). These include but are not limited to the metabolic syndrome, diabetes, obesity, dyslipidemia, and atherosclerosis. These conclusions are underscored by the findings of Berends and colleagues (2008), who confirmed shared constitutional risks for long-term vascular-related disorders in preeclamptic women and in their parents. Similar preliminary observations were reported by Smith (2009, 2012) and Stekkinger (2013) and their associates.

At least in some of these women, their hypertensive cardiovascular pathologies appear to have begun near the time of

FIGURE 40-25 Long-term cardiovascular consequences of preeclampsia. All differences $p \leq .001$. (Data from Bellamy, 2007.)

their own births. For example, individuals who are born preterm have increased ventricular mass later in life (Lewandowski, 2013). Women who have preeclampsia and who develop chronic hypertension later in life have an increased ventricular mass index before they become hypertensive (Ghossein-Doha, 2013). A similar phenomenon is associated with preterm birth and with fetal-growth disorders.

Renal Sequelae

Preeclampsia appears to also be a marker for subsequent renal disease. In a preliminary study, the possibility was raised that persistent podocyturia might be a marker for such disease (Garrett, 2013). In a 40-year study of Norwegian birth and end-stage renal disease linked registries, although the absolute risk of renal failure was small, preeclampsia was associated with a fourfold increased risk (Vikse, 2008). Women with recurrent preeclampsia had an even greater risk. These data need to be considered in light of the findings that 15 to 20 percent of women with preeclampsia who undergo renal biopsy have evidence of chronic renal disease (Chesley, 1978). In another long-term follow-up study, Spaan and coworkers (2009) compared formerly preeclamptic women with a cohort of women who were normotensive at delivery. At 20 years following delivery, preeclamptic women were significantly more likely to be chronically hypertensive—55 versus 7 percent—compared with control women. They also had higher peripheral vascular and renovascular resistance and decreased renal blood flow. These data do not permit conclusions as to cause versus effect.

Neurological Sequelae

Until recently, eclamptic seizures were believed to have no significant long-term sequelae. Findings have now accrued, however, that this is not always the case. Recall that almost all eclamptic women have multifocal areas of perivascular edema, and about a fourth also have areas of cerebral infarction (Zeeman, 2004a).

A Dutch group has reported several long-term follow-up studies in women with severe preeclampsia and eclampsia (Aukes, 2007, 2009, 2012). These investigators found long-term persistence of brain white-matter lesions that were incurred during eclamptic convulsions (Aukes, 2009). When studied with MR imaging at a mean of 7 years, 40 percent of formerly eclamptic women had more numerous and larger aggregate white matter lesions compared with 17 percent of normotensive control women. These investigators later also observed these white-matter lesions in preeclamptic women without convulsions (Aukes, 2012). In studies designed to assess clinical relevance, Aukes and colleagues (2007) reported that formerly eclamptic women had subjectively impaired cognitive functioning. They also reported that women with multiple seizures had impaired sustained attention compared with normotensive controls (Postma, 2009). And recently, Wiegman and associates (2012) described that formerly eclamptic women at approximately 10 years had lower vision-related quality of life compared with control subjects. Because there were no studies done before these women suffered from

preeclampsia or eclampsia, the investigators appropriately concluded that cause versus effect of these white-matter lesions remains unknown.

CONSUMPTIVE COAGULOPATHY 808

MANAGEMENT OF HEMORRHAGE 814

Obstetrical hemorrhage continues along with hypertension and infections as one of the infamous “triad” of causes of maternal deaths in both developed and underdeveloped countries. It is a leading reason for admission of pregnant women to intensive care units (ICUs) (Crozier, 2011; Small, 2012; Zeeman, 2003; Zwart, 2008). Hemorrhage was a direct cause of nearly 13 percent of 4693 pregnancy-related maternal deaths in the United States documented by the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention (Berg, 2010). Similarly, Clark and coworkers (2008) reported that 12 percent of maternal deaths recorded in

Obstetrics is a bloody business.
Dr. Jack Pritchard (1976b)

the Hospital Corporation of America database were caused by hemorrhage. In developing countries, its contribution is even more striking. Indeed, hemorrhage is the single most important cause of maternal death worldwide and is responsible for half of all postpartum deaths in developing countries (Lalonde, 2006; McCormick, 2002).

GENERAL CONSIDERATIONS

The decreasing maternal mortality rate from hemorrhage in this country has been a major achievement. Decreased deaths from hemorrhage have been a major contributor to the decrease in the maternal mortality rate during the 20th century—from approximately 1000 to only 10 per 100,000 births (Hoyert, 2007). But, as discussed in Chapter 1 (p. 5), probably half of maternal deaths are not reported, and at least a third are considered preventable. It thus seems unlikely that deaths from hemorrhage have reached an irreducible minimum.

Mechanisms of Normal Hemostasis

A major concept in understanding the pathophysiology and management of obstetrical hemorrhage is the mechanism by which hemostasis is achieved after normal delivery. Recall that near term an incredible amount of blood—at least 600 mL/min—flows through the intervillous space (Pates, 2010). As described in Chapter 5 (p. 96), this prodigious flow circulates through the spiral arteries, which average 120 in number. Also recall that these vessels have no muscular layer because of their endotrophoblastic remodeling, which creates a low-pressure system. With placental separation, these vessels at the implantation site are avulsed, and hemostasis is achieved first by myometrial contraction, which compresses this formidable number of relatively large vessels (Chap. 2, p. 26).

Contractions are followed by clotting and obliteration of vessel lumens.

If after delivery, the myometrium within and adjacent to the denuded implantation site contracts vigorously, fatal hemorrhage from the placental implantation site is unlikely. *Importantly, an intact coagulation system is not necessary for postpartum hemostasis unless there are lacerations in the uterus, birth canal, or perineum.* At the same time, however, fatal postpartum hemorrhage can result from uterine atony despite normal coagulation. Adhered placental pieces or large blood clots that prevent effective myometrial contraction will serve to impair hemostasis at the implantation site.

Definition and Incidence

Traditionally, postpartum hemorrhage has been defined as the loss of 500 mL of blood or more after completion of the third stage of labor. This is problematic because almost half of all women delivered vaginally shed that amount of blood or more when losses are measured quantitatively (Pritchard, 1962). These results are depicted in [Figure 41-1](#) and show further that approximately 5 percent of women delivering vaginally lose more than 1000 mL of blood. *These studies also showed that estimated blood loss is commonly only approximately half the actual loss.* Because of this, estimated blood loss in excess of “average” or 500 mL should alert the obstetrician to possible excessive bleeding. Calibrated delivery-drape markings improve estimation accuracy, but even this technique underestimates blood loss compared with more precise methods (Sosa, 2009; Toledo, 2007).

The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually increases by half, but increases range from 30 to 60 percent—1500 to 2000 mL for an average-sized woman (Pritchard, 1965). The equation to calculate blood volume is shown in [Table 41-1](#). It is axiomatic that a normal pregnant woman tolerates, without any decrease in postpartum hematocrit, blood loss at delivery that approaches the volume of blood that she added during

TABLE 41-1. Calculation of Maternal Total Blood Volume

Nonpregnant blood volume^a:

$$\frac{[\text{Height (inches)} \times 50] + [\text{Weight (pounds)} \times 25]}{2} = \text{Blood volume (mL)}$$

Pregnancy blood volume:

Average increase is 30 to 60 percent of calculated nonpregnant volume

Increases across gestational age and plateaus at approximately 34 weeks

Usually larger with low normal-range hematocrit (~30) and smaller with high normal-range hematocrit (~40)

Average increase is 40 to 80 percent with multifetal gestation

Average increase is less with preeclampsia—volumes vary inversely with severity

Postpartum blood volume with serious hemorrhage:

Assume acute return to nonpregnant total volume after fluid resuscitation

Pregnancy hypervolemia cannot be restored postpartum

^aFormula arrived at by measuring blood volume and blood loss in more than 100 women using ⁵¹Cr-labeled erythrocytes.

Modified from Hernandez, 2012.

FIGURE 41-1 Blood loss associated with vaginal delivery, repeat cesarean delivery, and repeat cesarean delivery plus hysterectomy. (Data from Pritchard, 1962.)

pregnancy. Thus, if blood loss is less than the pregnancy-added volume, the hematocrit remains the same acutely and during the first several days. It then increases as nonpregnant plasma volume normalizes during the next week or so. *Whenever the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy-added volume plus 500 mL for each 3 volume percent decrease of the hematocrit.* Blood loss in these women can also be calculated using the formula of Hernandez and associates (2012). Briefly, these investigators used admission-to-discharge red cell volumes to compute total blood loss.

Excessive blood loss has been estimated by several methods that include measuring loss directly, using a predetermined decline in hematocrit or hemoglobin concentration, or counting the number of women transfused. Of these, direct measurement was performed in a two-center investigation done in Argentina and Uruguay (Sosa, 2009). Specially constructed drapes were used to collect blood at vaginal delivery. These investigators reported that 10.8 percent of women had hemorrhage in excess of 500 mL, whereas 1.9 percent lost > 1000 mL. These estimates likely are too low.

Tita and colleagues (2012) used a 6-volume percent decrease in the postpartum

hematocrit to define clinically significant blood loss with vaginal delivery. This decrease easily signifies greater than 1000-mL blood loss in the averaged-sized women. They documented this amount in a fourth of women, which agrees with the findings in Figure 41-1.

A final marker used to estimate the hemorrhage incidence is the transfusion rate. Because of prevailing conservative attitudes toward blood replacement, rates cited more recently are lower than transfusion rates described in older studies. In the study by Tita and colleagues (2012) cited above, more than 6 percent of women delivered vaginally underwent interventional treatment and blood transfusions. In a study of more than 66,000 women delivered at Parkland Hospital from 2002 to 2006, Hernandez and associates (2012) reported that 2.3 percent overall were given blood transfusions for hypovolemia. Half of these women had undergone cesarean delivery. Importantly, for those transfused, these investigators calculated blood loss to average approximately 3500 mL! In a recent study from Australia, 1.6 percent of women delivered in 2010 were transfused (Patterson, 2014). Last, from a registry-based Norwegian study, Skjeldestad and Øian (2012) reported that blood loss exceeded 1250 mL in 2.7 percent of women undergoing cesarean delivery.

Thus, it is apparent that significant blood loss accompanies about a fourth of vaginal deliveries. The amounts and proportions for cesarean delivery are much greater.

When audits of discharge statistics are evaluated, it is apparent that hemorrhage is also underreported. In one example, Bateman and associates (2010) queried the Nationwide Inpatient Sample for 2004 and found a 2.9-percent reported rate of postpartum hemorrhage. Similarly, using a sample of nearly 185,000 delivery outcomes from the National Hospital Discharge Summary database that represented more than 40 million deliveries, Berg and coworkers (2009) reported postpartum hemorrhage incidence of 2.0 and 2.6 percent, for two epochs. In a population-based Canadian study, the incidence of postpartum hemorrhage from atony increased from 3.6 to 4.8 percent from 2001 to 2009 (Mehrabadi, 2013). In contrast, a study encompassing 1999 to 2008 by Kramer and associates (2013) cited a rate of severe postpartum hemorrhage that increased from only 1.9 to 4.2 per 1000 births. At the same time, reported transfusion rates between 1991 and 2003 increased from only 3 to 5 per 1000 deliveries—all rather meager compared with rates in previously cited prospective studies.

Predisposing Conditions

There are myriad clinical circumstances in which risks for obstetrical hemorrhage and its consequences are appreciably increased. The imposing list shown in Table 41-2 illustrates that hemorrhage can manifest at any time throughout pregnancy, delivery, and the puerperium. Thus, any description of obstetrical hemorrhage should include gestational age. Use of terms such as *third-trimester bleeding* is not recommended because of imprecision.

Importantly, inadequate obstetrical and anesthetic services in some areas contribute to maternal death from hemorrhage. This undoubtedly includes facilities in the United States. It was quantified in the United Kingdom by the 2002 Confidential

TABLE 41-2. Obstetrical Hemorrhage: Causes, Predisposing Factors, and Vulnerable Patients

Abnormal Placentation	Uterine Atony
Placenta previa	Uterine overdistention
Placental abruption	Large fetus
Placenta accreta/increta/percreta	Multiple fetuses
Ectopic pregnancy	Hydramnios
Hydatidiform mole	Retained clots
Injuries to the Birth Canal	Labor induction
Episiotomy and lacerations	Anesthesia or analgesia
Forceps or vacuum delivery	Halogenated agents
Cesarean delivery or hysterectomy	Conduction analgesia with hypotension
Uterine rupture	Labor abnormalities
Previously scarred uterus	Rapid labor
High parity	Prolonged labor
Hyperstimulation	Augmented labor
Obstructed labor	Chorioamnionitis
Intrauterine manipulation	Previous uterine atony
Midforceps rotation	Coagulation Defects—Intensify Other Causes
Breech extraction	Massive transfusions
Obstetrical Factors	Placental abruption
Obesity	Sepsis syndrome
Previous postpartum hemorrhage	Severe preeclampsia syndrome
Early preterm pregnancy	Acute fatty liver
Sepsis syndrome	Anticoagulant treatment
Vulnerable Patients	Congenital coagulopathies
Preeclampsia/eclampsia	Amnionic-fluid embolism
Chronic renal insufficiency	Prolonged retention of dead fetus
Constitutionally small size	Saline-induced abortion

Enquiry into Maternal and Child Health, which concluded that most maternal deaths from hemorrhage were associated with substandard care (Weindling, 2003). Similar experiences were reported from Japan and from the Netherlands (Nagaya, 2000; Zwart, 2008).

Timing of Hemorrhage

It has been traditional to classify obstetrical hemorrhage as *antepartum*—such as with placenta previa or placental abruption, or as *postpartum*—commonly caused by uterine atony or genital tract lacerations. In individual women, however, these terms are nonspecific, and it is reasonable to specify the cause and gestational age as descriptors.

Antepartum Hemorrhage

Bleeding during various times in gestation may give a clue as to its cause. Many aspects of bleeding during the first half of pregnancy from abortion or ectopic pregnancy are discussed in detail in Chapters 18 and 19, respectively. Discussions that follow concern pregnancies with a viable mature living fetus. In

these cases, rapid assessment should always consider the deleterious fetal effects of maternal hemorrhage.

Slight vaginal bleeding is common during active labor. This “bloody show” is the consequence of effacement and dilatation of the cervix, with tearing of small vessels. Uterine bleeding, however, coming from above the cervix, is concerning. It may follow some separation of a placenta previa implanted in the immediate vicinity of the cervical canal, or it may be from a placental abruption or uterine tear. Rarely, there may be velamentous insertion of the umbilical cord, and the involved placental vessels may overlie the cervix—*vasa previa*. Fetal hemorrhage follows laceration of these vessels at the time of membrane rupture. In many women near term, the source of uterine bleeding is not identified, symptomless bleeding ceases, and no apparent anatomical cause is found at delivery. In most of these cases, bleeding likely resulted from a slight marginal placental separation. *Despite this, any pregnancy with antepartum bleeding remains at increased risk for an adverse outcome even though bleeding has stopped and placenta previa has been excluded sonographically.*

Several reports address mid- to early third-trimester bleeding. Lipitz and colleagues (1991) reported that a fourth of 65 consecutive women with uterine bleeding between 14 and 26 weeks had placental abruption or previa, and a third of all 65 fetuses ultimately were lost. Similar outcomes were described subsequently (Ajayi, 1992; Leung, 2001). The Canadian Perinatal Network described 806 women with hemorrhage between 22 and 28 weeks’ gestation (Sabourin, 2012). Placental abruption (32 percent), previa (21 percent), and cervical bleeding (6.6 percent) were the most common causes identified, and in a third, no cause was found. Of all women, 44 percent were delivered \leq 29 weeks. Clearly, second- and third-trimester bleeding are associated with a poor pregnancy prognosis.

Postpartum Hemorrhage

In most cases, the cause of postpartum hemorrhage can and should be determined. Frequent causes are uterine atony with bleeding from the placental implantation site, genital tract trauma, or both (see Table 41-2). Postpartum hemorrhage is usually obvious. Important exceptions are unrecognized intrauterine and intravaginal blood accumulation and uterine rupture with intraperitoneal bleeding. Initial assessment should attempt to differentiate uterine atony from genital tract lacerations. Primary considerations are the predisposing risk factors shown in Table 41-2, lower genital tract examination, and uterine tone assessment. Atony is identified by a boggy, soft uterus during bimanual examination and by expression of clots and hemorrhage during uterine massage.

Persistent bleeding despite a firm, well-contracted uterus suggests that hemorrhage most likely is from lacerations. Bright red blood further suggests arterial bleeding. *To confirm that lacerations are a source of bleeding, careful inspection of the vagina, cervix, and uterus is essential.* Sometimes bleeding may be caused by both atony and trauma, especially after forceps or vacuum-assisted vaginal delivery. Importantly, if significant bleeding follows these deliveries, then the cervix and vagina are carefully examined to identify lacerations. This

is easier if conduction analgesia was given. If there are no lower genital tract lacerations and the uterus is contracted, yet supracervical bleeding persists, then manual exploration of the uterus is done to exclude a uterine tear. This also is completed routinely after internal podalic version and breech extraction.

Blood Loss Estimation

Estimated blood loss—like beauty—is in the eye of the beholder.

Estimation is notoriously inaccurate, especially with excessive bleeding (p. 781). Instead of sudden massive hemorrhage, postpartum bleeding is frequently steady. If atony persists, bleeding may appear to be only moderate at any given instant but may continue until serious hypovolemia develops. Bleeding from an episiotomy or a vaginal laceration can also appear to be only minimal to moderate. However, constant seepage can lead to enormous blood loss relatively quickly. In some cases, after placental separation, blood may not escape vaginally but instead may collect within the uterine cavity, which can become distended by 1000 mL or more of blood. In others, postpartum uterine massage is applied to a roll of abdominal fat mistaken for the uterus. Thus, monitoring of the uterus immediately postpartum must not be left to an inexperienced person (Chap. 27, p. 547).

All of these factors can lead to an underappreciation of the magnitude of hemorrhage over time. The effects of hemorrhage depend to a considerable degree on the maternal nonpregnant blood volume and the corresponding degree of pregnancy-induced hypervolemia as previously discussed. For this and other reasons, hypovolemia may not be recognized until very late. *A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost.* The normotensive woman initially may actually become somewhat hypertensive from catecholamine release in response to hemorrhage. Moreover, women with preeclampsia may become “normotensive” despite remarkable hypovolemia.

Late Postpartum Hemorrhage

Bleeding after the first 24 hours is designated *late postpartum hemorrhage*. Such bleeding is found in up to 1 percent of women and may be serious (American College of Obstetricians and Gynecologists, 2013b). It is discussed in Chapter 36 (p. 670).

Special Considerations

In certain conditions, a pregnant woman may be particularly susceptible to hemorrhage because her blood volume expansion is less than expected. This situation is most commonly encountered in small women—even those with normal pregnancy-induced hypervolemia. Women with severe preeclampsia or eclampsia are also more vulnerable to hemorrhage because they frequently do not have a normally expanded blood volume. Specifically, Zeeman and associates (2009) documented a mean increase above nonpregnant volume of only 10 percent in *eclamptic* women (Chap. 40, p. 737). A third example is the moderate to severely curtailed pregnancy-induced volume expansion in women with chronic renal insufficiency (Chap. 53, p. 1061). *When excessive hemorrhage is suspected in*

FIGURE 41-2 Contributions to maternal death from various causes of obstetrical hemorrhage. Percentages are approximations because of different classification schemata used. DIC = disseminated intravascular coagulation. (Data from Al-Zirqi, 2008; Berg, 2010; Chichakli, 1999; Zwart, 2008.)

these high-risk women, crystalloid and blood are promptly administered for suspected hypovolemia.

CAUSES OF OBSTETRICAL HEMORRHAGE
